This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

PREFACE TO THE SECOND EDITION.

THE gratifying reception given to the Text-book of Anatomy, not only in this country but also in America, has rendered it necessary to prepare a new edition. In carrying out this work the whole book has been carefully revised, and a large number of new illustrations have been added.

The sections in which the chief changes and additions have been made are those upon Embryology, the Joints, the Muscles, the Brain and Spinal Cord, the Genito-Urinary Organs, the Lymphatics, and Applied Anatomy. By pruning down in various directions, it has been found possible to incorporate a considerable amount of new matter in these and other sections without materially increasing the bulk of the book.

The lamented death of Professor Birmingham was felt by all the contributors to be not only a personal loss, but one which materially affected an important section of the book. Although in very bad health, Professor Birmingham was desirous to undertake his share of the work, and he had the sheets on the Digestive System in his possession for this purpose when he died. There was probably no part of the book which required less revision than his, and the Editor has taken upon himself the duty of making the alterations which seemed essential. In doing this he has been careful to avoid unnecessary changes and to preserve throughout the original character of the article.

In the section upon the Muscular System, a series of illustrations has been added in which the areas of muscle attachment are delineated upon the bones. For the preparation of the specimens, and for assistance in the mapping out of these areas, the Editor is indebted to Dr. E. B. Jamieson. Those who have attempted work of this kind will appreciate the amount of labour and judgment entailed, as it is only by taking the average condition in many specimens, and by the close study of the bones selected for the delineations, that a sufficiently accurate result can be attained.

With the exception of the figures which have been added to the sections of the book dealing with Embryology, Osteology, and the Genito-Urinary Organs, the many new illustrations which appear in this edition have been prepared in the Anatomical Department of the University of Edinburgh. In carrying out this work, the Editor has again had the good fortune to secure the co-operation of Mr.

J. T. Murray, an artist whose ability in the rendering of anatomical subjects is recognised on all hands. Wherever it was felt that colour would increase the artistic effect or the general usefulness of an illustration, it has been freely employed, both in the case of the old and of the new figures.

The Editor cannot conclude this preface to the second edition of the Text-book without expressing his grateful acknowledgment of the assistance which has been so freely extended to him by his fellow-contributors at every stage of the work. He has also to thank many readers of the first edition for calling his attention to typographical errors and other imperfections which had escaped his notice in passing the sheets through the press.

18 Grosvenor Crescent, Edinburgh,
August 1905.

PREFACE TO THE FIRST EDITION.

THE form which this book has taken expresses the desire of those who have contributed the various sections to produce something which they might dedicate to their former teacher and master, Sir William Turner. With one exception, all the contributors have studied under Sir William Turner, and all but two have for longer or shorter periods acted as his Assistants. Bound together by this common tie, and animated by affection and reverence for their great master, they have sought to produce a book worthy of him whose teaching it so largely reflects, and if this object has not been attained it is not for want of will, but of power, on the part of the writers.

In the preparation of a work such as this it is no easy matter to prevent overlapping of the different articles and to keep the various sections in harmony with each other. Yet in this direction it is believed that a fair amount of success has been attained. Differences of opinion on particular points were bound to arise, but the Editor found in those concerned the greatest readiness to come to a mutual understanding, and he is deeply grateful to his colleagues for the manner in which they endeavoured to lighten his work and assist him in his task. Of course when totally different views were held by two authors on a matter which had to be dealt with in two sections, no serious attempt was made to urge these writers to qualify their statements so as to produce an apparent agreement. It was felt that if this were done the individuality of the author, which forms a characteristic feature of each article as it stands, would thereby be damaged; and further, it was believed that the same question discussed from two different points of view could not fail to be of advantage to the reader. At the same time it is right to state that the places in which a divergence of opinion appears are very few, and taking into account that nine writers have co-operated with the Editor, a remarkable degree of harmony in the treatment of the different sections has been obtained.

The recent introduction of Formalin as a hardening and preserving reagent imposed an especially arduous duty upon those writers who had undertaken the chapters dealing with the thoracic and abdominal viscera. The possibilities for establishing a more accurate topography and of improving our conception of the forms assumed by the viscera under different conditions have by this means been greatly extended; and in preparing the sections which treat of these organs the writers have taken full advantage of the new method. Much, therefore, which appears in this book on the topographical relations of the viscera departs considerably from the older and more conventional descriptions hitherto in vogue.

The arrangement of the matter treated in the following pages is very much the same as that adopted in the various courses of lectures delivered in the schools from which the different sections of the work have emanated. The first chapter is

devoted to the general principles and elementary facts of Embryology. Then follow, in an order best suited for the student, the chapters dealing with the various systems of organs; whilst the last seventy-five pages are used for the purpose of applying the information conveyed in the preceding part of the book to the practice of medicine and surgery. Each chapter is more or less complete in itself, although an effort has been made to weld them all into one consistent whole.

The numerous illustrations which appear in the text are all new in the sense that in no case has an old drawing or an old block been used. Further, the vast majority of the illustrations are new in the sense that they are original. The very few that are not have been taken from monographs dealing with the subjects so illustrated, and in every case the source from which these have been obtained is acknowledged in the text. The drawings for each section were prepared under the personal supervision of its author, and, with the exception of the figures in two chapters, they are the work of Mr. J. T. Murray. This talented artist has devoted much time to the undertaking, and the reader can judge for himself the success which has attended his efforts. The Editor cannot sufficiently express his indebtedness to Mr. Murray for the great technical skill and the patience which he brought to bear upon this extremely trying and difficult work. The chapter on Osteology has been illustrated by Mr. W. C. Stevens; that upon Embryology by the authors themselves; whilst the microscopical drawings in the section on the Brain and Cord were executed by Mr. Wm. Cathie. It is also necessary to mention that the coloured outlines representing the attachments of the muscles on the figures of the bones were mapped in by Professor A. M. Paterson.

The Editor has to thank his former Assistant, Professor A. F. Dixon of Cardiff, for much help in the correction of the proofs.

TRINITY COLLEGE, DUBLIN,
June 1902.

LIST OF CONTRIBUTORS.

AMBROSE BIRMINGHAM, M.D., F.R.C.S.I.,
Formerly Professor of Anatomy, Catholic University School of Medicine, Dublin.
(*The Digestive System.*)

D. J. CUNNINGHAM, M.D., F.R.S.,
Professor of Anatomy, University of Edinburgh.
(*The Brain and Spinal Cord, The Respiratory System, The Ductless Glands.*)

A. FRANCIS DIXON, M.B., D.Sc. (Dubl.),
Professor of Anatomy, Trinity College, Dublin.
(*The Urinogenital System.*)

DAVID HEPBURN, M.D., F.R.S.E.,
Professor of Anatomy, University College, Cardiff.
(*Arthrology.*)

ROBERT HOWDEN, M.A., M.B.,
Professor of Anatomy, University of Durham.
(*The Organs of Sense and the Integument.*)

A. M. PATERSON, M.D.,
Professor of Anatomy, University College, Liverpool.
(*Myology, The Spinal and Cranial Nerves, The Sympathetic Nervous System.*)

ARTHUR ROBINSON, M.D.,
Professor of Anatomy, University of Birmingham.
(*General Embryology, The Vascular System.*)

HAROLD J. STILES, M.B., F.R.C.S. Ed.,
Surgeon to the Royal Hospital for Sick Children, Edinburgh.
(*Surface and Surgical Anatomy.*)

ARTHUR THOMSON, M.A., M.B.,
Professor of Human Anatomy, University of Oxford.
(*Osteology.*)

A. H. YOUNG, M.B., F.R.C.S.,
Professor of Anatomy, The Owens College, Manchester.
(*General Embryology, The Vascular System.*)

The Index is the work of Dr. T. W. P. LAWRENCE.

Arteries of Head and Neck	950
Arteries of Upper Limb	951
Iliac Arteries and their Branches	952
Arteries of Lower Limb	953
Abnormalities of Veins	954
Superior Vena Cava	954
Veins of Upper Extremity	955
Inferior Vena Cava	955
Veins of Lower Extremity	955
Abnormalities of Lymphatics	955

RESPIRATORY SYSTEM.

Organs of Respiration and Voice	957
Larynx or Organ of Voice	957
Cartilages of Larynx	958
Joints, Ligaments, and Membranes of Larynx	961
Interior of Larynx	964
Laryngeal Muscles	968
Trachea	972
Bronchi	975
Thoracic Cavity	976
Pleural Membranes	977
Mediastinal or Interpleural Space	982
Lungs	983
Root of Lung	989
Structure of Lung	990
Development of Respiratory Apparatus	992

DIGESTIVE SYSTEM.

Mouth	995
Palate and Isthmus Faucium	998
Tongue	1000
Glands	1007
Salivary Glands	1009
Development of Salivary Glands, Palate, and Tongue	1013
Teeth	1014
Permanent Teeth	1016
Milk Teeth	1022
Structure of Teeth	1023
Development of Teeth	1025
Morphology of Teeth	1029
Pharynx	1029
Development of Pharynx and Tonsil	1037
Œsophagus	1038
Development of Œsophagus	1042
Abdominal Cavity	1043
Subdivision of Abdominal Cavity	1045
Peritoneum	1048
Stomach	1050
Structure of Stomach	1058
Intestines	1060
Structure of Intestines	1061
Small Intestine	1064
Duodenum	1065
Jejunum and Ileum	1071
Large Intestine	1074
Cæcum and Appendix	1076
Colon	1082
Rectum	1087
Anal Canal	1091
Peritoneum	1097
Development of Intestinal Canal and Peritoneum	1105
Liver	1108
Gall-Bladder and Bile Passages	1118
Vessels of Liver	1120
Structure of Liver	1121
Development of Liver	1122
Pancreas	1124
Development of Pancreas	1129

URINOGENITAL SYSTEM.

URINARY ORGANS	1130
Kidneys	1130
Bladder	1144
Urethra	1157
MALE REPRODUCTIVE ORGANS	1159
Testis	1159
Vas Deferens	1162
Descent of Testis	1167

	PAGE		
Spermatic Cord	1168	Fallopian Tubes	1
Scrotum	1169	Uterus	1
Penis	1170	Vagina	1
Prostate	1173	Female External Genital Organs	1
Cowper's Glands	1176	Glands of Bartholin	1
Male Urethra	1177	Development of Urinogenital Organs	1
FEMALE REPRODUCTIVE ORGANS	1181	Mammary Glands	1
Ovary	1182	Development of Mammæ	1

DUCTLESS GLANDS.

Spleen	1210	Parathyroids	1
Suprarenal Capsules	1213	Thymus Gland	1
Thyroid Body	1216	Carotid and Coccygeal Bodies	1

SURFACE AND SURGICAL ANATOMY.

Head and Neck	1222	Upper Extremity	1
Cranium	1222	Shoulder	1
Face	1236	Axilla	1
Neck	1246	Upper Arm	1
Thorax	1253	Elbow	1
Lungs	1255	Forearm and Hand	1
Heart and Great Vessels	1262	Lower Extremity	1
Abdomen	1264	Buttock	1
Anterior Abdominal Wall	1264	Back of the Thigh	1
Abdominal Cavity	1267	Popliteal Space	1
Male Perineum	1277	Front of Thigh	1
Prostate	1278	Knee	1
Female Pelvis	1282	Leg	1
Back	1284	Foot and Ankle	1

INDEX 1

LIST OF ILLUSTRATIONS.

GENERAL EMBRYOLOGY.

FIG.		PAGE
1.	Horizontal Section through Trunk at Level of First Lumbar Vertebra	4
2.	Diagram of an Animal Cell	8
3.	Cell Division	9
4.	The Ovum and its Coverings	11
5.	Maturation of the Ovum: Extrusion of the "Polar Bodies"	12
6.	Diagram illustrating the Maturation of the Ovum	13
7.	Diagram illustrating the Process of Cell-Division resulting in the Formation of Spermatids which are afterwards modified into Spermatozoa	14
8.	Human Spermatozoa	15
9.	Structure of a Human Spermatozoon	15
10.	Fertilisation of the Ovum	16
11.	Segmentation of the Fertilised Ovum in the Rabbit	17
12.	Conversion of the Morula to the Blastula	18
13.	Surface View of the Blastodermic Vesicle	19
14.	The Upper Pole of the Blastodermic Vesicle	20
15.	Transverse Section of a Ferret Embryo	20
16.	Transverse Section of a Ferret Embryo	21
17.	Surface Areas of the Blastoderm	23
18.	Sections showing the different Areas of the Blastodermic Vesicle	24
19.	Extension of Mesoderm and Formation of Cœlom	25
20.	Surface View of an Early Embryo	25
21.	Early Stages in the Folding-off of the Embryo	27
22.	The Relative Positions of the Blastodermic Layers in the Body of the Embryo when the "Folding-off" is completed	28
23.	Transverse Section of a Ferret Embryo	29
24.	Further Differentiation of the Mesoderm	29
25.	Coronal Section of a Rat Embryo	30
26.	Transverse Section of a Rat Embryo	31
27.	Diagram of a Developing Ovum, seen in Longitudinal Section	32
28.	Diagram representing the Condition of the Alimentary Canal in a Human Embryo about fifteen days old (modified from His)	33
29.	Further Development of the Alimentary Canal, as seen in a Human Embryo about five weeks old	34
30.	Stages in the Formation of the Tongue and Upper Aperture of the Larynx in the Human Embryo (after His)	36
31.	Head of Human Embryo (four views; two after His)	39
32.	Head of Human Embryo (four views; two after His)	40
33.	Head of Human Embryo (two views; one after His)	41
34.	Vertical Section through Head of Rat Embryo	42
35.	Transverse Section through the Head of a Rat Embryo	43
36.	Figures, modified from His, illustrating the Formation of the Pinna	44
37.	Diagrams showing the Separation of the Cloacal Part of the Hind-gut into Genito-urinary Tract and Rectum	46
38.	Transverse Sections of the Uterus and Developing Ovum of a Ferret	49
39.	Very young Human Ovum almost immediately after its entrance into the Decidua	53
40.	Relation of the young Human Ovum to the Decidua	53
41.	Further Stage of Development of the Human Ovum and its Relation to the Decidual Tissues	54
42.	Completion of the Decidua Capsularis, etc.	54
43.	Enlargement of the Blood Sinuses in the Maternal Part of the Placenta and the Closure of the Amnion	55
44.	Fœtal Ectoderm surrounding the Maternal Blood Sinuses, etc.	55
45.	Further Growth of the Placental Sinuses and Villi, etc.	56
46.	Later Stage in the Development of the Placenta	58

FIG.		PAGE
47.	Development of Blood-Vessels in the Vascular Area of the Rat	61
48.	The Primitive Blood-Vessels of the Embryo	62
49.	Blood-Vessels of a Mammalian Embryo after the Formation of the Heart	63
50.	Diagram of the Fœtal Circulation	64
51.	Human Embryo at the end of the 12th, 13th, and 14th days of Development (after His)	65
52.	Human Embryo at the 21st, 23rd, and 27th days of Development (after His)	66
53.	Human Embryo at the 29th and 32nd days of Development (after His)	67
54.	Human Fœtus at the sixth week of Development (after His)	67
55.	Human Fœtus six and a half weeks old (after His)	67
56.	Human Fœtus eight and a half weeks old (after His)	68

OSTEOLOGY.

57.	Fifth Thoracic Vertebra	75
58.	Fifth Thoracic Vertebra	75
59.	Fourth Cervical Vertebra	77
60.	The Atlas from Above	78
61.	Axis from Behind and Above	79
62.	Axis from the Left Side	79
63.	First, Ninth, Tenth, Eleventh, and Twelfth Thoracic Vertebræ from the Left Side	81
64.	Third Lumbar Vertebra from Above and from the Left Side	82
65.	The Sacrum (anterior view)	84
66.	The Sacrum (posterior view)	85
67.	The Coccyx	86
68.	Vertebral Column from the Left Side	88
69.	Vertebral Column as seen from Behind	89
70.	Ossification of Vertebræ	91
71.	Ossification of Vertebræ	92
72.	Ossification of Sacrum	93
73.	The Sternum (anterior view)	95
74.	Ossification of the Sternum	96
75.	Fifth Right Rib as seen from Below	98
76.	Fifth Right Rib as seen from Behind	99
77.	First and Second Right Ribs as seen from Above	99
78.	The Thorax as seen from the Front	101
79.	The Thorax as seen from the Right Side	102
80.	Frontal Bone (anterior view)	104
81.	Frontal Bone as seen from Below	105
82.	Ossification of Frontal Bone	106
83.	Right Parietal Bone (outer side)	107
84.	Right Parietal Bone (inner surface)	108
85.	Occipital Bone as seen from Below	110
86.	Occipital Bone (inner surface)	111
87.	Ossification of Occipital Bone	113
88.	Right Temporal Bone as seen from the Outer Side	115
89.	Right Temporal Bone (inner side)	116
90.	Right Temporal Bone as seen from Below	118
91.	Vertical Transverse Section through Left Temporal Bone (anterior half of section)	120
92.	Vertical Transverse Section through Left Temporal Bone (posterior half of section)	120
93.	Horizontal Section through Left Temporal Bone (lower half of section)	121
94.	The Outer and Inner Surfaces of the Right Temporal Bone at Birth	122
95.	Sphenoid as seen from Behind	123
96.	Sphenoid as seen from the Front	123
97.	Ossification of Sphenoid	127
98.	Ethmoid as seen from Behind	128
99.	Ethmoid as seen from the Right Side	129
100.	Section showing Nasal Aspect of Left Lateral Mass of Ethmoid	129
101.	Showing Articulation of Inferior Turbinated Bone with Ethmoid	130
102.	Ethmoid as seen from Above	130
103.	Right Superior Maxilla (outer view)	132
104.	Right Superior Maxilla (inner aspect)	132
105.	Ossification of Superior Maxilla	135
106.	Right Malar Bone	136
107.	Inner Surface of Malar Bone at Birth	137
108.	Right Nasal Bone	138
109.	Right Lachrymal Bone	138
110.	Right Inferior Turbinated Bone	139
111.	Vomer as seen from the Right Side	140
112.	Right Palate Bone	141
113.	Right Palate Bone as seen from Behind	142
114.	The Lower Jaw as seen from the Left Side	144
115.	The Inner Side of the Right Half of the Lower Jaw	145
116.	Lower Jaw at Birth	146
117.	The Hyoid Bone as seen from the Front	147
118.	Norma Frontalis	150
119.	Norma Lateralis	153
120.	Coronal Section through the Spheno-maxillary Fossa of the Right Side	158
121.	Norma Basalis	161
122.	Base of the Skull as seen from Above	168
123.	Inner Aspect of Left Half of Skull sagittally divided	172
124.	Nasal Septum as seen from the Left Side	174
125.	Part of the Frontal, Nasal, and Superior Maxillary Bones removed in order to display the relation of the various cavities exposed	175
126.	Coronal Section passing inferiorly through interval between First and Second Molar Teeth	176
127.	View of the Chondro-Cranium of a Human Fœtus	182
128.	Right Clavicle as seen from Above	184
129.	Right Clavicle as seen from Below	185
130.	Ossification of the Clavicle	186
131.	The Right Scapula as seen from Behind	187

FIG. PAGE

132. The Right Scapula as seen from the Front 188
133. Ossification of the Scapula . . 190
134. Anterior View of the Right Humerus 191
135. Posterior View of the Right Humerus 192
136. The Head of the Right Humerus as seen from Above 193
137. The Lower Extremity of the Right Humerus as seen from Below . 193
138. The Lower End of the Right Humerus as seen from the Outer Side 193
139. Ossification of the Humerus . . 195
140. The Right Ulna as viewed from the Outer Side 196
141. The Radius and Ulna as seen from the Front 198
142. The Ossification of the Ulna . . 199
143. The Radius and Ulna as seen from Behind 200
144. The Ossification of the Radius . 202
145. The Bones of the Right Wrist and Hand as seen from the Front . 203
146. The Bones of the Right Wrist and Hand as seen from Behind . . 204
147. The Right Scaphoid Bone . . 205
148. The Right Semilunar Bone . . 205
149. The Right Cuneiform Bone . . 206
150. The Right Pisiform Bone . . 206
151. The Right Trapezium 206
152. The Right Trapezoid 207
153. The Right Os Magnum 207
154. The Right Unciform Bone . . 208
155. Radiograph of the Hand at Birth . 209
156. First Right Metacarpal Bone . . 210
157. Second Metacarpal Bone . . 210
158. Third Metacarpal Bone . . . 211
159. Fourth Metacarpal Bone . . 211
160. Fifth Metacarpal Bone . . . 211
161. The Phalanges of the Fingers . 213
162. Radiographs of Fœtal Hands. . 213
163. The Right Innominate Bone as seen from the Outer Side . . . 215
164. The Right Innominate Bone . . 216
165. Ossification of the Innominate Bone 220
166. Male Pelvis as seen from the Front 221
167. Female Pelvis as seen from the Front 221

FIG. PAGE

168. Right Femur as seen from the Front 224
169. Right Femur as seen from Behind. 225
170. Back View of Upper End of Right Femur 226
171. Lower End of Right Femur . . 228
172. Lower End of Right Femur as seen from below 228
173. Ossification of Femur 230
174. Right Patella 230
175. Upper Surface of Superior Extremity of Right Tibia . . 231
176. Right Tibia and Fibula as seen from the Front 232
177. Ossification of the Tibia . . 235
178. Right Tibia and Fibula as seen from Behind 236
179. Right Fibula as seen from the Inner Side 237
180. Ossification of Fibula 239
181. Bones of the Right Foot as seen from Above 240
182. Bones of the Right Foot as seen from Below 241
183. The Right Astragalus 242
184. The Right Astragalus 242
185. The Right Os Calcis as seen from Above 243
186. The Right Os Calcis as seen from Below 243
187. The Right Os Calcis 244
188. Right Navicular Bone 245
189. Anterior View of the three Cuneiform Bones of the Right Foot . 246
190. Right Internal Cuneiform . . 246
191. Right Internal Cuneiform . . 246
192. Right Middle Cuneiform . . 246
193. Right Middle Cuneiform . . 246
194. Right External Cuneiform . . 247
195. Right External Cuneiform . . 247
196. Right Cuboid Bone 248
197. Radiographs of the Fœtal Foot . 249
198. The First Metatarsal Bone of the Right Foot 250
199. View of the Bases and Shafts of the Second, Third, and Fourth Metatarsal Bones of the Right Foot 250
200. Fifth Right Metatarsal Bone . . 251
201. The Phalanges of the Toes . . 252
202. Radiographs of the Fœtal Foot . 252

THE ARTICULATIONS OR JOINTS.

203. Vertical Section through a Suture. 255
204. Section through the Occipito-sphenoid Synchondrosis . . 256
205. Sutura Serrata 256
206. Diagram of a Diarthrodial Joint . 257
207. Diagram of a Diarthrodial Joint . 258
208. Mesial Section through a portion of the Lumbar part of the Spine . 262
209. Anterior Common Ligament of the Vertebral Column, and the Costo-vertebral Joints as seen from Front 262
210. Posterior Common Ligament of the Vertebral Column . . . 263
211. Ligamenta Subflava 264
212. Mesial Section through the Occipito-atloid and Atlo-axoid Joints 265
213. Dissection from Behind of the Ligaments connecting the Occipital Bone, the Atlas, and the Axis with each other 266
214. Temporo-mandibular Joint . . 267
215. Section through Temporo-mandibular Joint 268
216. Internal Lateral Ligament of the Temporo-maxillary Joint . . 268
217. Sterno-clavicular and Costo-sternal Joints 272
218. Capsule of the Shoulder-joint and Coraco-acromial Ligament . . 276
219. Capsular Ligament of Shoulder-joint cut across and Humerus removed 277
220. Vertical Section through the Shoulder-joint 278

FIG.		PAGE
221.	Anterior View of Elbow-joint	279
222.	Elbow-joint (inner aspect)	280
223.	Vertical Section through the Trochlear part of the Elbow-joint	281
224.	Orbicular Ligament of the Radius.	282
225.	Carpal Articular Surface of the Radius, and Triangular Fibro-Cartilage of the Wrist	282
226.	Ligaments on Anterior Aspect of Radio-carpal, Carpal, and Carpo-metacarpal Joints	284
227.	Coronal Section through the Radio-carpal, Carpal, Carpo-metacarpal, and Intermetacarpal Joints to show Joint Cavities and Inter-osseous Ligaments (diagrammatic)	286
228.	Metacarpo-phalangeal and Inter-phalangeal Joints	288
229.	Coronal Section of Pelvis	290
230.	Posterior View of the Pelvic Ligaments and of the Hip-joint.	291
231.	Dissection of the Hip-joint	294
232.	Dissection of the Hip-joint from the Front	296
233.	Dissection of the Knee-joint from the Front	298
234.	The Knee-joint (posterior view)	299
235.	The Knee-joint opened from behind by the removal of the Posterior Ligament	301
236.	Upper End of Tibia	302
237.	Ankle-joint dissected from Behind	305
238.	Articular Surfaces of Tibia and Fibula which are opposed to the Astragalus	306
239.	Ankle and Tarsal-joints from the Tibial Aspect	307
240.	Ligaments on the Outer Aspect of the Ankle-joint and on the Dorsum of the Tarsus	308
241.	The Composite Articular Socket for the Head of the Astragalus.	309
242.	Plantar Aspect of Tarsal and Tarso-metatarsal Joints.	310

THE MUSCULAR SYSTEM.

243.	Muscle-Attachments to the Clavicle	319
244.	Superficial Muscles of the Back	320
245.	Muscle-Attachments to the Scapula (posterior surface)	321
246.	Muscle-Attachments to the Front of the Sternum	322
247.	Anterior Muscles of the Trunk	323
248.	Muscle-Attachments to the Clavicle (under surface)	324
249.	The Serratus Magnus Muscle.	325
250.	Muscle-Attachments to the Scapula (anterior aspect)	325
251.	Deltoid Region and Back of the Arm	327
252.	Posterior Wall of the Axilla and the Front of the Arm.	328
253.	Muscle-Attachments to the Front of the Humerus	329
254.	Muscle-Attachments to the Scapula (posterior surface)	330
255.	Superficial Muscles on the front of the Arm and Forearm.	333
256.	The Muscles on the Back of the Arm, Forearm, and Hand	334
257.	Muscle-Attachments to the Front of the Humerus	335
258.	Muscle-Attachments to the Back of the Humerus	335
259.	The Palm of the Hand	337
260.	The Muscles and Tendons in the Palm of the Hand	338
261.	Section Across the Forearm in the Middle Third	340
262.	The Muscles and Nerves on the Front of the Forearm and Hand.	341
263.	The Tendons attached to the Index Finger.	342
264.	Muscle-Attachments to the Radius and Ulna (Anterior Aspects)	343
265.	Deep Muscles on the Front of the Forearm and Hand	344
266.	Short Muscles of the Hand	345
267.	Muscle-Attachments to the Palmar Aspect of the Carpus and Metacarpus	346
268.	The Palmar Interosseous Muscles	347
269.	Muscle-Attachments to the Dorsal Aspect of the Metacarpus	348
270.	Dorsal Interosseous Muscles of the Hand	348
271.	Muscle-Attachments to the Radius and Ulna	351
272.	The Muscles of the Back of the Forearm	352
273.	The Groin	356
274.	The Groin	357
275.	Superficial Muscles of the Back	358
276.	The Muscles on the Front of the Thigh	360
277.	Muscle-Attachments to the Anterior Surface of the Upper Part of the Femur	361
278.	Transverse Section of the Thigh (Hunter's Canal).	362
279.	Muscle-Attachments to the inner side of the Upper Part of the Tibia	363
280.	Muscles and Nerves of the Lumbo-Sacral Plexus	364
281.	Muscle-Attachments to the Posterior Aspect of the Upper Part of the Femur.	365
282.	Muscle-Attachments to the Outer Surface of the Pubis and Ischium	366
283.	Scheme of the Course and Distribution of the Obturator Nerve	367
284.	Posterior Surface of the Thigh	368
285.	Muscle-Attachments to the Dorsum Ilii and Tuber Ischii	369
286.	Muscle-Attachments to the Posterior Aspect of the Upper Part of the Femur.	370
287.	The Gluteus Maximus Muscle	370
288.	The Muscles and Nerves of the Buttock	371
289.	Muscle-Attachments to the Upper Aspect of the Great Trochanter of the Femur	371
290.	Muscle-Attachments to the Dorsum Ilii and Tuber Ischii	373

FIG. PAGE

291. The Muscles on the Back of the Thigh 374
292. Muscle-Attachments to the Inner Side of the Upper Part of the Tibia 374
293. Coronal Section through the Left Ankle Joint (Astragalus and Calcaneum) 377
294. The Plantar Fascia and Plantar Cutaneous Nerves . . . 378
295. Muscle-Attachments to Tarsus and Metatarsus 379
296. Muscles of the Front of the Right Leg and Dorsum of the Foot . 380
297. The Insertions of the Peroneus Longus and Tibialis Posticus Muscles in the Sole of the Right Foot 381
298. The Soleus Muscle 382
299. Muscle-Attachments to the Posterior Surface of the Tibia . . . 383
300. The Deep Muscles on the Back of the Left Leg 383
301. The Muscles of the Right Foot . 384
302. Muscle-Attachments to Tarsus and Metatarsus 386
303. The Muscles of the Right Foot . 387
304. The Muscles of the Right Foot . 387
305. Interosseous Muscles of the Foot . 388
306. Transverse Section through the Abdomen, opposite the Second Lumbar Vertebra 391
307. Schematic Representation of the parts of the Erector Spinæ Muscle 392
308. Scheme of Muscular-Attachments to the Transverse Processes of the Cervical Vertebræ . . . 393
309. Deeper Muscles of Back . . 394
310. The Suboccipital Triangle . . 396
311. Muscle-Attachments to the Sacrum 396
312. Muscle-Attachments to Occipital Bone 397
313. Transverse Section in the Cervical Region 400
314. The Muscles of the Face and Scalp 402
315. Transverse Vertical Section through the Orbit behind the Eyeball to show the arrangement of Muscles 405
316. Muscles of the Orbit . . . 405
317. Muscles of the Orbit 406
318. Schematic Representation of the Nerves which traverse the Cavity of the Orbit 406
319. Muscle-Attachments to the Outer Aspect of the Lower Jaw . . 407
320. Muscles of Mastication . . . 408
321. Muscle-Attachments on the inner side of the Lower Jaw . . 408
322. Muscles of Mastication, deeper view 409

FIG. PAGE

323. Pterygoid Region 409
324. Muscle-Attachments to Occipital Bone 411
325. Muscles of the Hyoid Bone and Styloid Process, and the Extrinsic Muscles of the Tongue, with their Nerves 412
326. Triangles of the Neck 413
327. Muscle-Attachments on the inner side of the Lower Jaw . . 414
328. Posterior view of the Pharynx and Constrictor Muscles . . . 417
329. Lateral View of the Wall of the Pharynx 418
330. Muscle-Attachments to the Upper Surface of the First Rib and the Outer Surface of the Second Rib 420
331. The Prævertebral Muscles of the Neck 420
332. Scheme of Muscular-Attachments to Cervical Vertebræ . . . 421
333. Muscle-Attachments to Occipital Bone 421
334. Muscles of the Thoracic Wall . 423
335. The Diaphragm (from below) . 424
336. View of the Posterior Abdominal Wall, to show the Muscles and the Nerves of the Lumbo-sacral Plexus 425
337. The Groin 427
338. Transverse Section through the Abdomen 428
339. The Groin 428
340. Anterior Muscles of the Trunk . 429
341. The Groin 430
342. The Groin 431
343. Sheath of the Rectus Abdominis Muscle 432
344. View of the Posterior Abdominal Wall to show the Muscles and the Nerves of the Lumbo-Sacral Plexus 433
345. Muscles and Nerves of the Male Perineum 435
346. Muscles of the Female Perineum (after Peter Thompson) . 436
347. Triangular Ligament of the Perineum, and the Termination of the Pudic Nerve 437
348. Dissection of the Pelvic Fascia from above 438
349. Oblique Section across the Pelvis . 439
350. Outer Wall of the Pelvis . . 439
351. Fascial and Muscular Wall of the Pelvis after removal of part of the Left Innominate Bone . . 440
352. Scheme to illustrate the disposition of the Myotomes in the Embryo in relation to the Head, Trunk, and Limbs 442

THE NERVOUS SYSTEM.

353. Nerve-fibre from a Frog (after v. Kölliker) 444
354. Three Nerve-Cells from the Anterior Horn of Gray Matter of the Human Spinal Cord . . . 445
355. Two Multipolar Nerve-Cells . . 446
356. Nerve-Cell from Cerebellum (Professor Symington) . . . 446
357. Transverse Section through the early Neural Tube (Alfred H. Young) 447
358. Developmental Stages exhibited by

FIG.		PAGE
	a Pyramidal Cell of the Brain (after Ramón y Cajal)	447
359.	Diagram of the Connexion established by a Ganglionic and a Motor Neuron (Ramón y Cajal)	449
360.	Three Stages in the development of a Cell from a Spinal Ganglion	449
361.	Nerve-Cells as depicted by Bethe	450
362.	Section through the Central Canal of the Spinal Cord of a Human Embryo (after v. Lenhossek)	451
363.	Human Fœtus in the third month of Development, with the Brain and Spinal Cord exposed from behind	452
364.	The Conus Medullaris and the Filum Terminale exposed within the Spinal Canal	453
365.	The Roots of Origin of the Seventh Dorsal Nerve	453
366.	Section through the Conus Medullaris and the Cauda Equina as they lie in the Spinal Canal	453
367.	Diagram of the Spinal Cord as seen from behind	455
368.	Transverse Section through the Upper Part of the Cervical Region of the Cord of an Orang	456
369.	Section through each of the Four Regions of the Cord	458
370.	Section through the Fifth Cervical Segment of the Cord	462
371.	Section through the eighth Dorsal Segment of the Spinal Cord	463
372.	Section through the Third Lumbar Segment of the Spinal Cord to show the grouping of the Motor Cells	463
373.	Section through the first Sacral Segment of the Spinal Cord	464
374.	Transverse Section through the White Matter of the Cord	465
375.	Diagram to show the Arrangement of the Fibres of the Posterior Nerve-Roots in the Posterior Columns of the Cord	467
376.	Diagram to show the manner in which the Fibres of the Posterior Nerve-Roots enter and ascend in the Posterior Column of the Cord (from Edinger)	467
377.	Diagrammatic Representation of a Transverse Section through the Spinal Cord	469
378.	Schema of a Transverse Section through the Early Neural Tube (Young)	471
379.	Three Stages in the Development of the Spinal Cord (His)	472
380.	The Base of the Brain with Cranial Nerves attached	474
381.	Schema showing the Connexions of the several parts of the Brain	476
382.	Two Stages in the Development of the Human Brain (after His)	477
383.	Two Cross Sections through the Fore-Brain	477
384.	The Brain of a Human Embryo in the Fifth Week (after His)	478
385.	Profile View of the Brain of a Human Embryo of Ten Weeks (His)	479
386.	Diagrams to illustrate the Alar and Basal Laminæ	
387.	Front View of the Medulla, Pons, and Mesencephalon of a full-time Human Fœtus	
388.	Back View of the Medulla, Pons, and Mesencephalon of a full-time Human Fœtus	
389.	Diagram of the Decussation of the Pyramids (modified from van Gehuchten)	
390.	Lateral View of the Medulla, Pons, and Mesencephalon of a full-time Human Fœtus	
391.	Floor of the Fourth Ventricle	
392.	Section through the Lower End of the Medulla Oblongata of a Chimpanzee to show the Decussation of the Pyramids	
393.	Transverse Section through Lower End of the Medulla of a full-time Fœtus	
394.	Section through the Closed Part of Human Medulla immediately above the Decussation of the Pyramids	
395.	Section through the Lower Part of the Medulla of the Orang	
396.	Transverse Section through the Closed Part of a Fœtal Medulla	
397.	Transverse Section through the Human Medulla in the Lower Olivary Region	
398.	Transverse Section through the Middle of the Olivary Region of the Human Medulla	
399.	Inferior Olivary Nucleus as reconstructed and figured by Miss Florence R. Sabin	
400.	Diagram which shows in part the Fibres which enter into the Constitution of the Restiform Body	
401.	Section through the Junction between the Cord and Medulla of the Orang	
402.	Diagram of the Cerebello-olivary Fibres	
403.	Section through the Lower Part of the Human Pons Varolii immediately above the Medulla	
404.	Diagram to show Connexions of the Direct Cerebellar and the Olivo-Cerebellar Tracts	
405.	Transverse Section through the Pons Varolii at the Level of the Nuclei of the Trigeminal Nerve (Orang)	
406.	Section through the Upper Part of the Pons Varolii of the Orang, above the Level of the Trigeminal Nuclei	
407.	Two Sections through the Tegmentum of the Pons at its Upper Part, close to the Mesencephalon	
408.	Upper Surface of the Cerebellum	
409.	Lower Surface of the Cerebellum	
410.	Sagittal Section through the Left Lateral Hemisphere of the Cerebellum	
411.	From a Dissection by Dr. E. B. Jamieson, showing Corpus Den-

TEXT-BOOK OF ANATOMY.

TEXT-BOOK OF ANATOMY.

INTRODUCTION.

ANATOMY is a comprehensive term, which includes several closely related branches of study. Primarily it is employed to indicate the study of the several parts which build up the body, and the relationship which these present to each other. But during the period of its existence the individual exhibits many structural changes: its structure is not the same at all stages of its life. The ovum or starting-point of every individual is very different from the finished organism as represented by the adult, and the series of changes through which the organism passes until its structure is perfected and full growth is attained constitute the study of **development**. The general term "development" includes not only the various and striking structural changes which occur during the intrauterine life of the individual, to the study of which the term **embryology** is more specially applied, but also many growth processes which occur after birth, such as the later stages in the ossification and growth of the bones, the eruption of the two series of teeth, the adjustment of the vascular system to its new requirements, etc. The actual observation of the processes by which the parts of the body are gradually formed, and of the structural arrangements by means of which a temporary connexion is established between the ovum and the mother, through which an interchange of nutritive and other matters between the two takes place, renders embryology one of the most interesting of all the departments of anatomy. The term **ontogeny** is also used to denote the development of the individual. There is, however, another form of development, slower, but just as certain in its processes, which affects not only the individual, but every member of the animal group collectively to which it belongs. The theory of descent or evolution leads us to believe that between man of the present day and his remote ancestors there is a wide structural gap, which, if the geological record were perfect, would be seen to be completely occupied by long-lost intermediate forms. In the process of evolution, therefore, structural changes have gradually taken place which have modified the entire race. A more or less close or remote blood-relationship links together all the members of the animal kingdom. These evolutionary phases constitute the ancestral history or **phylogeny** of the individual. Ontogeny and phylogeny are intertwined in a remarkable manner, and present certain extraordinary relationships. In other words, the ancestral evolutionary development appears to be so stamped upon an individual that it repeats certain of the phylogenetic stages with more or less clearness during the process of its own individual development. Thus at an early period in the embryology of man we recognise evanescent gill-slits comparable with those of a fish, whilst a study of the development of his heart shows that it passes

through transitory structural conditions in many respects similar to the permanent condition of the heart in certain of the lower animals. It is in connexion with this that the phrase has arisen that every animal in its individual development or ontogeny climbs up its own genealogical tree—a saying which, taking it even in the broadest sense, is only partially true.

The higher conceptions of anatomy, which are obtained by taking a general survey of the structural aspects of the entire animal kingdom, constitute **morphology**. The morphologist investigates the laws of form and structure, and in his generalisations he gives attention to detail only in so far as this is necessary for the proper establishment of his views. The knowledge of anatomy which is required by the student of medicine is different. It is essentially one of detail, and often details important from the practical and utilitarian points of view have little or no morphological value. This want of balance in the interest attached to anatomical facts, according to the aspect from which they are examined, so far from being unfortunate, affords the teacher the means of making the study of anatomy at once fascinating and attractive. Almost every fact which is brought under the notice of the student can be accompanied by a morphological or a practical application. This it is that lightens a study which, presented to the student of medicine in any other way, would be at once dry and tedious.

Certain terms employed in morphology require early and definite explanation. These are homology, serial homology, and homoplasy. The same organ repeated in two different animals is said to present a case of **homology**. But this morphological identity between these two organs must be proved beyond dispute before the homology between them can be allowed. In deciding this identity the great and essential test is that the two organs in question should have a similar developmental origin. Thus the fore-limb of a quadruped is homologous with the upper limb of man; the puny collar-bone of a tiger, the fibrous thread which is the only representative of this bone in the horse, and the strongly marked clavicle of the ape or man, are all, strictly speaking, homologous with each other. Homologous organs in different animals usually present a similar position and a similar structure, but not invariably so. It is not uncommon for a muscle to wander somewhat from its original position, and many cases could be quoted in which parts have become completely transformed in structure, either from disuse or for the purpose of meeting some special demand in the animal economy. In the study of the muscles and ligaments instances of this will be brought under the notice of the reader. Identity or correspondence in the function performed by two organs in two different animals is not taken into consideration in deciding questions of homology. The gills of a fish and the lungs of a higher vertebrate perform very much the same physiological office, and yet they are not homologous. The term **analogy** is often used to express functional correspondence of this kind. Often organs which perform totally different functions are yet perfectly homologous. Thus the wing of a bat or the wing of a bird, both of which are subservient to flight, are homologous with the upper limb of man, the office of which is the different one of prehension.

In the construction of vertebrates and certain other animal groups a series of similar parts are repeated along a longitudinal axis, one after the other. Thus the series of vertebræ which build up the backbone, the series of ribs which gird round either side of the chest, the series of intercostal muscles which fill up the intervals between the ribs, the series of nerves which arise from the brain and spinal cord, are all examples of this. An animal exhibiting such a condition of parts is said to present the **segmental type** of organisation, and in the early stages of development this segmentation is much more strongly marked, and is to be seen in parts which

subsequently lose all trace of such a subdivision. The parts thus repeated are said to be **serially homologous**. But there are other instances of serial homology besides those which are manifestly produced by segmentation. The upper limb is serially homologous with the lower limb: each is composed of parts which, to a large extent, are repeated in the other, and the correct adjustment of this comparison between the several parts of the upper and lower limbs constitutes one of the most difficult and yet interesting problems of morphology.

Homoplasy is a term which has been introduced to express a form of correspondence between organs in different animals which cannot be included under the term homology. Two animal groups, which originally have sprung from the same stem-form, may independently develop a similar structural character which is altogether absent in the ancestor common to both. Thus the common ancestor of man and the carnivora in all probability possessed a smooth brain, and yet the human brain and the carnivore brain are both richly convoluted. Not only this, but certain anatomists seek to reconcile the convolutionary pattern of the one with the convolutionary pattern of the other. What correspondence there is does not, in every instance, constitute a case of homology, because there is not in every case a community of origin. Correspondence of this kind is included under the term "homoplasy." Another example is afforded by the heart of the mammal and that of the bird. In both of these groups the ventricular portion of the heart consists of a right and a left chamber, and yet the ventricular septum in the one is not homologous with the corresponding septum in the other, because the common ancestor from which both have sprung possessed a heart with a single ventricular cavity, and the double-chambered condition has been a subsequent and independent development in the two groups.

Systematic Anatomy.—The human body is composed of a combination of several systems of organs, and the several parts of each system not only present a certain similarity in structure, but also fulfil special functions. Thus we have—

1. The *skeletal system*, composed of the bones and certain cartilaginous and membranous parts associated with them, the study of which is known as **osteology**.

2. The *articulatory system*, which includes the joints or articulations, the study of which is termed **arthrology**.

3. The *muscular system*, comprising the muscles, the study of which constitutes **myology**.

4. The *nervous system*, in which are included the brain, the spinal cord, the spinal and cranial ganglia, the sympathetic ganglia, and the various nerves proceeding from and entering these. The study of these parts is expressed by the term **neurology**. In this system the organs of sense may also be included.

5. The *vascular* and *lymphatic* system, including the heart, blood-vessels, the lymphatic vessels, and the lymphatic glands. **Angeiology** is the term applied to the study of this system.

6. The *respiratory system*, in which we place the lungs, windpipe, and larynx.

7. The *digestive system*, which consists of the alimentary canal and its associated glands, and parts such as the tongue, teeth, liver, pancreas, etc.

8. The *urogenital system*, composed of the urinary organs and the reproductive organs—the latter differing in the two sexes.

The term **splanchnology** denotes the study of the organs included in the respiratory, digestive, and genito-urinary systems.

9. The *integumentary system*, consisting of the skin, nails, hair, etc.

These numerous organs which form the various systems are themselves built up of tissues, the ultimate elements of which can only be studied by the aid of the

microscope. The study of these elements and the manner in which they grouped together to form the various tissues of the body forms an important br of anatomy, which is termed **histology**.

The structure of the human body may be studied in two different ways. several parts may be considered with reference to their relative positions, eithe they are met with in the course of an ordinary dissection, or as they are see the surface of a section through the body. This is the *topographical method.* the other hand, the several systems of organs may be treated separately an sequence. This constitutes the *systematic method,* and it is the plan whic adhered to in this treatise.

Descriptive Terms.—Anatomy is a descriptive science founded on observa and in order that precision and accuracy may be attained it is absolutely neces that we should be provided with a series of well-defined descriptive terms. It r be clearly understood that all descriptions are framed on the supposition that body is in the erect position, with the arms by the side, and the hands held so

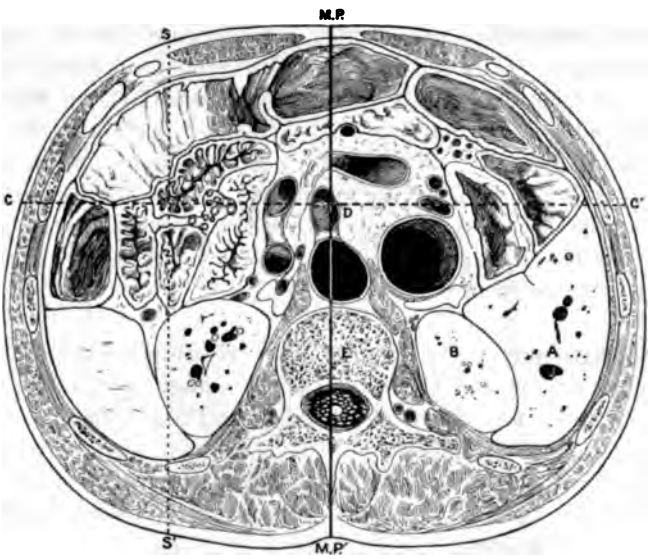

FIG. 1.—HORIZONTAL SECTION THROUGH THE TRUNK AT THE LEVEL OF THE FIRST LUMBAR VERTE

the palms look forwards and the thumbs outwards. An imaginary plan section, passing longitudinally through the body so as to divide it accurately in right and left half, is called the **mesial plane**, Fig. 1 (M.P.). When the right left halves of the body are studied it will be found that both are to a large ex formed of similar parts. The right and left limbs are alike; the right and halves of the brain are the same; there are a right and left kidney and a r and left lung, and so on. So far the organs are said to be **symmetrically** arran But still a large amount of **asymmetry** may be observed. Thus the chief bul the liver lies to the right side of the mesial plane, and the spleen is an o which belongs wholly to the left half of the body. Indeed, it is well to state perfect symmetry never does exist. There always will be, and always must certain want of balance between symmetrically placed parts of the body. T the right upper limb is, as a rule, constructed upon a heavier and more ma plan than the left, and even in those organs where the symmetry appears perfect, as for instance the brain and spinal cord, it only requires a closer stud reveal many points of difference between the right and left halves. The on the front of the body along which the mesial plane reaches the surfa

termed the **anterior median line**; whilst the corresponding line behind is called the **posterior median line**.

It is convenient to employ other terms to indicate other imaginary planes of section through the body. The term **sagittal** is, therefore, used to denote any plane which cuts through the body along a path which is parallel to the mesial plane (S S'); and the term **coronal** or **frontal** is given to any vertical plane which passes through the body in a path which cuts the mesial plane at right angles (C C'). The term **horizontal** as applied to a plane of section requires no explanation.

Any structure which lies nearer to the mesial plane than another is said to be **internal** or **mesial** to it; and any structure placed further from the mesial plane than another is said to lie **external** or **lateral** to it. Thus in Fig. 1, A is external to B; whilst B is internal to A.

The terms **anterior** and **ventral** are synonymous, and are used to indicate a structure (D) which lies nearer to the front or ventral surface of the body than another structure (E) which is placed nearer to the back or dorsal surface of the body, and which is thus said to be **posterior** or **dorsal**. In some respects it would be well to discard the terms "anterior" and "posterior" in favour of "ventral" and "dorsal," seeing that the former are only applicable to man in the erect attitude, and cannot be applied to an animal in the prone or quadrupedal position. They have, however, become so deeply ingrained into the descriptive language of the human anatomist that it would hardly be advisable at the present moment to adopt this course. A similar objection may be raised to the terms **superior** and **inferior**, which are employed to indicate the relative levels at which two structures lie with reference to the upper and lower ends of the body. The equivalent terms of **cephalic** and **preaxial** are, therefore, frequently used in place of "superior," and **caudal** and **postaxial** in place of "inferior."

The terms **proximal** and **distal** should only be applied in the description of the limbs. They denote relative nearness to or distance from the trunk. Thus the hand is distal to the fore-arm, whilst the upper arm or brachium is proximal to the fore-arm.

GENERAL EMBRYOLOGY.

By ALFRED H. YOUNG and ARTHUR ROBINSON.

ALTHOUGH the tissues and organs of the body when fully formed differ greatly not only in respect of their functional characteristics, but also with regard to their structural features, they are developed from cell elements so similar in appearance at first that they cannot be distinguished from one another. They are all the offspring of parent cells—the female cell or **ovum**, and the male cell or **spermatozoon**. Developmental processes apparently take place in the female cell alone, but they cannot occur unless the essential elements of a sperm or male cell previously unite with it.

Like all animal cells, the ovum is a mass of protoplasm (*cytoplasm*) containing a nucleus. In many cells the cytoplasm or cell body is itself enclosed by an external investing membrane, the cell wall, and such a membrane is present in the ovum. Speaking generally, animal cells are minute structures, those of the human body rarely attaining a diameter of more than about ·083 mm., but they vary somewhat in size, they assume different forms, and they acquire characteristic peculiarities associated with their positions and functions; thus, whilst the majority of the constituent cells of an individual form the various tissues and organs of the body, others are reproductive or germinal cells.

Ova are simply specialised cells modified and adapted for the purpose of reproduction and the continuance of the species. They are enclosed, and partially or entirely matured, in the ovaries, or female generative glands, in the cell-lined spaces known as Graafian follicles.

When an ovum has reached a certain stage of development it is discharged from the ovary, and passing along the oviduct or Fallopian tube it eventually reaches the cavity of the uterus. Though mature and capable of being fertilised it may not be impregnated, in which case it does not remain in the uterus, but is cast out from that organ. If, however, it becomes fertilised, by union with the male germinal element, it is retained in the uterus, and develops into an embryo which possesses all the characteristic features of the species to which it belongs and most of the special peculiarities of its parents.

When the embryo, or the fœtus as it is termed after it has assumed definite form, is capable of independent existence, its intrauterine life terminates, and it is separated from the rest of the ovum and is born. The development of the individual, however, is not complete, nor does it become complete until the new being reaches the adult condition.

The term embryology is sometimes used to include the consideration of all the developmental changes and processes which take place in the ovum from the beginning up to the final adult stage. It is more convenient, however, to restrict its application to the study of those changes which take place during the development and growth of the organism before the fœtus is separated from the rest of the ovum, or, in other words, during its intrauterine existence.

Briefly epitomised, the sequence of changes is as follows:—Impregnation of the mature ovum is followed by segmentation or cleavage. By a series of successive divisions the egg-cell is divided into two, four, eight, and ultimately into a large

number of cells, and so is transformed into a multicellular mass, the morula. The majority of the "segmentation masses" or cells, or blastomeres, as they are termed, are differentiated into tissue elements, but a certain number retain the characters of the original germ-cells and become ova or sperm-cells, which form the "points of departure" of succeeding generations. Every germ-cell is derived, therefore, "by a continuous and unbroken series of cell-divisions" which have extended through the past from the most primitive ancestor, and it forms a point from which, under ordinary circumstances, all future generations will commence. It is in this sense that the changes through which a living being passes in the course of its life "may, in their completest form, be considered as constituting a morphological cycle, beginning with the ovum and ending with the ovum again."

To follow these changes it is necessary that the characters and capabilities of the constructive elements should be clearly understood. The animal cell, which plays an all-important part in the life-history of the individual, and the modified germ-cells must be carefully studied, and as far as possible the exact nature of their constituent parts ascertained.

The phenomena of impregnation and segmentation, and the subsequent developmental processes and morphological changes which result in the formation of the embryo, and, finally, the arrangements for the nutrition and protection of the ovum during its intrauterine existence, will then be considered.

THE ANIMAL CELL.

Cells are the structural units of the body. Each cell has an individual life-history within the tissue or organ to which it belongs, it is produced by a pre-existing cell, it develops and grows, is modified by circumstances, reproduces other cells similar to itself, or it dies.

A cell possesses a body and a nucleus. An external investing membrane or cell wall may or may not be differentiated.

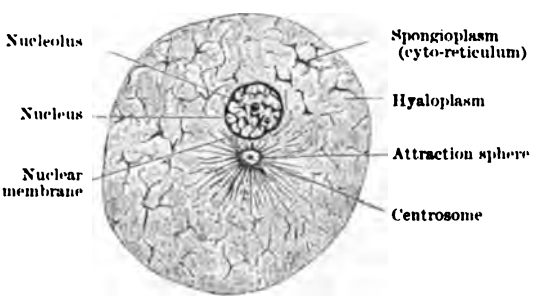

FIG. 2.—DIAGRAM OF AN ANIMAL CELL.

The **cell body** consists of protoplasm—an unstable, highly complex organic substance, the constitution of which is approximately represented by the formula $C_{60}H_{100}N_{16}O_{20}$. It is colourless, semi-fluid, viscous, insoluble in water, capable of osmosis, and it is contractile and irritable. In the living condition it always contains a certain amount of water and various inorganic matters. It is to be observed, however, that there are many varieties of protoplasm, differing somewhat in nature and qualities.

The protoplasm of the cell body is called **cytoplasm**. Under low powers of the microscope it is homogeneous or slightly granular, but with higher magnification, and especially after the application of staining agents, it is possible to distinguish—

(1) A highly refractile, elastic, and extensile network—the **cyto-reticulum** or **spongioplasm**—the meshes of which are filled with

(2) A clear, semi-fluid substance—the **cytolymph** or **hyaloplasm**.

The fibres of the reticulum present some few minute rounded bodies of doubtful nature, which are termed **microsomes**.

The **nucleus** is a spherical vesicle embedded in the cell body. It is surrounded by a distinct nuclear membrane, and usually contains nucleoli.

It consists of modified protoplasm, which is termed **karyoplasm**, the precise relation of which to the cytoplasm is not clear. Structurally it resembles cytoplasm in that it presents a fine reticulum, the fibres of which seem to be continuous with the cyto-reticulum through the nuclear membrane, whilst its meshes are occupied by **nuclear juice**.

The reticulum forms a fine network composed of **linin** fibres (achromatic substance). There is also a coarser network, more readily stainable, consisting of **chromatin**, granular portions of which may also be embedded in the linin. Instead of forming a coarse network the chromatin may be arranged in the form of a convoluted cord, or as a number of separate filaments, and in certain cases it constitutes a series of loops from which secondary branches are projected, the apices of the loops being grouped together at one pole of the nucleus round a clear area known as the "polar field."

The **nuclear membrane** consists of both chromatin and linin.

Nucleoli are of two kinds, true and false. A true nucleolus is a small, refractile particle, of spherical outline, embedded in the reticulum. It stains deeply, and is said to consist of a special modification of the karyoplasm which is called pyrenin. False nucleoli are simply the nodes of the chromatin reticulum.

The nucleus is capable of motion; it has been seen to alter its shape in the living cell, and it undoubtedly plays an active part in the process of cell reproduction.

In addition to the nucleus many cells contain one or more small rounded bodies called **centrosomes**. The centrosomes are modified portions of the protoplasm, and they lie, as a rule, in a modified, clear-looking area of the cytoplasm, which is known as the **attraction sphere**. This is generally situated close to the nucleus, and from its surface a number of fine radiating lines project into the adjacent cytoplasm.

Centrosomes become very evident when reproduction commences, but are not so distinct at other times.

The attraction sphere also becomes more evident when cell-division commences, and the radii which project from it, as well as the contained centrosome, appear to play important parts in the reproductive process.

Reproduction of Cells.—Cell division or reproduction may take place either—

1. By direct division—**amitosis**;
2. By indirect division—**mitosis** or **karyokinesis**.

In the **amitotic or direct form of division** the nucleus, and then the cell body, are equatorially constricted, the constrictions deepen until both are completely divided, and so two daughter cells are produced. Apparently the attraction sphere

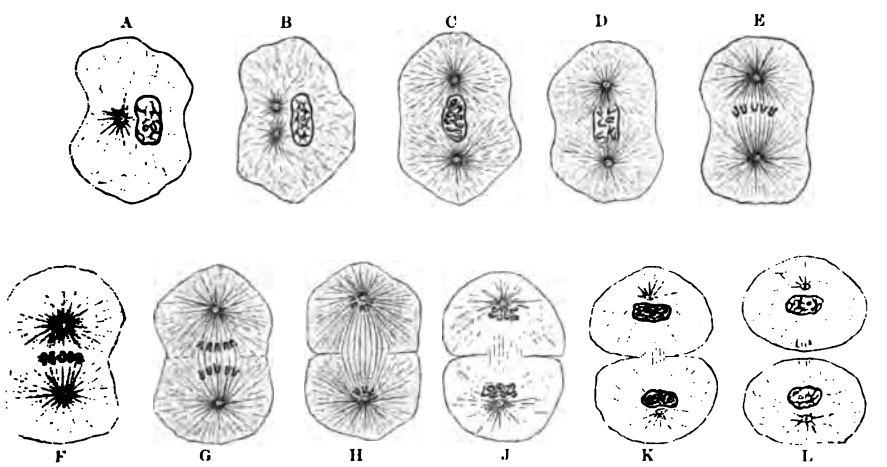

FIG. 3.—CELL DIVISION.

Successive stages of mitosis or karyokinesis (diagrammatic, modified from Henneguy). A, B, C, D, and E illustrate the phenomena of the prophase; F those of the metaphase; G and H those of the anaphase; J, K, and L those of the telophase.

and centrosome play some part in this process, but whether their influence is initiative or directive is unknown.

Mitosis, the process of indirect division, is by far the most common mode of

cell-division. It is a complex process, and the phenomena observable during it progress are classified into four groups: (1) the *prophase*, (2) the *metaphase*, (3) th *anaphase*, and (4) the *telophase*.

The phenomena of the *prophase* commence with the division of the centrosom and attraction sphere into two parts which travel to opposite poles of the nucleu At the same time the reticulum of the nucleus disappears, and in its place a con voluted cord of chromatin, the skein or spirem, is formed (Fig. 3, A, B, and C) this is afterwards broken up into a number of segments which may be mere rod but which more frequently have the form of V-shaped loops (Fig. 3, D). Th nucleoli disappear, and some of the filaments which radiate from the newly-formec attraction spheres seem to penetrate the nuclear membrane at the poles of th nucleus. The nuclear membrane subsequently disappears, and the filament passing from the attraction spheres into the nucleus form two cones, the bases o which meet at the equator of the nucleus, where they fuse together, forming a achromatic spindle which extends between the two attraction spheres (Fig. 3, E).

The loops, or rods, of chromatin are gradually grouped at the equator of th spindle, each rod, or chromosome, being apparently connected with one of th achromatic fibrils; and the prophase is completed.

In the *metaphase* each chromosome is split longitudinally into two halves— daughter chromosomes—which separate from one another; the separation com mences at the apex of each V-shaped chromosome, which appears to be attached t an achromatic fibril (Fig. 3, F).

In the *anaphase* the daughter chromosomes pass to the opposite poles of th spindle. It is suggested that this movement is brought about by the contractio of the spindle fibrils, but this is doubtful, though it is noteworthy that in som cases fine achromatic fibrils connecting the separated daughter chromosomes ar present (Fig. 3, G and H). Slightly before, or simultaneously with, the completio of the anaphase the cell body is equatorially constricted.

During the *telophase* the constriction deepens and the cell is divided into tw daughter cells. Whilst this division is taking place the daughter chromosome which are grouped in the neighbourhood of each attraction sphere at opposite end of the spindle, unite into a convoluted cord, round which a nuclear membrane formed, whilst the cord is converted into a reticulum, and nucleoli appear (Fig. J, K, L). Therefore when the separation of the daughter cells is completed, at th end of the telophase, each possesses all the characteristic features of the mother cel

Reproductive Cells.—The germinal elements, the union of which is essenti to the formation of a new being, are the ovum or female element, and the sperm tozoon or male element.

THE OVUM.

Structurally an ovum presents all the characteristic features of a typical cel It is peculiar because of the large size of the nucleus and nucleolus and in th possession of two investing membranes, an inner one, the vitelline membran which corresponds to the cell wall, and an outer one, the oolemma or zona pellucid Moreover, the nucleus always occupies an excentric position in the cytoplasm, an the cell body contains nutritive material in the form of yolk granules.

The constituent parts of an ovum have received distinctive names, however thus the cell body is known as the yolk or vitellus, the nucleus is termed th germinal vesicle, and the true nucleolus is called the germinal spot.

Vitellus or Yolk.—The body of the ovum, consisting as in an ordinary cell cytoplasm resolvable into reticulum and cytolymph, contains also numerous granul of small but varying size called yolk granules. These are highly refractile, fatt and albuminoid bodies containing phosphorus and mineral salts; collectively the constitute the **deutoplasm** or **nutritive yolk**, in contradistinction to the **cytoplasm** **formative yolk**.

Nutritive or food yolk plays an important part in development. In son animals it is the only means of support for the embryo in the early stages development; in most mammals, on the other hand, the embryo is supplied almo from the first with food not from the egg itself, but directly from the moth

through the placenta. The amount of deutoplasm present in the ova of different animals therefore varies greatly.

Ova in which there is no deutoplasm are spoken of as *alecithal*. Such ova, if they exist, are very rare; most of those usually classed under this head undoubtedly contain a certain amount of deutoplasm granules scattered throughout the cytoplasm, and are better described by the term *oligolecithal*. The size of an ovum is determined by the amount of food yolk present, and all oligolecithal ova are small; the human ovum, which may be taken as a type of the class, is about ·2 mm., or $\frac{1}{125}$th of an inch in diameter.

As the deutoplasm is increased in amount the ovum is increased in size. The deutoplasm also tends to accumulate in certain situations; if the accumulation is at one extremity of the cell the ovum is described as *telolecithal*; such ova are naturally divisible into two areas or poles, a cytoplasmic or formative pole, and a deutoplasmic or nutritive pole.

In *entelolecithal* ova the deutoplasm almost entirely displaces the cytoplasm from one pole, as in the egg of the fowl, in which the cytoplasm is represented by a disc spread over one pole of a large deutoplasmic mass. In many of the arthropoda the deutoplasm accumulates at the centre of the ovum, which is therefore termed *centrolecithal*.

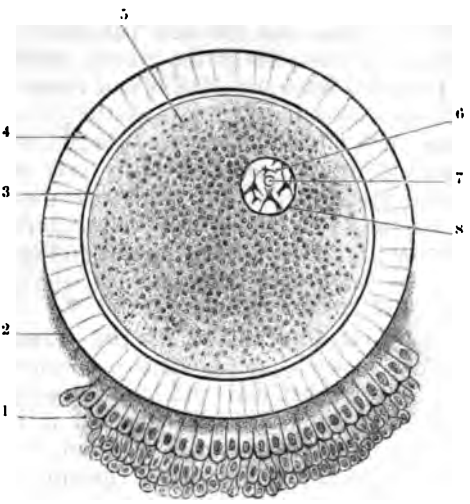

FIG. 4.—THE OVUM AND ITS COVERINGS (Diagrammatic).

The corona radiata, which completely surrounds the ovum, is only represented in the lower part of the figure.

1. Corona radiata.
2. Granular layer.
3. Vitelline membrane.
4. Zona pellucida (oolemma).
5. Vitellus or Yolk.
6. Germinal vesicle (nucleus).
7. Germinal spot (nucleolus).
8. Nuclear membrane.

The **germinal vesicle** or nucleus of the human ovum is about ·05 mm. or $\frac{1}{500}$th of an inch in diameter, *i.e.* $\frac{1}{4}$ the diameter of the whole ovum. It lies excentrically in the yolk, and has the usual characters of a cell nucleus, *i.e.* it possesses a nuclear membrane within which is the karyoplasm, divisible into reticulum or nucleoplasm, and nuclear juice. The nucleoplasm consists of chromatin and achromatic fibres (linin), and the nuclear juice contains one or more spherical and highly refractile true nucleoli or germinal spots; the nodes of the reticulum constitute false nucleoli.

In addition to the nucleus, the vitellus, at certain periods, also contains a structure known as the **vitelline body, body of Balbiani**, or accessory nucleus. It is readily seen in young ova lying near the nucleus. It contains one or more centrosomes, and probably represents an attraction sphere.

Vitelline Membrane. — The vitelline membrane is simply the peripheral portion of the vitellus, modified and transformed into a fine structureless envelope which covers the outer surface of the yolk. It is usually closely applied to the inner aspect of the outer membrane, the zona pellucida, and is best seen in the dead ovum and after treatment by reagents. It is therefore thought by some to be merely a condensation of the outer part of the vitellus produced by the action of the reagents. There is evidence, however, to show that it is present in the normal living ovum.

Zona Pellucida or Oolemma.—This membrane is thick, tough, and refractile. It serves as a protective covering for the ovum, and persists for a considerable time after fertilisation, only disappearing when the ovum becomes attached to the uterus. It is perforated by numerous fine canals, which give to the broad clear membrane a finely striated appearance, from which circumstance it has been called the "zona striata." The zona pellucida is not formed by the ovum, but is secreted by the cells of the Graafian follicle in which the ovum lies; it is consequently regarded as a secondary membrane, and is altogether different from the vitelline

membrane. The perforations in the zona serve for the passage of nutritive material to the ovum.

When the ovum leaves the Graafian follicle it is surrounded by several layers of cells, the innermost of which are columnar. They are derived from the cells of the follicle, and collectively constitute the **corona radiata**; the cells gradually diminish in size, and ultimately disappear. Their function is unknown, but between them and the zona pellucida there is a layer of granular matter, probably formed by the cells of the corona radiata, which rapidly swells up when the ovum is liberated from the follicle, and forms a gelatinous elastic layer called **the albumen**; this increases in thickness as the ovum passes along the oviduct, and persists for some time after it enters the uterine cavity. The function of the albumen has not been definitely ascertained; it may act merely as a protective covering against undue pressure, possibly it may be nutritive, whilst in the dog it apparently helps to fix the ovum to the wall of the uterus. It has not been found in all mammalian ova, and it has not been seen round the human ovum; still it may be present, for human ova at the stage when it might be expected to develop have not yet been observed.

Special Characters of the Ovum.—The ovum as it lies in the Graafian follicle presents no obvious structural modifications when compared with an ordinary animal cell, but undoubtedly differs greatly in its capabilities and life history. Unlike an ordinary cell, it has no inherent power of division into two *equal* parts, but before it is capable of fertilisation it twice undergoes *unequal* division during the period of ripening or maturation; again, its history is different from that of ordinary tissue cells, though it corresponds closely with that of the male germinal elements or spermatozoa.

Maturation of the Ovum.—As it lies in the Graafian follicle before matura-

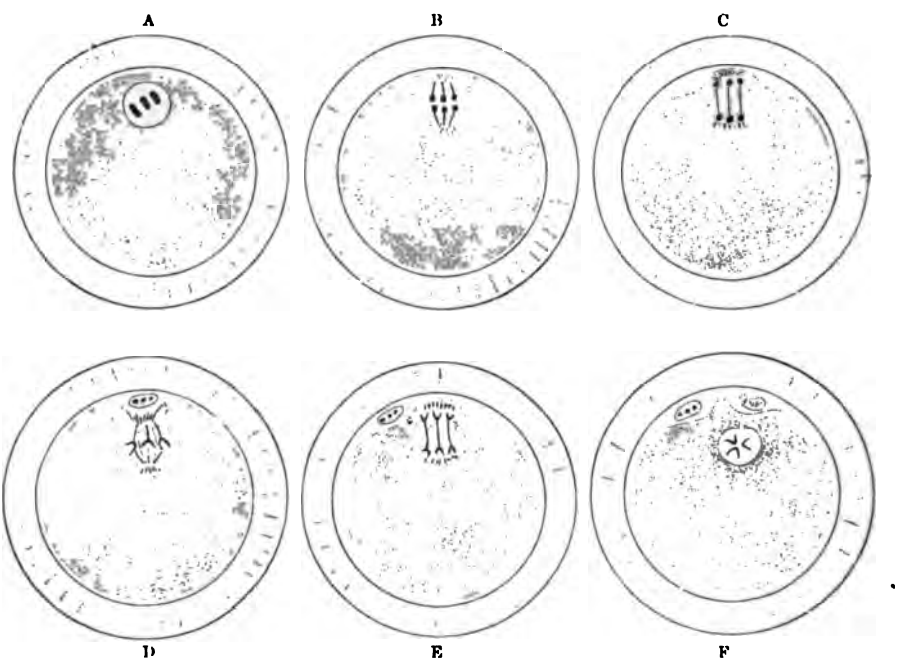

FIG. 5. -THE MATURATION OF THE OVUM: EXTRUSION OF THE "POLAR BODIES" (Diagrammatic).

A, An ovum at the commencement of the process; B, After the formation of the spindle. The chromosome are gathered at the equator of the spindle. C, One apex of the spindle has projected into a bud on th surface, and half of the divided dyads have passed to each pole; D, The separation of the first pola body; E, The commencement of the second polar body; F, The completion of the second polar body.

tion commences, the ovum is, strictly speaking, an oocyte of the first order, derive by a process of cell-division and growth from a primitive germinal cell whic became embedded in the ovary. The more direct descendants of this primitiv germ cell are called **oogonia**, and from them **oocytes of the first order** are developed

The oocyte of the first order is at first small, but as the Graafian follicle in which it lies grows the oocyte also increases in size, and either before or immediately after its extrusion from the follicle it undergoes the changes which constitute maturation or preparation for fertilisation; in other words, it divides twice into unequal parts by a modified process of mitotic division.

It is a well-known fact that all animal cells contain in their nuclei a definite number of chromosomes, the number varying in different groups of animals, but being constant in any given species, and both the primitive germ cells and the oogonia descended from them contain the same number of chromosomes as ordinary tissue cells. But when the oocyte of the first order begins to prepare for the first division during the process of maturation, it is seen that the number of chromosomes it contains is only half that of the ordinary tissue cells. Moreover, the chromosomes are not slender V-shaped loops, but short, thick rods in rings or groups of four granules, and if they are rod-like they do not lie in the prophase with their long axes at an angle with the achromatic spindle, as in ordinary mitosis, but parallel with the filaments of the spindle. During the metaphase the chromosomes do not split longitudinally as in ordinary mitosis, but transversely. This modifica-

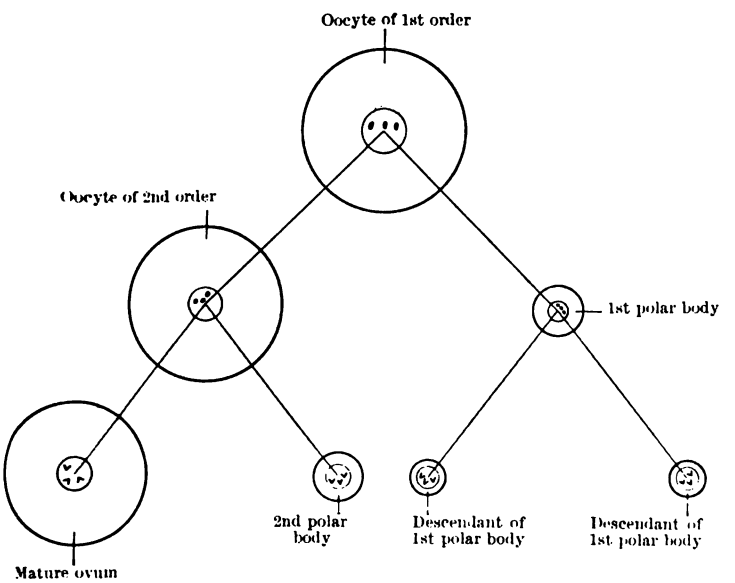

FIG. 6.—DIAGRAM ILLUSTRATING THE MATURATION OF THE OVUM. It must be remembered that in some cases only one polar body is formed, and in others the first polar body does not divide into two parts.

tion of ordinary or *homotype mitosis* is known as *heterotype mitosis*; it takes place not only in oocytes of the first order at the commencement of maturation, but also in the cells of malignant tumours, and its exact signification is not understood. If we imagine that the nuclei of the tissue cells of the animal with which we are dealing contain six chromosomes each, then at the commencement of the first maturation division of the oocyte only three chromosomes will be seen on the spindle which forms. The spindle at its appearance is parallel with one surface of the ovum, but it gradually rotates till it stands at right angles to the surface upon which it impinges, pushing a small part of the cytoplasm before it in the form of a small bud (Fig. 5, B and C). In the anaphase the chromosomes divide transversely, and three half chromosomes pass to the inner end of the spindle and three to the outer end, that is, into the bud-like projection. When the telophase is completed the oocyte of the first order is divided into a small part, the **first polar body**, and a larger part, the **oocyte of the second order**, and each contains three chromosomes (Fig. 5, D). Almost immediately the heterotype division is followed in the oocyte of the second order by a homotype division, no resting stage intervening. A new spindle appears, the three chromosomes radiate from its equator in the usual way, and they divide longitudinally. Three of the daughter

chromosomes pass to the inner end of the spindle and three to the outer, w projects into a second polar bud. Division now occurs, and the oocyte of second order divides into the **mature ovum** and the **second polar body**, each of w contains three chromosomes in its nucleus (Fig. 5, E and F). Thus at the en maturation there lie within the zona pellucida the mature ovum and two p bodies, and the nucleus of the mature ovum, or female pronucleus as it is ca contains half the number of chromosomes which were present in the primi germ cell.[1]

THE SPERMATOZOON.

Spermatozoa are modified cells produced in the testicles or male genera glands. They are formed from the spermatogonia or sperm mother cells which derived from the primitive germ cells of the testicle, and which ultimately pro the **spermatocytes of the first order** (Fig. 7), the latter constituting the immed point of departure in the production of a spermatozoon, and corresponding there with the ovum or oocyte of the first order immediately before its matura commences. The daughter cells of the spermatocytes of the first order **spermatocytes of the second order**, and their descendants the **spermatids** are granddaughter cells of the spermatocytes of the first order. The sperm become closely associated with special sustentacular or nurse cells, and during association are converted into spermatozoa.

Each spermatid is a cell possessing a cell body, a nucleus, two centrosomes, a structure known as an idiosome. The latter is believed by some authoriti

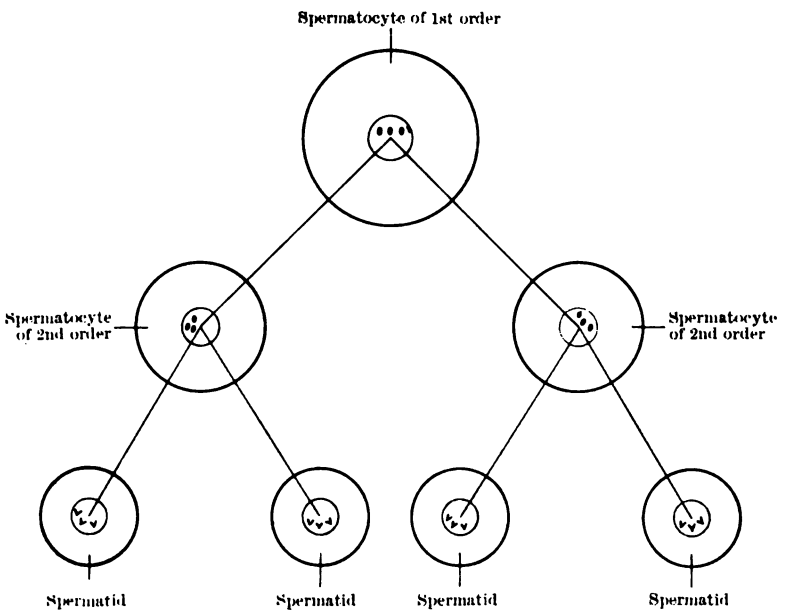

FIG. 7. -DIAGRAM ILLUSTRATING THE PROCESS OF CELL-DIVISION RESULTING IN THE FORMATION SPERMATIDS WHICH ARE AFTERWARDS MODIFIED INTO SPERMATOZOA.

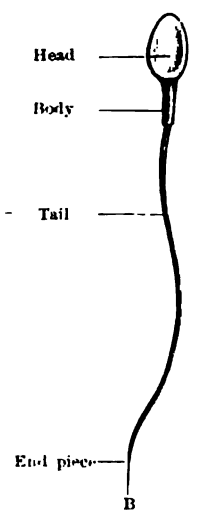
represent the attraction sphere, whilst others look upon it as a special modifica of the protoplasm only established during the process of mitosis, and distinct f the attraction sphere. However this may be, the nucleus of the spermatid bec the head of the spermatozoon (Fig. 9). The idiosome forms the head cap, a filament grows out from the region of the centrosomes, and the body of spermatid forms part if not all of the neck, body, tail, and end piece of spermatozoon. The centrosomes become embedded in the neck, one at its cepl and the other at its caudal end. The axial filament is closely connected the posterior centrosome, which has possibly united with the cytoplasm ir formation.

[1] In the mouse, and probably also in some other mammals, only one polar body is formed in many ca

ere is no doubt that the mature ovum and the spermatozoon, so far as their pment is concerned, are very similar. Each is derived from a primitive ell, which becomes embedded in the generative gland. From the primitive ell in the one case oogonia are formed and in the other spermatogonia, and he oogonia and spermatogonia respectively oocytes and spermatocytes of the der are derived. The oocyte of the first order divides by heterotype mitosis oocyte of the second order and the first polar body, and the spermatocyte first order divides, also by heterotype mitosis, into two spermatocytes of the order. By a second and homotype mitosis the oocyte of the second order into a mature ovum and a second polar body, and the spermatocyte of the order divides into two spermatids. Thus the final result of the division of rmatocyte of the first order is the formation of four granddaughter cells or tids, each of which contains half the number of chromatic particles present primitive germ cell, whilst the final result of the division of the oocyte of st order is the production in some cases of only three granddaughter he mature ovum and two polar bodies, but in many cases the first ody divides in the homotype manner simultaneously with the division oocyte of the second order, and thus the final result of the division oocyte is four granddaughter cells, the mature ovum and three polar each containing half the number of chromosomes present in the primitive ell. There are, however, two differences of importance between the male and the female elements. The final result of the division of the female element is one mature ovum immediately capable of fertilisation and further development, and two or three polar bodies which are incapable of further development and which ultimately disappear. On the other hand, the result of the division of the male element is the production of four equal parts, the spermatids, each of which undergoes further modification, and is transformed into a spermatozoon capable of fertilising a mature ovum.



UMAN SPERMATOZOA
fter Retzius).
iew; B, Front view.

A **spermatozoon**, like an ovum, is a nucleated mass of cytoplasm, but it presents striking modifications in structure. It is very small, and possesses a head, a neck, a body, a tail, and piece (Fig. 8). In addition it is provided with cap which covers more than the anterior half head (Fig. 9). This cap is modified over the apex head into a sharp cutting edge, by means of which rmatozoon, driven forward by the movement of the rces its way through the oolemma of the ovum. the short neck are an anterior and a posterior ome separated by an intermediate disc, and from sterior centrosome an axial filament extends h the body and tail, and terminates posteriorly as l piece. The axial filament is surrounded by a which is thicker in the body than in the tail. Outside the sheath of the lament, in the body, is a spiral sheath, and this is enclosed by a sheath of orm substance, the mitochondrial sheath, which rests at the lower end of y on an annulus or terminal disc.

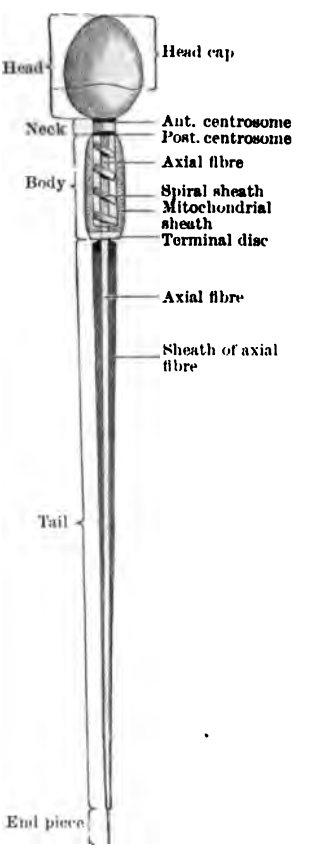


FIG. 9. STRUCTURE OF A HUMAN SPERMATOZOON (after Meeves).

A transverse striation of the head, a spiral filament, a spiral sheath associa with the body and tail, and a terminal spear connected with the head have b described by Bardleben and others, but apparently they do not exist normally parts of the human spermatozoon.

The head of the spermatozoon is ovoid and laterally compressed, so that w viewed from the side it appears pointed; it is about 4·5 μ long, 2·5 μ broad, 1·5 μ thick. The body is somewhat longer than the head, and the tail is six ti as long as the body, therefore the total length of the spermatozoon is about fifth of the diameter of the ovum.

FERTILISATION OF THE OVUM AND THE RESULTS THAT ENSU

Fertilisation.—The mature ovum is fertilised by a spermatozoon. The generative elements meet, and fertilisation takes place as a rule in the u part of the Fallopian tube. The spermatozoon penetrates the zona pellucid the ovum, cutting through it by means of the sharp edge of its head cap. At same time a conical projection, the **cone of attraction**, appears on the surfac the ovum, within the zona pellucida, directly beneath the point at which

spermatozoon is entering. The head, and probably a portion of the body of spermatozoon, plunge into the cone of attraction; the remainder of the body and tail are cast off and disappear. The portion of the spermatozoon which enters cytoplasm of the ovum is converted into a nucleus, the **male pronucleus**, whic accompanied by its attraction sphere and centrosome. When the male pronuc is distinctly formed the granules of the cytoplasm in its neighbourhood begi radiate around it, as if under its influence, and the pronucleus itself tra inwards.

As the male pronucleus approaches the female pronucleus the latter sl

of activity, it undergoes changes of form, and moves to meet the male cleus. For a time the two pronuclei lie in juxtaposition, and ultimately they gether, forming the **first segmentation nucleus.**

e first segmentation nucleus is accompanied by two centrosomes which lie at posite poles, and are the products of the male centrosome which divides as nuclei fuse.

e **fertilised ovum**, the product of the fusion of the mature ovum and the tozoon, contains in its nucleus, the first segmentation nucleus, the same of chromosomes as the primitive ovum or the sperm-mother cell, but the somes of the segmentation nucleus are derived partly from a male and rom a female individual.

rding to some authorities, both the male and female pronuclei are accompanied by nes, and at the moment of union of the pronuclei each centrosome divides; thus four rosomes are formed, two male and two female. From the four half-centrosomes two new nes are formed by the union of half a male centrosome with half a female centrosome. view be correct, each of the two centrosomes which accompany the first segmentation ontains both male and female elements.

mentation.—Segmentation is the division of the fertilised ovum (oosperm) number of cells. These cells are afterwards arranged in layers—the germinal r layers of the blastoderm; ultimately they are differentiated into the tissue s of the body.

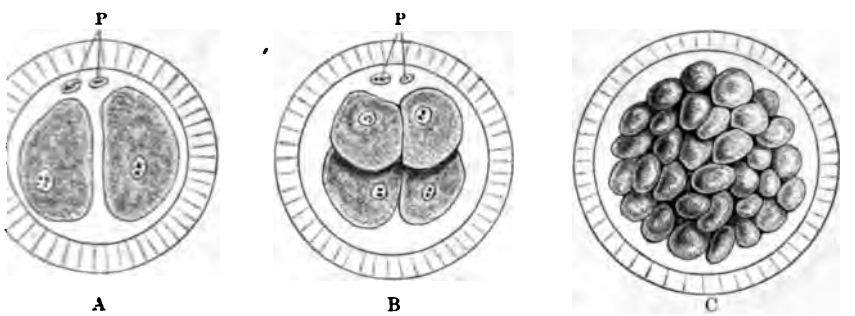

FIG. 11.—SEGMENTATION OF THE FERTILISED OVUM IN THE RABBIT.

Formation of blastomeres and morula (Diagrammatic).
A, Division into two segments; B, Division into four segments; C, Morula; P, Polar bodies.

the phenomena of segmentation have not been observed in the human ovum, is to be understood that the following description is based chiefly upon the ons met with in rodents, more especially in the rabbit, an animal well l for the study of these phenomena.

er a period of quiescence, which succeeds the fusion of the male and female lei, a period of activity supervenes, during which repeated divisions of the nated ovum result in the production of a solid mass of cells called a **morula.** isions are mitotic, and all the phenomena associated with mitosis are readily ble in properly prepared specimens.

planes which separate the several segments of the divided ovum in its stages are termed the "planes of segmentation," and in some animals the ane by which the ovum is divided into the first two daughter cells coincides e future mid-axial or mesial plane of the body, the descendants of the cell the right of it being developed into the right half of the body, and those cell to the left into the left half. There is no proof, however, that this in mammals; all that is definitely known is that the first division separates um into two parts of unequal size but of similar colour and structure.

second plane of segmentation is at right angles to the first, and it separates daughter cells into four granddaughter cells, of which, in some cases, two larger and two smaller. The subsequent divisions occur irregularly, and sult in the formation of numerous cells (blastomeres) which apparently only n size in the rabbit, but which also differ in appearance in many mammals. are mixed together so irregularly that it is impossible to distinguish the

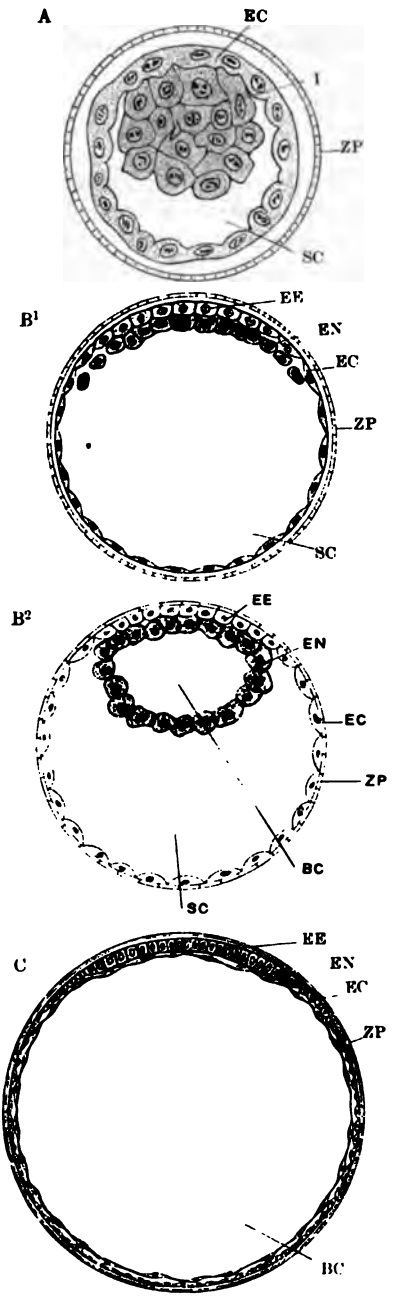

FIG. 12.—CONVERSION OF THE MORULA TO THE BLASTULA.

Formation of blastodermic vesicle and membrane.

A, Appearance of segmentation cavity and attachment of inner cell mass to ectoderm at upper pole of ovum; B^1, Extension and flattening of inner cell mass as it occurs in rabbit and some other mammals; B^2, Extension of entoderm as it occurs in insectivora, monkeys, apes, and man; C, Completion of bilaminar blastodermic vesicle. descendants of one daughter cell from th the other, and in this, the **morula stage,** is frequently no indication of any sepa of the cells into layers. In the meantin polar bodies have disappeared.

The next phenomenon of importance appearance of a cavity—**the segmentation** —in the morula; the ovum assumes a ve character, and is now termed a **blastula.** taneously with the appearance of the the cells of the morula are arranged in two —an outer and an inner. The cells of th group form a layer, the primitive **ectod epiblast**; those of the inner group remain t together and constitute the **inner cell mass** two groups are in contact at one pole ovum, and it is in this region that the e develops (Fig. 12, A).

In the rabbit and in some other ma the outer cells of the inner mass at the emb pole of the ovum blend with the supe primitive ectoderm (Rauber's cells) to fo embryonic ectoderm. This is merely a fication of the more general plan, by whi inner cell mass becomes the inner layer now vesicular ovum, but the conversion inner mass into the entoderm may take in two different ways.

(1) In the rabbit and in many other mals the inner mass gradually flattens o its cells form a layer at the embryonic and the wall of the vesicular ovum, which called a blastodermic vesicle, is partly unil and partly bilaminar (B^1, Fig. 12). Gra however, the margins of the entodermal extend, and ultimately the cavity of the is surrounded by two complete layers, ect and entoderm.

In the hedgehog, in monkeys, apes, a human subject, a cavity appears in the cell mass (B^2, Fig. 12), and the cells arc assume a laminar character, constituting t toderm, which is separated from the ect except in the embryonic area, by the o cavity of the blastodermic vesicle.

In the case of the hedgehog the in the entoderm expands until the entod forced into contact with the ectoderm, condition is attained similar to that m in the rabbit (C, Fig. 12), but in monkey and the human subject the expansion entoderm cavity is not so great, and the en does not attain contact with the ect except in the embryonic area.

In amphioxus and many of the invertebr results of the segmentation are not quite t as in mammals, for at a very early period, the definite formation of a morula mass, the se tion cells arrange themselves in a layer round a

form a complete unilaminar blastoderm. In these cases the bilaminar condition
l by the invagination of a portion of the wall of the vesicle. The opening at
invagination occurs is called the **blastopore**. The cavity enclosed by the
cells is the archenteron, or primitive alimentary cavity or gastrula cavity.
the blastopore the cavity is surrounded by two layers of cells, an outer the
nd an inner the entoderm, and the animal at this period of its development is

In the mammal the cells which become invaginated in amphioxus to form
n are enclosed in the interior of the morula mass at a very early period of the
n, before the vesicular condition is attained, but eventually, as already pointed
rm a layer inside the ectoderm and they enclose a cavity, the blastodermic
h is homologous with the archenteron or gastrula cavity of the lower forms,
ity is closed and the blastopore is not obvious. In amphioxus, however, the
ecomes elongated antero-posteriorly, and along the margins a third layer, the
grows out between the two primitive layers. In the mammal, on the other
the entoderm and ectoderm are definitely established, a linear streak, called
e streak, to which further reference will be made, appears on the surface of
this becomes perforated at its anterior end, and from its margins and mesoderm
wards; clearly, therefore, it represents the blastopore of amphioxus though
rforation is only present for a short time, and the mammalian ovum at this
be looked upon as a gastrula.

oderm and entoderm together constitute the blastoderm or blastodermic
which is bilaminar, and the vesicle of which they form the wall is no
en of as the blastula, but as the **blastodermic vesicle**.

ire of the Ectoderm and Entoderm.—The cells of the ectoderm are at
lar in size and shape, and their outlines are indistinct; but after a short
toderm cells at one pole of the blastodermic vesicle become cubical or
umnar, whilst the remaining cells of the outer layer are flattened and
lar outlines.

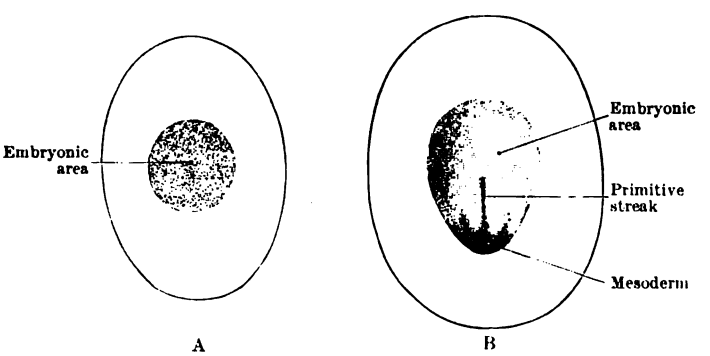

FIG. 13.—SURFACE VIEW OF THE BLASTODERMIC VESICLE.
Showing the embryonic area and the commencement of the mesoderm.
A, Before the appearance of the primitive streak—the embryonic area is circular in form and bilaminar throughout; B, After the appearance of the primitive streak. The posterior end of the primitive streak shows a crescentic thickening, which indicates the commencement of the mesoderm or middle layer of the blastodermic membrane.

later period they are transformed into polygonal plates which appear
ped in section (Fig. 12).

onic Area.—When the upper pole of the bilaminar blastodermic
xamined in surface view from above, a dark, somewhat opaque circular
ble; this is known as the embryonic area. It is coextensive with the
portion of the ectoderm. Very soon after it appears the embryonic area
oid; the small end of the ovoid area is posterior, that is, it lies in the
ch is afterwards converted into the posterior part of the embryo. At
end of the ovoid area a still darker patch of triangular form is developed;
ecomes crescentic, and is the first indication of the primitive streak and
ation of a third blastodermic layer termed the **mesoderm** or **mesoblast**.

mitive streak consists of thickened ectoderm which is seen in transverse
jecting downwards, and resting upon the entoderm in the form of a ridge.

From the sides and the posterior extremity of the ectodermal ridge a lamina of cells projects outwards, and gradually insinuates itself between the ectoderm and the entoderm over the whole area of the vesicle, except in certain regions to be afterwards described. This lamina is the rudiment of the mesoderm. With the formation of the mesoderm the blastodermic membrane becomes trilaminar.

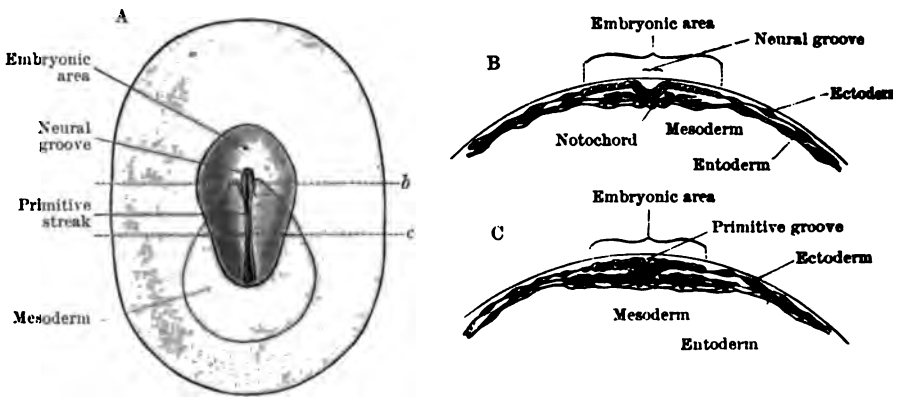

FIG. 14.—THE UPPER POLE OF THE BLASTODERMIC VESICLE.

Showing the embryonic area, the primitive streak with the extension of the mesoderm from its sides at posterior end, and the commencement of the neural groove.

A, Surface view (diagrammatic); B and C, Transverse sections through the blastoderm of the ferret a stage represented in A and along the lines *b* and *c* respectively.

The majority of the cells of the mesoderm are derived from those of primitive streak, but it is said that cells from the entoderm also take part in formation. Young mesodermal cells are round or ovoid, and some give off numer processes. In later stages they may assume various shapes, and many clo resemble the cells of the ectoderm or those of the entoderm.

As the blastodermic vesicle grows, the embryonic or germinal area beco pyriform and increases in length, principally in the posterior part of its ex where the primitive streak is situated; at the same time the streak lengthens

becomes more linear. For a short time a groove, the **primitive groove**, appear the surface of the streak. It is deepest in front, where in some mammals, inc ing man, a small transitory perforation is formed, the **neurenteric canal.**

A second broader and shallower groove then appears in the embryonic immediately in front of the primitive streak; this is the **neural groove**, the rudir of the nervous system. The neural groove, its bounding folds, and the ner system subsequently developed from them are formed entirely of ectodermal elem which at first are continuous with those forming the outer layer of the em The posterior end of the neural groove embraces the anterior end of the prim streak and groove, and at this period the neurenteric canal forms a communica

tween the interior of the ovum and the bottom of the neural groove, which ter afterwards becomes the closed canal of the central nervous system. In some tebrates the neurenteric canal persists for a considerable period, and upon the lopment of the alimentary canal it constitutes a communicating channel ween it and the cavity of the neural tube.

ls the neural groove grows backwards the anterior part of the primitive streak sorbed, and although the posterior part continues to grow, the primitive streak whole diminishes in length; ultimately the greater part of the primitive k disappears, but a portion is recognisable for a considerable time extending the base of the tail, a transitory structure in the human embryo, to the al wall of the body. This portion forms the posterior boundary of the tive alimentary canal; it remains bilaminar, and is called the cloacal brane.

e primitive streak is of great morphological importance; recent researches have shown rom it and the cells in its neighbourhood the greater part of the body of the embryo, he exception of the anterior part of the head and heart region, is developed. It possibly ents the mouth of a remote (pre-vertebrate) ancestor, the fused lips of which formed the of a primitive vertebrate animal. The aperture of this mouth is still represented in lower rates by an opening known as the blastopore. The neurenteric canal is the only represen- of the opening in the human subject.

ace the anterior end of the primitive streak. The neural groove increases ngth both in front and behind. The backward increase takes place at the se of the primitive streak, whilst the anterior increase is due to the rapid th of the anterior part of the embryonic area; at the same time, not because ough coincident with, an increase of the mesoderm which has grown beneath , the medullary folds are gradually elevated, and their apices bending inwards together over the neural groove, which is thus converted into a tube or canal **neural tube**. The medullary folds unite, in the first place, in the region afterwards becomes the neck; and subsequently they unite progressively, rds and backwards.

long the line of union the neural tube is connected, for a time, with the ce ectoderm by a ridge of cells, the **neural crest**. The crest soon separates the surface, but it remains connected with the neural tube, and is utilised in ormation of the cranial and spinal nerve ganglia, the sympathetic ganglia, the id and coccygeal bodies, and the medullary parts of the suprarenal bodies, st the walls of the neural tube are converted into the nervous and sustentacular e elements of the whole of the central nervous system (brain and spinal cord).

Before the tube is closed the neural groove is dilated at each end (see Fig. The posterior dilatation is single; it constitutes the rhomboidal sinus, which u ordinary circumstances soon disappears. Anteriorly, numerous dilatations distinguishable at first. The exact number of these dilatations (neuromeres) said to be eleven. As the tube closes they resolve themselves into three distin vesicles termed the **primary cerebral vesicles.** These constitute the rudiments of t fore- mid- and hind-brains, and their respective ventricular cavities. The remainde of the cavity of the tube becomes the central canal of the spinal cord.

After the separation of the neural crest from the surface the mesoderm co pletely surrounds the whole of the neural tube, and from it are formed t membranes of the brain and spinal cord and their skeletal environments.

The ectodermal cells which form the wall of the primitive neural tube are defined, but they soon differentiate into two sets, **spongioblasts** and **germinal c** The spongioblasts are the more numerous, they are columnar in form, and extend from an internal limiting membrane which is developed round the periphe of the central canal to an external limiting membrane which forms the out limit of the neural tube. There is frequently considerable difficulty in recogni their columnar character, even in the early stages, partly because their nuclei not all lie at the same level, and partly because they are so closely opposed. T spongioblasts are converted into the sustentacular tissue, or **myelospongium,** of t brain and spinal cord, but all do not undergo precisely the same transformatio The inner portions of those spongioblasts whose nuclei lie near the central ca retain a columnar form, and cilia grow from their free surfaces into the lumen of th canal; in other words, they are converted into the ciliated epithelium of the centr canal, but the outer portions of the same cells are transformed into fibrillar proces which terminate externally by fusing with the external limiting membrane. Th remaining spongioblasts entirely lose their columnar form, they become mu branched, and their branches interlace with the fibrillar processes of the ciliate epithelial cells, and with similar branches of neighbouring cells, forming th reticular sustentacular tissue or myelospongium; the external limiting membran is produced by the close interweaving of the peripheral myelospongial fibrils.

The germinal cells are spherical in outline, and contain clear protoplasm an darkly-staining nuclei. They lie between the inner ends of the spongioblasts clo to the central canal where, at the fourth or fifth week, they form an irregular laye and it is believed that they very soon give rise to a new generation of cells, th **neuroblasts,** or young nerve-cells—at all events neuroblasts appear as the germin cells disappear. Each neuroblast rapidly becomes pyriform by the outgrowth of a **axial process** or **axon,** which projects from its outer end towards the periphery o the tube.

Shortly after their formation the neuroblasts migrate outwards, and ultimately those of the cord are arranged in longer or shorter columns in the myelospongium whilst those of the brain are grouped together in definite areas to form th cerebral nuclei.

Each neuroblast as it develops gives off many processes, which vary in lengt and thickness. The first formed of these is the axial process or axon alread referred to. It carries impulses from the cell, gives off lateral branches, an terminates either in association with a special end-organ or by ramifying amid other nerve-processes or round a nerve-cell of the central or peripheral nervou system. The remaining processes of the neuroblast are called **dendrites** protoplasmic processes. They are usually shorter and more branched than th axon, and they carry impulses to the cell. The whole system of cell body, axo and dendrites into which a neuroblast develops is termed a **neuron.**

Every neuron is probably a separate and distinct entity. Its processes neith anastomose together nor with the processes of other neurons. They lie, howeve in close contiguity with either the body or processes of other neurons, or wit special end-organs, and it is possible for impulses to pass from one neuron t another although there is no structural continuity between them.

Extension of the Mesoderm and Division of the Blastodermic Membran into Areas.—It has already been pointed out that when the primitive streak fir

it consists of a thickened ridge of ectoderm situated in the posterior part mbryonic area and resting upon the entoderm. The anterior end of the on fuses with the entoderm beneath it, and from its sides and posterior y a lamelliform outgrowth, the mesoderm, is projected between the and entoderm. At its commencement the mesoderm is an outgrowth primitive streak, but during its subsequent extension it is probably added ls proliferated from the entoderm.

extends the mesoderm forms a semilunar sheet of cells, the concavity of lune being turned forwards, whilst the convexity is gradually projected he margins of the embryonic area. The cornua of the semilunar sheet vards on either side of, and at some little distance from the middle line, ely beneath the medullary folds. Each cornu on reaching the anterior e embryonic area bifurcates, and the resulting processes unite with their f the opposite side.

ie same time the mesoderm grows from its convex margin, and extends rest of the ovum as a continuous sheet. But even when the extension is d, in the majority als, three areas on r aspect of the main devoid of n, and consist only rm and entoderm. rgest of these areas ctly in front of yonic region. In mmals it is folded and backwards in the head of the when this becomes shable, and it takes the formation of e protecting fœtal es, viz. the amnion; refore called the n, and the area ich it is developed es the **proamniotic area.** Probably it is not present in the human blasto- if it exists it is very transitory.

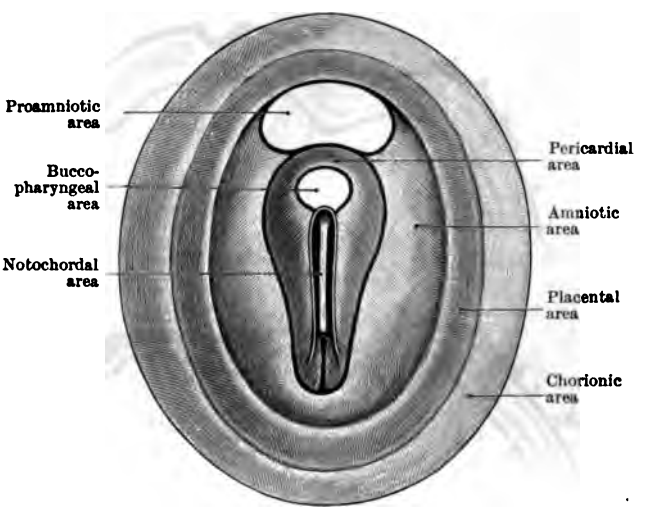

FIG. 17.—SURFACE AREAS OF THE BLASTODERM.

econd of the areas into which the mesoderm does not extend lies in the ic region. It is separated from the proamniotic area by a bar of mesoderm the pericardial cavity afterwards appears. The anterior part of this rea is situated in front of the neural groove, and as, at a later period, it septum between the primitive mouth and the pharynx, it may be termed **o-pharyngeal area.** The posterior part of the area forms the floor of the y groove, and as the notochord is formed from its entodermal layer we ned it the **notochordal area.**

third area corresponds to the posterior part of the primitive streak. It from the base of the tail towards the umbilicus, forming the **cloacal mem-** hich itself forms the posterior boundary of the primitive alimentary canal. ntually perforated by the genito-urinary and anal apertures.

pt in the areas just described, the blastodermic membrane is trilaminar, and rly period it is possible to distinguish the regions in which the heart and um, the amnion, and the placental and non-placental parts of the chorion equently developed. These regions form fairly well-defined areas, to the positions of which reference may now be made.

anterior part of the embryonic area in front of the bucco-pharyngeal area gion in which the pericardium and heart are developed, and it may therefore d the **pericardial area.**

blastodermic membrane immediately surrounding the embryonic area,

including the proamniotic part in those animals in which it exists, is the **amniotic area**, and this is bounded externally by a band of elevated and thickened ectoderm which indicates the **placental area**. The latter, together with the blastoderm over the rest of the ovum, forms the **chorionic area**, which is separable, therefore, into placental and non-placental portions.

These areas are further referred to in the description of the folding off of the embryo and the formation of the fœtal membranes and placenta.

Formation of the Notochord.—The notochord is the primitive skeletal axis of the embryo. When differentiated it forms a rod which intervenes between the ectodermal neural tube and the entoderm of the primitive alimentary canal. It is developed from the entoderm beneath the neural groove in the notochordal area. A linear strip of entoderm thickens and then separates as a solid rod of cells, the continuity of the entodermal layer being restored beneath it. When it is completed the notochord extends from a point immediately behind the primitive fore-brain, and

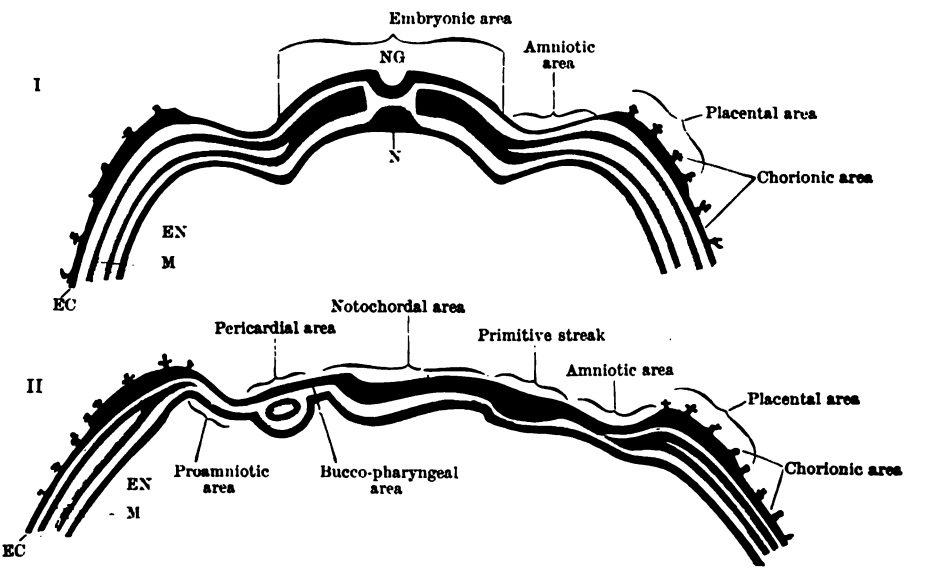

FIG. 18.—SECTIONS SHOWING THE DIFFERENT AREAS OF THE BLASTODERMIC VESICLE (Diagrammatic).

beneath the anterior end of the mid-brain, to the anterior end of the primitive streak, and in later stages, as the skeleton is formed, the notochord can be traced from the post-sphenoid section of the base of the skull, which is situated beneath the mid-brain, to the tip of the coccyx.

The separation of the notochord from the entoderm commences in the cervical region, and extends forwards and backwards. The anterior extremity is the last part to be detached, the separation occurring shortly after the perforation and disappearance of the bucco-pharyngeal membrane.

The cellular notochord develops a cuticular sheath ; it is subsequently surrounded by mesoderm which separates it both from the neural tube and the entoderm, and which is ultimately transformed into the vertebræ and their ligaments, the intervertebral discs, the basi-sphenoid and basi-occipital parts of the skull, and the membranes of the brain and cord.

As the surrounding mesoderm is differentiated the notochord becomes nodulated ; the thickened portions are situated in the regions of the intervertebral discs, and the intermediate constricted portions in the regions of the vertebral bodies. The vertebral portions gradually disappear, and the intervertebral parts are converted into a kind of mucoid tissue, the pulp of the intervertebral discs.

Formation of the Cœlom.—In all animals in which the entoderm and ectoderm

lie in close relation with each other over the whole surface of the ovum, the

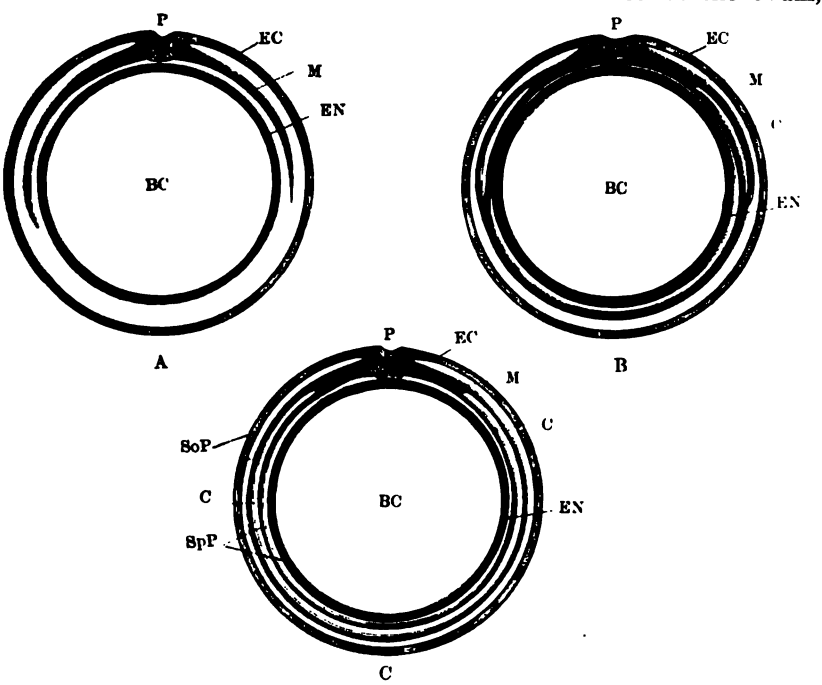

Fig. 19.—Extension of Mesoderm and Formation of Cœlom (Diagrammatic).

A. Mesoderm spreading from the sides of the ectodermal primitive streak, and extending between the ectoderm and entoderm. B. Further extension of the mesoderm and appearance of cœlomic cleft-like spaces. C. Complete delamination of the mesoderm and formation of cœlom.

mesoderm as it extends from the primitive streak forms a single layer, and where this exists the blastoderm is trilaminar, but in monkeys, apes, and the human subject, as the ectoderm and entoderm are separated from each other by the segmentation cavity Fig. 12, B², the mesoderm almost from its commencement extends in two layers, one the splanchnic on the entoderm, and the other the somatic on the inner surface of the ectoderm. In other mammals before the extending mesoderm entirely separates the ectoderm from the entoderm, a cavity is formed in it by the union of a series of cleft-like spaces which appear near the margin of the embryonic area and rapidly fuse together, forming the cœlom or body cavity. Thus in the majority of mammals the cœlom is formed by the cleavage of the mesoderm, but in the higher forms it represents the segmentation cavity which has become surrounded by two extending layers of mesoderm. In those animals

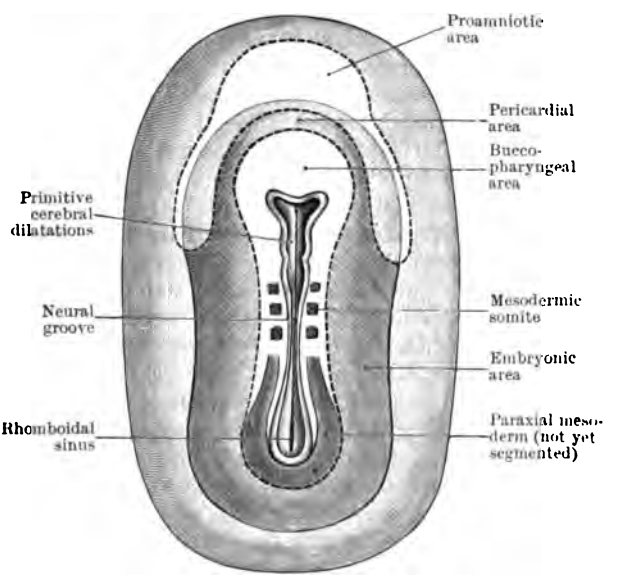

Fig. 20.—Surface View of an Early Embryo (Diagrammatic). Showing the neural groove, dilated in the head region but still unclosed, and the first protovertebral somites. The margins of the cœlomic space are indicated by dotted lines.

in which it appears by cleavage of the mesoderm, it extends towards both pc of the ovum, but in the higher forms only towards the embryonic pole, and both groups its extension in the embryonic area is arrested before it qu reaches the side of the notochord and the mesial plane of the primitive streak. extends across the pericardial area, however, and forms the rudiment of t pericardial cavity, which appears as a transverse tubular passage continuous each side with the general body cavity. The outer or parietal layer of t mesoderm becomes more or less closely attached to the ectoderm, and with forms the **somatopleure**, whilst the inner or visceral layer is similarly associat with the entoderm to form the **splanchnopleure**.

When the cœlom is fully formed the blastoderm contains two cavities, one, t cœlom or body cavity, situated between the two layers of the mesoderm, and t other the cavity of the blastodermic vesicle, usually called the vitelline cavity, wh lies inside the entoderm.

Mesodermic or Protovertebral Somites.—During the formation of the cœl the undivided mesoderm at each side of the notochord thickens, principally b dorsal upgrowth which is coincident with the uprising of the ectodermal medull folds which bound the neural groove. There are thus formed two thickened bars mesodermal tissue, one on each side of the neural tube, and they together constitu the **paraxial mesoderm** (Fig. 15); the more laterally situated portions of the mesode are known as the **lateral plates.**

The paraxial mesoderm is soon divided, except in the head region, by a numl of transverse clefts into a series of cubical masses termed the **mesodermic somit** These are at first partially, and afterwards more completely separated from t lateral plates by longitudinal grooves. After the longitudinal grooves are form the mesodermic somites of each side are connected with the lateral mesoderm b somewhat contracted strand of cells, the **intermediate cell mass** (Fig. 16). T strand is represented in lower vertebrates by a series of separate cords of ce the stalks of the somites, each somite possessing one stalk.

The separation of the paraxial mesoderm from the lateral plates and t segmentation of the former into somites extends forwards to the region of the hi brain, where the first protovertebral somite is formed. In front of this t mesoderm, in mammals at least, does not become segmented.

The cavity of the cœlom may extend into the paraxial mesoderm before it segmented into protovertebral somites, or it may stop just outside the limits of paraxial mesoderm. In the former case each somite, when separated from lateral plate, contains a cavity, and the intermediate cell mass is also hollow fo time. In the latter case the protovertebral somites and the intermediate cell mas are solid; at a later period, however, a cavity which contains a few spherical c appears temporarily in each somite.

Folding Off of the Embryo from the Blastodermic Vesicle.—Although many rudiments of the embryo become distinguishable at an early period in development (the embryonic area, the primitive streak and groove, the neu groove, the notochord, and the protovertebral somites), the body of the embryo d not assume its characteristic form until it becomes raised and folded off from general surface of the blastodermic vesicle.

The main cause of the folding off of the embryo from the surface of the vesi is the more rapid growth of the embryonic area as contrasted with the slower grov and expansion of the remainder of the wall of the vesicle; and the moulding of increasing embryonic area into the form of the embryo is due to differences in rate of growth of the various parts of the area itself.

The manner in which the area is folded, and the changes in the relat positions of its various parts which necessarily result, will be easily understood reference to Figs. 21 and 27.

The embryonic area at an early period increases rapidly, especially in leng Its margins, however, appear to remain comparatively fixed, and hence as the a increases it must fold upon itself. It becomes more convex externally, and raised slightly above the general surface, but at the same time it apparently sin into the interior of the ovum, and the amnion folds close over it.

The antero-posterior growth is greater than the lateral; consequently the folding of the embryonic area is most marked in front and behind. Anterior and posterior, or cephalic and caudal folds are formed, which indicate the head and tail extremities of the embryo. Similarly, lateral folds define the lateral limits of the body.

When the body of the embryo thus becomes folded off it contains a portion of the blastodermic cavity and of the cœlom; the former is the primitive alimentary canal, and the latter is the rudiment of the pericardial, pleural, and peritoneal cavities.

The communication between the pleuro-peritoneal and the extra-embryonic

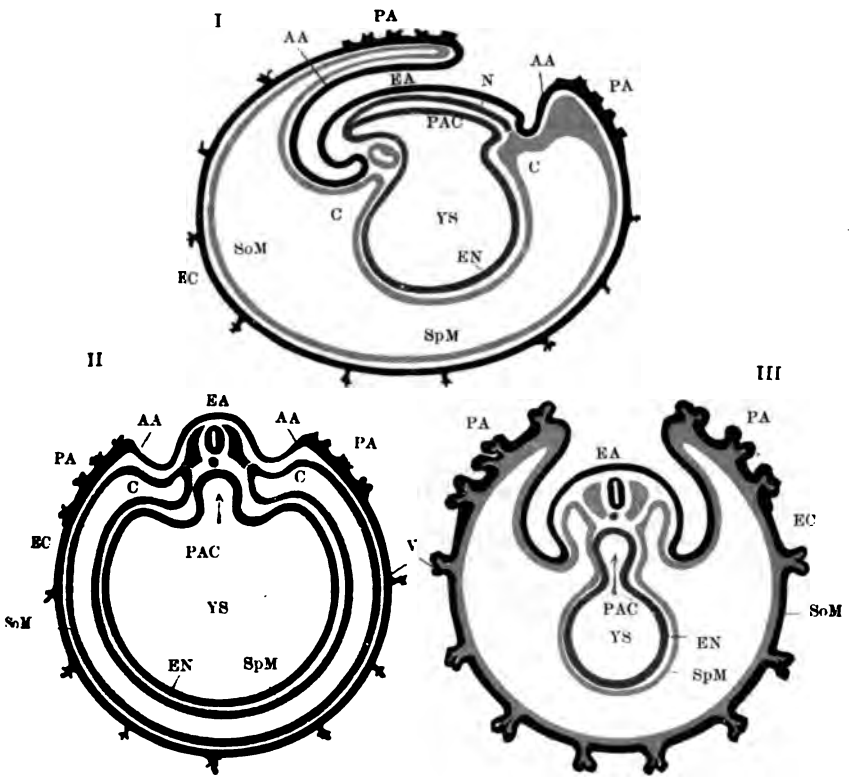

FIG. 21.—EARLY STAGES IN THE FOLDING OFF OF THE EMBRYO (Diagrammatic).

I. Longitudinal section of a developing ovum. The folding off of the embryo has commenced, and the head fold, bending down in front, has invaginated the amniotic area. The tail fold is partly formed, and the primitive alimentary canal, closed in front, communicates freely with the yolk-sac by a wide umbilical aperture.

II. Transverse section of a developing ovum showing the commencement of the "folding off." The thickened embryonic area is convex externally, and it already appears to sink below the surface of the ovum.

III. Transverse section showing the "folding off" more advanced. The changes seen in II. are more marked, and by apparent constriction at the junction of the embryonic area with the rest of the blastodermic vesicle the embryo is still further nipped off, and distinct lateral folds are formed.

The division of the cavity of the blastodermic vesicle into that of the primitive alimentary canal and that of the yolk-sac is shown in all the figures.

The amniotic area, directed upwards and inwards in II., forms with the placental area the amniotic fold, and in III. the amniotic folds of opposite sides are approaching one another over the back of the embryo to enclose the cavity of the amnion. The relative positions of the different areas of the blastoderm are correspondingly modified.

portion of the cœlom is obviously bounded by the margins of the embryonic area, which constitutes the limits of the umbilical orifice.

The margins of the embryonic area retain approximately their original positions, and in its further growth the embryo extends beyond them in all directions.

THE EMBRYO.

The embryo, now easily distinguishable from the rest of the ovum, is already sufficiently developed to give some indication of the general plan of its organisation, and of the ultimate relation and fate of the three layers of the blastoderm which enter into its constitution. There are as yet no limbs, but the general contour of the head and body are defined. It possesses a notochord, afterwards replaced by the permanent vertebral column, which constitutes a longitudinal central axis. On the dorsal aspect of the notochord the neural groove is closing to form the neural canal, or primitive cerebro-spinal nervous system, whilst on its ventral side a portion of the blastodermic cavity is being included as a primitive tubular alimentary canal, which freely communicates with the remainder of the blastodermic cavity now called the cavity of the yolk-sac.

The formation of the mesodermic somites has commenced, and this is the first indication of that segmentation which is such a characteristic feature in the structure of the vertebrate body.

The general relations of the three layers of the blastoderm remain unaltered. Thus, externally, there is a layer of ectoderm forming the surface of the body; internally, a layer of entoderm lining the primitive alimentary canal; and between them is the mesoderm enclosing the cœlom.

The **surface ectoderm** forms the epithelial elements[1] of the skin and its appendages, and of the glands which open on it. Thus the hairs and hair-follicles, the nails, the enamel of the teeth, the epithelium of the sebaceous glands, of the sweat glands, and of the mammary glands are all ectodermal. The epithelium of the conjunctivæ and of the lachrymal glands is also derived from ectoderm. The roof of the mouth, the inner surfaces of the cheeks, the nasal passages and their associated cavities, together with the adjacent part of the pharynx and the anterior lobe of the pituitary body, as well as the external auditory canal and the outer layer of the tympanic membrane, are all developed from the surface, and their epithelium, with that of their glands, is ectodermal in origin. The epithelium of the sense organs, except that of taste (the tongue), is derived from ectoderm; the auditory and olfactory epithelial elements, and those of the lens and cornea, are from surface ectoderm; whilst the epithelial elements of the retina are from neural ectoderm.

The **neural ectoderm** is removed from the surface to form the neural tube and neural crest, from which the cells and fibres of the whole of the nervous system,[2]

[1] The term "Epithelium" is applied to tissues consisting of cells which are united with one another by means of a small amount of intercellular substance.

The cells constituting epithelium are always arranged in one or more layers; they cover free surfaces and line the various cavities of the body, including the vascular and lymphatic systems; they also form the active elements in secretory glands and line their ducts. Epithelium is always non-vascular, and the cells receive their nourishment from blood-vessels which are in their vicinity. Epithelial cells are modified in accordance with the particular functions they are called upon to serve, and they present many variations in shape, size, and structure, *e.g.* the neuro-epithelial cells of the central nervous system and of the peripheral sense organs differ considerably from the more ordinary epithelial type; but they are simply more specialised, and therefore more modified.

[2] It seems possible that this statement may, before long, require modification, for evidence is being brought forward to show that some portions of the system are developed from peripherally situated ectodermal cells

both central and peripheral, and the sustentacular tissue of the brain and spinal

The **entoderm** lines the alimentary canal and the spaces and glands which open into it, except the upper parts of the mouth and pharynx and the terminal portion of the rectum; thus the epithelium of the Eustachian tube and tympanic cavity, the trachea, the bronchi, the air-vesicles of the lungs, the gall-bladder, the urinary bladder, and part of the urethra is entodermal. It forms the epithelial constituents of the taste buds or organs of taste, the liver and the pancreas, the

of the connective tissues, fasciæ, and vessels of the ventro-lateral walls of the body and in mammals, apparently, it also gives origin to the ventro-lateral body muscles and the muscles of the limbs. The splanchnic portions of the lateral plates form the fasciæ, the connective tissues, the smooth muscles of the walls of the alimentary canal, the heart and great blood-vessels, the visceral layers of the pleural and peritoneal membranes, the spleen, and the germinal epithelium, which becomes transformed into the mother cells of the ova and spermatozoa.

In the cephalic region, in higher vertebrates, lateral plates are not recognisable, except so far as they may be represented by the walls of the pericardium; but in some lower vertebrates lateral plates can be distinguished, corresponding in number with the cephalic somites, and it has been asserted that the muscles of the face and the muscles of mastication are developed from the lateral plates associated with the second and third cephalic somites. The subject, however, is one which is still obscure, and requires further investigation before any very positive conclusion can be arrived at.

Intermediate Cell Mass.—As already mentioned, the lateral plates and the mesodermic somites are connected by the intermediate cell masses, which are intimately associated with the development of the ducts and tubules of the genital and urinary organs in man and other mammals. On each side the mass soon separates from the mesodermic somites, and is transformed by rapid proliferation of its cells into an elongated body, the Wolffian body or primitive kidney, which projects downwards into the dorsal angle of the body cavity. In early stages it extends from the fifth somite of the body, backwards to its posterior end, but is most clearly differentiated in the middle portion. The Wolffian duct and tubules and the Müllerian duct are developed in connexion with it; after the second month of intrauterine life it degenerates, and is replaced by the permanent kidney, which is formed dorsal to its posterior extremity.

THE DEVELOPMENT OF THE PRIMITIVE ALIMENTARY CANAL.

When the cephalic, caudal, and lateral folds are established, and the general outline of the embryo is clearly defined, its dorsal and lateral surfaces and it

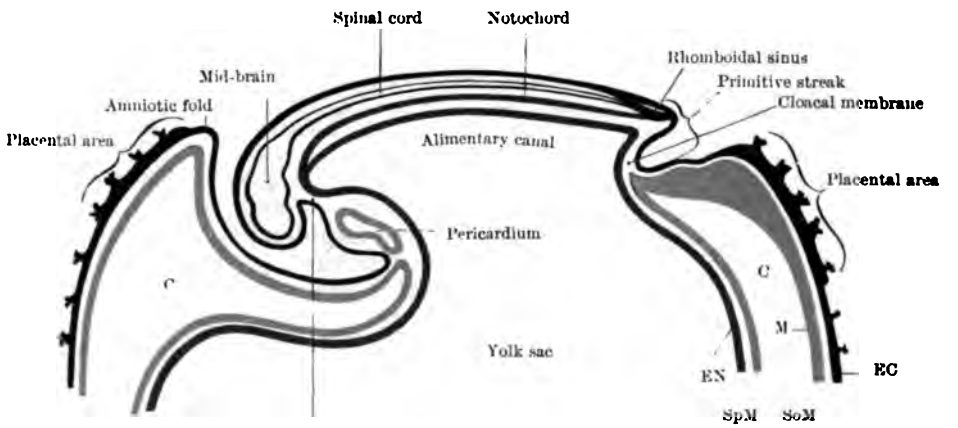

FIG. 27.—DIAGRAM OF A DEVELOPING OVUM, SEEN IN LONGITUDINAL SECTION.

The folding off of the embryo has commenced, and the downward bend of the head fold in front has invaginated the amniotic area. The tail fold is partly formed, and the primitive alimentary canal, closed in front by the bucco-pharyngeal membrane and behind by the cloacal membrane, is distinguishable; it communicates freely with the yolk sac by a wide umbilical aperture.

anterior and posterior extremities are easily recognisable, and, as the embryo is folded off from the surface of the blastodermic vesicle, a portion of the blastodermic cavity is enclosed within it; this is the primitive alimentary canal. It is simply an incomplete tubular cavity, situated beneath the notochord, which is bounded

y the head fold, behind by the tail fold, and laterally by the lateral folds, videly open below and continuous with the cavity of the yolk-sac.

the head of the embryo grows more rapidly than any other part, the head more marked than the other folds, and with its formation the pericardial bent round until it becomes ventral in position, its original upper and lower s being reversed (Fig. 27). It is owing to this change of relative position ie ventral wall of the alimentary canal is completed in front, and it is that its anterior limit corresponds to the bucco-pharyngeal area of the erm. The part of the blastodermic cavity enclosed in the head fold con- the **fore-gut.**

tail fold at this period is small, but it limits the primitive gut behind. ventral closing of the posterior end of the primitive alimentary canal to **hind-gut** is produced, ie case of the fore-gut, ling of the embryonic This takes place in the of the tail fold; but terior part of the em- area retains for a con- e time its original , and forms a connect- lk, termed the **body-** between the embryo chorionic area of the erm. Ultimately, how- is terminal section of lbryonic area is re- n position, its posterior ng carried forwards till s the posterior boundary mbilical orifice, and the wall of the hind-gut is mpleted.

rest of the primitive tary canal constitutes **d-gut.** It remains for ime in free communica- ith the cavity of the ic, and this communica- etween the alimentary and the yolk-sac at a stage forms a tubular e, the **vitello-intestinal**

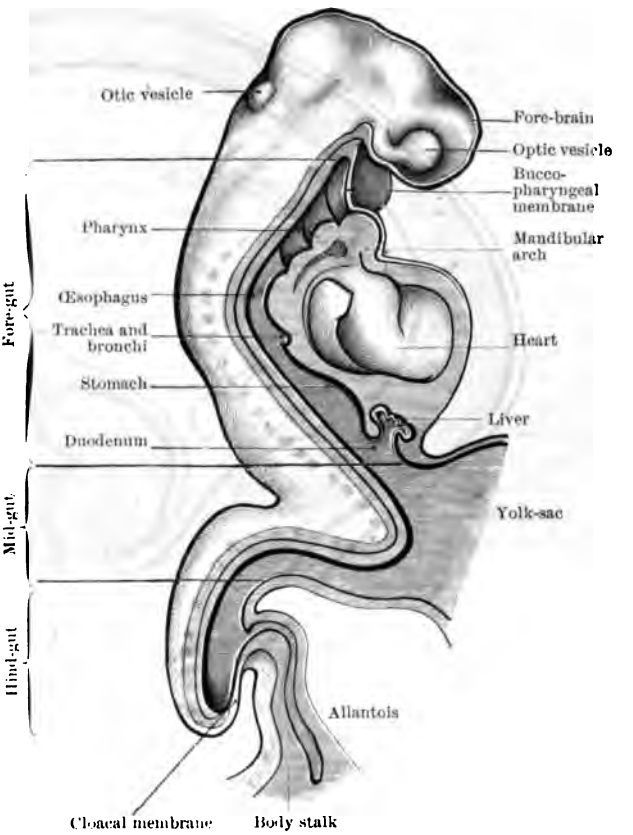

FIG. 28.—DIAGRAM REPRESENTING THE CONDITION OF THE ALIMENTARY CANAL IN A HUMAN EMBRYO ABOUT FIFTEEN DAYS OLD (modified from His).

The visceral clefts are formed, and the subdivisions of the fore-gut, together with the rudiments of the bronchi and liver, are distinct.

e entoderm forms the epithelium of the ali- y canal, but this is d by the splanchnic layer of the mesoderm, which is separated from the pleure or body wall by the cœlom or body cavity. As the splanchnic erm passes on each side to its continuity with the somatic mesoderm it forms by which the gut is suspended from the under surface of the primitive al column; this fold is the **mesentery.**

nen the diaphragm is formed at a later period it separates the thorax from lomen, and divides the cœlom into pleural and peritoneal portions.

e primitive alimentary canal is almost a straight tube, blind at both its ities, and communicating only with the cavity of the yolk-sac. As yet there outh and no anal passage or aperture. The simple tubular canal is divisible ore-gut, mid-gut, and hind-gut, parts which are conveniently associated mentally with definite portions of the fully-formed alimentary canal.

Thus the fore-gut is converted into the pharynx, œsophagus, stomach, and the greater part of the duodenum; whilst from the mid-gut and the hind-gut the rest of the small intestine (jejunum and ileum), and the whole length of the large intestine (cæcum, colon, and rectum), are formed. There is no sharp limit between the mid-gut and the hind-gut, or between the portions of the intestinal canal which develop from them.

Diverticular outgrowths from the entoderm of the primitive alimentary canal form the rudiments of the intestinal glands, including the liver and pancreas; of the respiratory apparatus; and of the thyroid and thymus glands. Details of the formation of these structures are given in the special description of the development of the system to which each belongs.

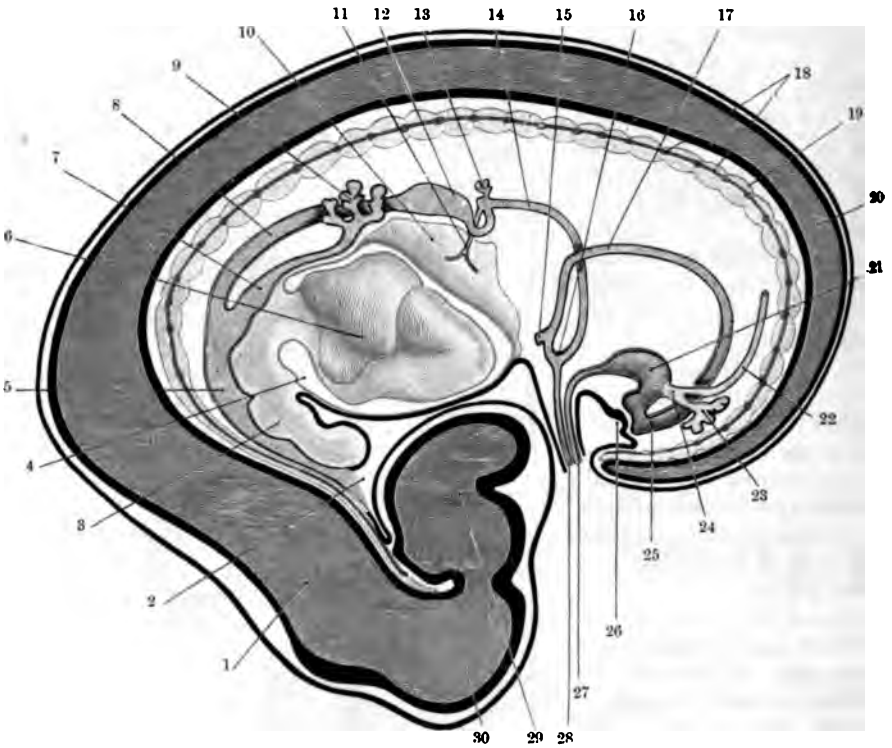

FIG. 29.—FURTHER DEVELOPMENT OF THE ALIMENTARY CANAL, AS SEEN IN A HUMAN EMBRYO ABOUT FIVE WEEKS OLD (Diagrammatic).

The tongue is well formed, the trachea and œsophagus are separated, the bronchi have commenced to branch; the duodenal curve is well formed, and the cæcum has appeared in the loop of the mid-gut. The cloaca is partially separated into genito-urinary and rectal portions.

Except with respect to the anterior part of the fore-gut, the changes in shape and position which the originally simple alimentary tube undergoes during its conversion into its final or adult form are described in the account of the development of the digestive organs; but the development of the pharynx and the structures associated with it, and the formation of the mouth and anus, may be considered now.

Development of the Pharynx and Stomatodæum.—The development of the anterior part of the fore-gut into the pharynx and the floor of the mouth is so intimately associated with the formation of a primitive mouth, the stomatodæum, that the two must to a certain extent be considered simultaneously.

The **stomatodæum** first appears as a depression between the head and the peri-

cardial region. It is produced by the downward growth of the fore-part of the head in front and the bulging forward of the pericardium behind, and it is separated from the anterior end of the fore-gut by the bilaminar bucco-pharyngeal membrane. When the stomatodæum first appears it is not enclosed laterally; but at a later period side boundaries are formed, and the space is developed into the upper part of the mouth and the nasal cavities.

The fore-gut, a relatively wide space, continuous posteriorly with the mid-gut, is at first closed anteriorly by the bucco-pharyngeal membrane, which separates it from the stomatodæum. About the fifteenth day, in the human embryo, the bucco-pharyngeal membrane disappears, the fore-gut is then thrown into continuity with the stomatodæal space, and the anterior opening of the alimentary canal is formed.

As development proceeds the cavity of the fore-gut is gradually compressed dorso-ventrally until its transverse section assumes a triangular outline; but in the earliest stages there are no indications of the various organs which are ultimately developed from its walls. After a short interval, however, two elevations appear in its ventral wall. The anterior of these is a rounded elevation, termed the **tuberculum impar**. It is situated directly behind the lower ends of two raised bars or **arches**, called the mandibular arches, which are growing down into the floor of the fore-gut from the anterior parts of its lateral walls. The tuberculum impar is the rudiment of the anterior two-thirds of the tongue, which is thus formed in the floor of the entodermal portion of the alimentary canal. The more posterior elevation, termed the **furcula**, is a curved ridge, which bounds a mesial longitudinal depression. It is separated from the lateral walls of the fore-gut and from the tuberculum impar by a groove, the **sinus arcuatus**. The anterior part of the furcula is transformed into the epiglottis and the margins of the upper aperture of the larynx; the median depression becomes the cavity of the larynx and of the trachea, and from its posterior end hollow outgrowths extend and form the rudiments of the epithelial lining of the bronchi and lungs. Still more posteriorly, behind the region of the furcula, a dilatation of the fore-gut is formed, which projects forwards and downwards towards the pericardium. This is the first indication of the stomach.

Visceral Clefts and Visceral Arches.—In the lateral wall of the anterior part of the fore-gut, on each side, four incomplete and more or less transverse clefts, the visceral clefts, appear. They are due to outward linear pouchings of the entoderm, and corresponding, but less marked, inward depressions of the ectoderm. The anterior cleft is the best marked, and the rest diminish in size from before backwards. At the bottoms of the clefts the ectoderm and the entoderm are in contact, but the thin membranes thus formed, which intervene between the cavity of the fore-gut and the exterior, are only exceptionally and abnormally perforated in the human subject, though in lower vertebrates they invariably disappear, and the pharyngeal or anterior part of the fore-gut is thrown into continuity, laterally, with the exterior by a number of narrow slits, the gill slits, which are used for respiratory purposes. In man and other mammals, however, the floors of the second, third, and fourth clefts are utilised in the formation of the sides of the neck; that of the first cleft is transformed into the tympanic membrane, which separates the external auditory meatus from the cavity of the tympanum.

In the further consideration of the fate of the visceral clefts, it must be borne in mind that each consists of an inner or entodermal portion and an outer or ectodermal portion. The inner part of the first cleft is converted into the tympanum and the Eustachian tube, and the outer part becomes the external auditory meatus. No traces of the outer part of the second cleft are left, but a portion of the inner part can be recognised as a slight depression above the tonsil in the lateral wall of the pharynx and in a recess, the fossa of Rosenmüller, behind the pharyngeal end of the Eustachian tube. Both the outer and inner portions of the third and fourth clefts disappear, but from their inner parts diverticula are given off which form the rudiments of the thymus and the lateral lobes of the thyroid body. The diverticula from which the thymus is developed are derived from the third clefts, whilst each lateral lobe of the thyroid body, in the majority of mammals, is formed by a diverticulum from the fourth cleft, but in some mammals the lateral lobes are

derived from the median diverticulum, and the outgrowths from the posterior pa of the fourth clefts constitute the post-branchial bodies.

The margins of the visceral clefts are thickened by the growth of the mesode between the entodermal and ectodermal layers, and they are moulded into a se of five rounded bars, the **visceral arches**, of which the fifth is not recognisa externally, though it is easily seen internally. The dorsal extremities of the arc terminate at the sides of the head below the level of the neural tube, and in t early stages the ventral ends rest upon the pericardial region. When the neck formed, it grows forwards from the pericardial region and carries with it the lo ends of the visceral arches, which henceforth terminate in its ventral wall. As t visceral arches are carried forwards the head is strongly curved towards the vent aspect, and the lower ends of the visceral arches are pushed backwards over ea other till t fourth is ov lapped by t third, and t third by t second.

C. Cœlom.
E. Epiglottis.
F. Furcula.
FC. Foramen cæcum.
G. Glottis.
SA. Sinus arcuatus.
T. Tongue.
TI. Tuberculum impar.

The first a is the man bular, the sec the hyoid, third the thy hyoid; the fou and fifth have special desig tions. Each a is covered— ternally by e derm, interna by entoderm, its core is for of mesoderm which there developed a of cartilage a blood-ve called a ceph aortic arch.

At first e arch is limite the side wal the fore-gut; after a time i prolonged into the ventral wall, encroaching, with the exception of the first, u the sinus arcuatus.

The **first**, or **mandibular arch**, is formed between the first visceral cleft and bucco-pharyngeal membrane. As it develops it forms the lateral and lo boundaries of the stomatodæal space, and it grows downwards till it meets fellow of the opposite side in the ventral middle line, immediately in front of tuberculum impar. The greater part of this arch is converted into the lower and the soft tissues which invest it. From its upper part a process grows forwa the **maxillary process**, from which the upper lateral part of the face, between orbit and the mouth, is developed, and in which the superior maxillary, the ma and the palate bones, and possibly the internal pterygoid plate also, are develo and ossified.

From the posterior border of the outer aspect of the mandibular arch the tra and a portion of the helix of the pinna of the external ear are formed. The ca laginous bar in its interior is known as **Meckel's cartilage**. It forms the primit

columnar or cubical epithelium, or as cords of cells, and these occasionally undergo abnormal development, forming tumours at the base of the tongue or in the upper part of the neck.

The portion of the sinus arcuatus which lies behind the conjoined lower extremities of the second and third arches of opposite sides, and in front of the furcula, persists in a modified form in the adult, and is recognisable as glosso-epiglottidean pouches or valleculæ at the base of the tongue.

The furcula and the groove in the ventral wall of the fore-gut, which it embraces antero-laterally, are both of considerable importance. The anterior part of the furcula is situated in the ventral wall of the pharyngeal portion of the fore-gut, but its backward prolongations and the furrow between them lie in what may be termed the intermediate part of the fore-gut, that is, in that part of the fore-gut which intervenes between the pharyngeal and stomach regions. Gradually the furrow deepens, and its posterior extremity dilates on each side. Afterwards the margins of the furrow coalesce from behind forwards, and in this manner the cavity of the furrow is separated from the fore-gut, its walls are converted into the trachea and the lower part of the larynx, whilst the diverticula which are projected from its posterior end form the rudiments of the bronchi. The fusion of the margin of the furrow ceases a short distance behind its anterior extremity, which latter persists as the superior aperture of the larynx. The anterior part of the furcula, which bounds this aperture in front, becomes the epiglottis, and its lateral extensions, which form the margins of the aperture, are converted into the arytenoepiglottidean folds in the substance of which the arytenoid cartilages and the cartilages of Santorini and Wrisberg (cuneiform cartilages) are formed.

DEVELOPMENT OF THE MOUTH AND THE NOSE.

The nose is formed entirely from the stomatodæum. The mouth has a double origin; the roof and fore-part, including the teeth, are developed from the stomatodæum, whilst the floor and the tongue are developed from the pharyngeal portion of the fore-gut.

It has already been pointed out (p. 34) that the stomatodæal depression lies between the anterior part of the head (*i.e.* the tissues forming the base of the primary fore-brain) and the pericardial region, and that it is separated posteriorly from the fore-gut by the bucco-pharyngeal membrane. At first it has no distinct lateral boundaries, but subsequently the mandibular arches, which are developed at the sides of the bucco-pharyngeal membrane, project forward beyond the membrane and form lateral limits of the depression. If the stomatodæal space is examined from the front at this period the following boundaries are recognisable:—Above and in front is the projecting anterior part of the head which is termed the **fronto-nasal process**, laterally are the mandibular arches, and below and posteriorly is the anterior part of the pericardial region. After a short time the lower ends of the mandibular arches meet in front of the pericardial region, and, fusing together, form the posterior or lower margin of the aperture; simultaneously the lateral boundaries of the space are still further completed by the forward growth of a nodular projection, the **maxillary process**, from the upper end of each mandibular arch. About the fifteenth day the bucco-pharyngeal membrane disappears, and the stomatodæal space and pharynx are thenceforth continuous. No trace of the bucco-pharyngeal membrane is recognisable in the adult, but its position may be represented by an imaginary plane extending from the anterior part of the basi-sphenoid above to the base of the alveolar process of the lower jaw, on its lingual surface, below.

Whilst the boundaries of the stomatodæal space are being defined, two oval depressions, lined with thickened epithelium, appear in its upper boundary on the lower and anterior surfaces of the fronto-nasal process; these are the **olfactory pits** or depressions. A portion of the epithelium of their walls is separated off and takes part in the formation of the olfactory bulbs, whilst the remainder is transformed into the olfactory epithelium, from which the olfactory nerve-fibres grow inwards to the olfactory bulbs. As the olfactory pits deepen they grow backwards into the roof of the stomatodæal space, and at the same time they separate the lower portion

upon the globular processes, and ultimately their upper borders and anterior extremities fuse with the lateral nasal and globular processes, completing the lower boundaries of the anterior nasal orifices and the lateral parts of the primitive upper lip. At the same time the oculo-nasal sulci are converted first into solid cords of cells, and afterwards into the lachrymal sacs and the nasal ducts, which henceforth constitute the channels of communication between the conjunctival sacs and the nose.

The result of the ingrowth of the maxillary processes and their fusion with the

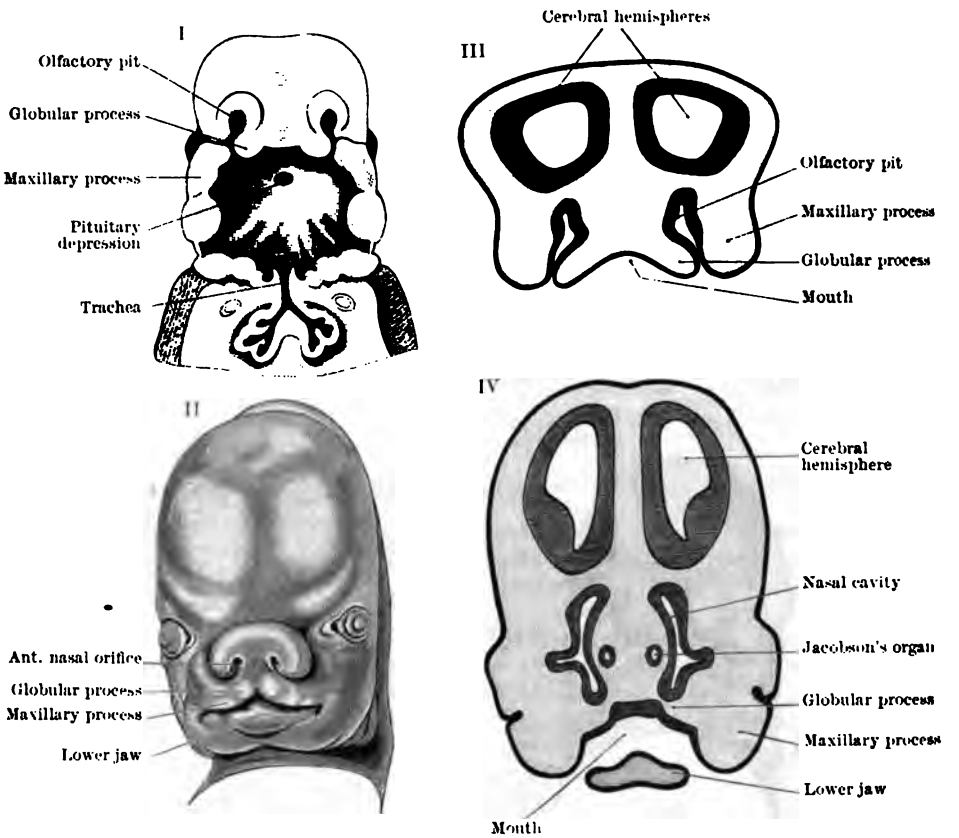

FIG. 32.

I. Portion of the head and neck of a human embryo 32 days old. The floor of the mouth and pharynx and the ventral part of the anterior portion of the body have been removed. By the approximation of the globular and maxillary processes the boundaries of the anterior nares are almost complete, but the olfactory pits still open in the whole of their lengths into the roof of the mouth (from His).

II. Transverse section of the head of an embryo, showing the close apposition of the globular and maxillary processes.

III. Head of human embryo about 2 months old, showing the union of the globular processes and their fusion with the maxillary processes. The anterior nasal apertures are now completely defined (from His).

IV. Transverse section of the head of an embryo, showing the fusion of the maxillary processes with the globular processes, and the separation anteriorly of the nose from the mouth.

lateral nasal and globular processes is the division of the large orifice which led into the stomatodæal space into three parts—a large lower, and two smaller upper apertures. The lower opening is the aperture of the mouth; it is bounded below by the united mandibular arches, and above by the fused mesial nasal and maxillary processes. The smaller upper openings are the anterior nares, which on their first formation are merely foramina of communication between the exterior and the upper part of the stomatodæal space; the latter is not yet separated into nasal and oral chambers.

Formation of the Palate and the Separation of the Nasal and Buccal Cavities.—This separation is effected by the formation of the palate, which is developed to a slight extent by the backward growth of the globular processes

The outer part of the cleft is moulded into the external auditory passage. remains relatively shallow and devoid of bony boundaries till after birth, but the subcutaneous tissue round the lower margin of the tympanic membrane incomplete ring of bone is formed during the third month, and at an earlier perio above the upper part of that membrane, the rudiment of the squamous part of th temporal bone appears. To the outer side of the tympanic ring in the subcutaneou tissue of the pinna and the outer part of the external auditory passage three piece of cartilage appear, and they afterwards join to form the cartilage of the pinna an the external auditory meatus.

After birth the external meatus is deepened by the outgrowth of the tympanic ring below and of the squamous part of the temporal bone above, together with a coincident increase of the outer part of the canal.

HM. Hyo-mandibular cleft.
OV. Otic vesicle.

The tympanic cavity and the Eustachian tube are both formed from the inner part of the first visceral cleft, and consequently they are both lined by entoderm.

The tympanic cavity is developed from the dorsal or upper end of this portion of the cleft and it is prolonged upwards on the outer side of the otic vesicle which simultaneously descends in the tissues of the head. Thus the upper end of the inner portion of the cleft which is somewhat dilated, comes to lie between the otic vesicle, which is developed into the internal ear on the inner side, and the tympanic membrane which separates it from the external auditory meatus on the outer side, and remains in the adult as a laterally compressed space, the tympanic cavity, which is continuous through the Eustachian tube with the upper part of the pharynx. In the mesoderm round the inner, upper, and back part of the cavity the petrous part of the temporal bone is developed and ossified, and in the lower and anterior part the tympanic ossification extends outwards during the formation of the tympanic plate.

The upper part of the tympanic space is prolonged backwards between the ossifying petrous and squamous parts of the temporal bone, where it forms a recess known in the adult as the mastoid antrum, from which at a later period diverticula are projected into the mastoid portion of the temporal bone, forming the mastoid air cells.

The lower portion of the inner part of the cleft is moved obliquely forward. As development proceeds it is contracted and carried downwards and forwards in front of the developing otic vesicle. It is the rudiment of the Eustachian tube and, as the septum which separates the nasal chambers from the mouth is formed

its lower end attains a position just behind and at the side of the posterior narial orifice in the upper and lateral part of the pharynx. Apparently, therefore, the lower end of the Eustachian tube has a much higher position than that originally occupied by the lower end of the cleft from which it is formed, for it will be remembered that the lower end of the first visceral cleft is situated, in the early stages, at the side of the tuberculum impar from which the anterior two-thirds of the tongue is formed. This alteration in relative position is due, however, not to elevation of the lower end of the first visceral cleft during its transformation into the Eustachian passage, but to the enormous downgrowth of the mandibular arches, which carry with them the tongue, as they enlarge to form the lower jaw.

THE HIND-GUT, THE ANAL PASSAGE, AND THE POST-ANAL OR TAIL-GUT.

By the formation of the mouth the primitive alimentary canal opens anteriorly; it remains closed posteriorly until a later date, when the anal passage and orifice are developed.

The posterior end of the hind-gut which is enclosed in the tail-fold is termed the cloaca. The **cloaca** is dilated, and, assuming a conical form, receives the terminations of the genito-urinary ducts. It is bounded postero-inferiorly by the **cloacal membrane** which extends from the root of the tail to the body stalk by which the embryo is attached to the chorion. The cloacal membrane is modified from the posterior part of the primitive streak; this remains on the surface of the body after the anterior part has been separated and enclosed during the completion of the posterior part of the neural canal, and it forms a septum between the cavity of the cloaca and the exterior. It consists at first of ectoderm and entoderm alone, and it is only at its lower and anterior part that it is subsequently invaded to a slight extent by mesoderm.

During the second month of intrauterine life the cloaca is divided into a ventral or genito-urinary, and a dorsal or rectal section, by the formation and fusion of lateral folds, which gradually unite, from before backwards, till finally the posterior end of the septum approaches and fuses with the cloacal membrane, and the rectum is separated from the genito-urinary chamber. Before this separation is completed an eminence appears in the region of the anterior part of the cloacal membrane at the junction of the ventral surface with the posterior extremity of the body, *i.e.* in that part which afterwards becomes the region of the symphysis pubis. This eminence is the **genital eminence**, and from it are formed the penis in the male and the clitoris in the female. The genital eminence is surrounded by an oval fold of skin, **genital fold**, which extends from the front of the eminence to the root of the tail and encloses a shallow fossa, the **cloacal fossa**, at the bottom of which is the **cloacal membrane**. The posterior part of the cloacal fossa is afterwards separated from the anterior part by a transverse fold, the **perineal fold**, which crosses the external surface of the cloacal membrane in a position which corresponds internally with that occupied by the lower end of the septum separating the genito-urinary from the rectal portions of the cloacal. The posterior part of the cloacal fossa, behind the transverse fold, is the proctodæal depression or **proctodæum**; at first its long axis lies transversely, afterwards it assumes a triangular and then a circular form, the sphincter ani muscle develops in its walls, and it is transformed into the greater part, if not the whole, of the anal canal of the adult. It is separated from the rectum by the posterior part of the cloacal membrane, but when that disappears, at a date which has not yet been definitely ascertained, but probably about the third month, the anal passage forms the canal by which the rectum communicates with the exterior of the body.

The orifices of the alimentary canal are thus completed.

The Post-anal or Tail-Gut.—When the hind-gut is first enclosed there is no tail, but a rudimentary tail is subsequently developed as an outgrowth from the dorsal end of the tail-fold, *i.e.* from the posterior extremity of the body of the embryo. As the tail is formed, a narrow tube, which communicates in front with the hind-gut, is developed within it. This is called the post-anal or tail-gut. As a rule it only exists for a short

time, disappearing from before backwards about the period when cartilage begins t formed in the body and limbs, and before the cloaca is divided into its rectal and ge urinary portions. In the few cases in which it pe it retains its continuity with the rectum, whic formed from the dorsal part of the cloaca.

The tail-gut appears in the human subject v the embryo is 3 mm. long, and the rudimentary t just visible as a small nodule. When the em attains the length of 4·8 mm. the anterior pa the tail-gut begins to degenerate, its cavity disapp and it is converted into a solid cord of cells whi still attached in front to the hind-gut. In emb 11·5 mm. long, when the tail has been enclosed i posterior part of the body, the connexion of the gut with the hind-gut is lost, and the tail-g represented by a small vesicle with a short cor degenerating cells attached to its anterior part.

In larger embryos the tail-gut entirely disapp When, as in the human subject, the rudimentary t eventually embedded in the posterior end of the b any rudiments of the tail-gut which persist wil found in this situation; it is stated that such ments occasionally develop into tumour format In mammals with free tails, rudiments of the tai may be met with in any part of the tail, and appar the anterior portion occasionally persists and main its connexion with the rectum, from which it ext backwards as a narrow and blind diverticulum.

THE LIMBS.

Though the body of the embryo begins to ass definite form as soon as it is folded and nippe from the rest of the ovum, it does not present distinguishable human characteristics until anterior and posterior limbs are formed. Then no traces of these before the third week of trauterine life when two longitudinal ridges, **Wolffian ridges**, are developed, one on each lat surface of the body, just external to the o margins of the mesodermic somites, and opp the line of the intermediate cell mass. The r ments of the fore- and hind-limbs are discern almost from the first, as slight prominences of Wolffian ridges, and in the fourth week they pr as bud-like outgrowths in the thoracic and p regions respectively. The development of the fore-limb or arm is throug slightly in advance of that of the hind-limb or leg. At the fourth week limb-bud is a flattened semilunar projection, as long as it is broad, with a d and a ventral surface and an anterior or preaxial, and a posterior or post border. As growth proceeds the elongating limb-buds are bent ventrally, an the fifth week two transverse furrows, on the ventral aspect of each, indicate positions of the joints and the division of each limb into three segments—di middle, and proximal—representing the hand, fore-arm, and arm in the upper l and the foot, leg, and thigh in the lower limb. The terminal or distal segm are broad, flat plates with rounded margins, but each is soon divided into a s what enlarged basal part, and a thinner and more flattened marginal part. where these two parts are continuous that the rudiments of the digits ap They become distinguishable about the end of the fifth week as small lobes w gradually extend outwards. In the fore-limb the fingers project beyond the ma of the hand-segments in the sixth week, but the toes do not reach the margi

the foot till the early part of the seventh week. The nails appear at the third month, and reach the ends of the digits at the sixth month.

In the primary position of the limbs the elbow and the knee appear alike to be directed outwards, but this is soon altered. At the end of the sixth week each limb undergoes a partial rotation, the direction of which is different in the fore- and hind-limbs respectively. In the former the elbow is turned backwards, the ventral surface therefore becomes anterior, and the preaxial (thumb) margin is directed outwards; in the hind-limb the knee is turned forwards, and the ventral surface of the limb becomes posterior, whilst the preaxial (great toe) margin is directed inwards; thus in the adult the anterior surface and outer border of the upper extremity correspond with the posterior surface and inner border of the lower extremity, whilst obviously the posterior surface and inner border of the former are homologous with the anterior surface and outer border of the latter.

Each limb-bud may be regarded as an extension from a definite number of the segments of the body; it contains a core of mesoderm, and the anterior or ventral primary divisions of the corresponding spinal nerve segments are apparently prolonged into it.

The central part of the mesoderm, except in the regions of the joints where cavities appear, is condensed and then converted first into cartilage, and afterwards into bone. The proximal part of the bony skeleton of each limb, the limb girdle, is not, however, developed in the limb-bud, but in the body-wall at its base. The more superficially situated mesoderm is transformed into muscles and subcutaneous tissues, the extensor muscles appearing on the dorsal and the flexor muscles on the ventral aspect.

As the nerve trunks pass into the free portion of the limb they bifurcate, the branches passing respectively to the dorsal or extensor aspect of the limb, and to the ventral or flexor aspect.

Apparently in mammals the whole of the mesodermal core of each limb-bud is formed from the somatic mesoderm of the lateral plates. If this is the case the muscles of the limbs differ in origin from those of the back, for the latter are developed from the muscle plates of the protovertebral somites. In lower vertebrates (cartilaginous fishes) buds are given off to the limbs from the muscle plates and cutaneous lamellæ in the thoracic and pelvic regions, and as the muscle plates pass downwards in the somatopleure towards the ventral aspect of the body, these buds grow outwards into the limb-rudiments and develop into the muscles of the limbs. Presumably this is the more primitive arrangement, and that met with in man and other mammals is secondary, and it is stated that although no distinct buds from the muscle plates pass into the limbs of mammals, nevertheless the limb-muscles are formed by cells, proliferated from the muscle plates, which have migrated into the somatopleural mesoderm of the limbs.

THE NUTRITION AND PROTECTION OF THE EMBRYO DURING ITS INTRAUTERINE EXISTENCE.

The impregnated ovum during its passage down the Fallopian tube, and for a brief period also after it enters the uterus, lives either on the yolk granules (deutoplasm, embedded in its own cytoplasm, or upon material absorbed from the fluids by which it is surrounded. The human ovum is very small, and consequently it is almost from the first dependent for its nutrition upon sources of supply outside itself. The urgent necessity for adequate arrangements whereby this may be effected leads to that early establishment of an intimate vascular connexion between the embryo and the mother which is so characteristic a feature in the development of the human ovum. At the end of the second week, after fertilisation of the ovum, the embryo is separated by a slight constriction from the rest of the blastodermic vesicle, and already a primitive heart and rudimentary blood-vessels are distinguishable.

The development of the vascular system, and the establishment of the fœtal

circulation, however, cannot well be understood until the formation and structure features of the group of closely associated extra-embryonic organs or appendages have been considered.

This group includes the yolk-sac, the chorion, the amnion, the allantois, and the placenta.

THE FŒTAL MEMBRANES AND APPENDAGES.

Yolk-Sac or Umbilical Vesicle.—That portion of the blastodermic cavity and its wall which is not included in the body of the embryo to form the primitive alimentary canal constitutes the umbilical vesicle or yolk-sac. Its walls, like its cavity, are continuous with the corresponding parts of the intestine, and their structural features are identical, there being an inner layer of entodermal cells and an outer layer which is formed by the splanchnic layer of the mesoderm.

In the human embryo the yolk-sac is a small flask-like body, suspended from the ventral wall of the alimentary canal by a hollow stalk, the **vitello-intestinal duct**, which passes through the umbilical orifice. It lies in the extra-embryonic continuation of the body-cavity (cœlom), and is filled with fluid. Possibly the contents of the yolk-sac are utilised in the nutrition of the embryo in its earliest stages, and the first rudiments of the blood vascular system, viz. blood corpuscles and vessels, appear in its walls. In the human embryo, however, it is of little nutritional importance; it soon atrophies and almost entirely disappears, but leaves traces of its existence in the umbilical cord.

Amnion.—The amnion is a protective sac which surrounds the embryo. It is formed, after the development of the cœlom, from the amniotic area of the blastoderm, and its wall is continuous, at the margins of the umbilical orifice, with the body-wall of the embryo. Both walls consist of a layer of ectoderm and a layer of somatic mesoderm, but whilst in the body-wall the ectoderm is external and the mesoderm internal, the relative positions of the layers are reversed in the amnion, the mesoderm being external and the ectoderm internal.

The cavity enclosed between the amnion and the embryo, the **amniotic cavity**, is filled with fluid, the **amniotic fluid**, in which the embryo floats. The amniotic cavity is quite shut off for some time from all the neighbouring spaces, but after the disappearance of the bucco-pharyngeal and cloacal membranes it communicates both anteriorly and posteriorly, with the alimentary canal of the embryo.

The development of the amnion in mammals is closely associated with the attachment of the ovum to the uterine wall and with the subsequent formation of the placenta. Thus in the carnivora, before the cœlom is formed, the ectoderm of the chorionic area becomes attached to the uterine tissues by small villous outgrowths which invade the uterine mucous membrane. This attachment is most complete in the placental region, that is, around the margins of the amniotic area. As the embryo is folded off from the blastoderm and the cœlom develops, both the embryo and the amniotic area remain quite free from the uterine tissues, indeed, it may be said that, at this period, the embryo is suspended from the margins of the placental area by the amniotic membrane.

As development proceeds the amniotic area increases in extent by interstitial growth, and thereupon the embryo, the membrane which suspends it being relaxed, sinks more and more into the interior of the ovum, or, to be more precise, into the cœlomic space, which, in the meantime, has considerably increased. At the same time the growth of the placental area causes all parts of its inner margin to converge, and as the inner margins of the placental area are continuous with the outer margins of the amniotic membrane, the amnion is gradually carried over the dorsal surface of the embryo till its margins meet and fuse. After the fusion of its margins the amnion separates entirely from the chorionic area, henceforth known as the chorion, and forms a closed sac which completely surrounds the embryo.

On reference to Figs. 21 and 27 it will be seen that as the wall of the blastodermic vesicle is carried inwards over the dorsal surface of the embryo it is folded, the outer part of the fold consists of the chorionic portion, and the inner part of

tic portion of the blastoderm. The fold is called the **amnion fold**; it is quite uous round the whole margin of the embryo, but some parts of it are more ed than others, or in other words the convergence of the inner margin placental area of the blastoderm over the dorsal surface of the embryo does ke place at the same rate or to the same extent in all parts. For convenience ription it is usual to divide the amnion fold into four parts—the cephalic, the , and the two lateral amnion folds; these, however, are all continuous with nother.

ie inner part of the hich is formed from amniotic area, is l the **true amnion**, ie outer part, formed the chorionic area, **alse amnion**. The term is, however, ymous with chorion, s it is misleading, it l be avoided.

s the amnion is d from the amniotic of the blastoderm he extension of the n, it must consist, as usly mentioned, of erm and somatic erm, and as the sur- f the amniotic area versed during the tion of the amnion it is obvious that in ully-formed amnion ectodermal layer is al and the somatic lerm external.

onic part of the surface of the ovum is closely attached to the surrounding , but the amniotic and embryonic areas are free. If this is the case the process mion folding can take place in the human ovum exactly as in the ovum of a rorous animal, the inner margin of the chorionic area growing inwards over mniotic and embryonic areas, the only difference being that the process takes in a cavity in the mucous membrane and not on its surface. This conclusion pported by Spee's observations on human ova and by those of Selenka on the f monkeys and apes, but it is, however, possible that, as in some rodents and ivora, the amnion cavity appears in a mass of ectoderm which lies at the onic pole of the ovum, the mass being cleft by the appearance of the cavity mbryonic and amniotic sections. The two parts are then continuous at the

margin of the embryonic area, and the mesoderm growing round the amnio ectoderm separates it from the chorionic ectoderm.

After the amnion is completed its cavity is distended with fluid. As it expa it gradually obliterates the extra-embryonic part of the cœlomic cavity, and fina its outer surface, of somatic mesoderm, comes into contact and fuses with the somat mesoderm on the inner surface of the chorion. At this period the cavities in t ovum are the amniotic cavity, the remains of the yolk-sac, and those portions of t original blastodermic and cœlomic spaces which have been included in the embry

In the human ovum, when the amnion folds unite and the true amnion separat from the chorion, the embryo and its enclosing amnion would be free within t cavity of the chorion, or extra-embryonic cœlom, were it not that a very short co of somatic mesoderm and ectoderm, the body-stalk, connects the posterior end of t embryo with the somatic mesoderm on the inner surface of the chorion.

Body-Stalk.—To thoroughly understand how this union is effected in t human ovum, and to comprehend the nature of the body-stalk, it is necessary t refer to some striking peculiarities which are to be observed in the earlier stag in the development of the human embryo. When segmentation is completed, a the morula is converted into a blastula by the appearance of a cavity in its interi the human ovum consists of an outer layer, the ectoderm, and an inner cell-ma (Figs. 12 and 39). The latter, however, which is attached to a small area of t ectoderm, does not, as in many mammals, extend itself by migration round the inn surface of that layer, and so transform the unilaminar into a bilaminar blastoder and convert the cavity of the blastula into the blastodermic cavity. The sequen of events is different: a cavity or space appears in the inner cell-mass itself (Fig 41, 42, and 44), and this expanding rapidly, is ultimately converted into the yol sac and the alimentary canal of the embryo; it corresponds, therefore, with t blastodermic cavity of other mammals.

Thus the entoderm, though derived from the inner cell-mass, never lines t inner surface of the ectoderm except in the embryonic area, for soon after t appearance of the cavity of the inner cell-mass the mesoderm grows rapidly fro the primitive streak and extends, not in a single layer, as in the majority mammals, but as two layers, one over the outer surface of the entoderm, t splanchnic layer, and the other, the somatic layer, over the inner surface of t ectoderm. The cavity of the blastula is thus ultimately enclosed between t somatic and splanchnic layers of the mesoderm, and so becomes converted into t cœlomic space (Fig. 42).

As the mesoderm extends, the several areas of the blastoderm are differentiat as in other mammals, but the embryonic and amniotic areas remain of relative small size. The separation of the amnion from the chorion is effected at a ve early period, before the folding off of the embryo has commenced, but the somat mesoderm growing from the posterior end of the embryonic area still retains i connexion with the similar layer on the inner surface of the chorion, and it forn a short, and for a time a broad stalk which unites the embryo, and consequent the amnion and the blastodermic cavity, with which the embryo is connected, to t chorion (Fig. 42). In addition to forming a bond of union between the embr and the chorion the mesodermal stalk conducts blood-vessels from the embryo the chorion, and more especially to its placental part.

At an early period a pouch-like diverticulum projects from the posterior pa of the entodermal sac. This is the **allantoic diverticulum**; it lies beneath t posterior part of the embryonic area, and the area is curved upon itself so that i convexity looks towards the entodermal sac, and its concavity towards the amnio

After the embryonic area has increased in extent, and when the folding off the embryo has commenced, the anterior end of the area and the posterior end the primitive streak remain relatively stationary as in other mammals, the cephal and caudal folds appear, and the curvature of the greater part of the area reversed, but the most posterior part retains its original position, lying for a tim parallel with the caudal fold; afterwards, however, it assumes a more horizont position. This posterior section of the embryonic area contains the divert process of the entodermal sac which is called the allantois; it also conta

blood-vessels, allantoic arteries and veins, which pass between the embryo and the placenta. It is in relation at first with the amnion, it appears to be entirely behind the embryo, and it is called the "body-stalk." At a later period, when the stalk of mesoderm—the allantoic stalk—which connects it with the outer surface of the chorion is elongated, this part of the embryonic area is reversed in position, its anterior end is carried forwards till it forms the posterior boundary of the umbilical orifice, and the area in question forms the ventral wall of the body from the umbilical to the genital region.

Allantois.—The allantois plays an important part in the formation of the placenta. It consists of two portions, an entodermic diverticulum from the ventral wall of the cloacal part of the hind-gut, and a mesodermal covering. The entodermic diverticulum appears in the human subject, before the hind-gut is defined, as a hollow blind protrusion from the blastodermic cavity; it extends behind the primitive streak into the mesoderm of the body-stalk, but as the folding off of the embryo proceeds, and the body-stalk is carried forward into the ventral wall of the embryo, the position of the diverticulum is altered, and ultimately, when the folding off is completed, it springs from the ventral part of the cloaca, runs forward to the umbilical orifice, and passing through it, projects for a short distance still invested with the mesodermal covering primarily obtained from the body-stalk. The ventral part of the cloaca is afterwards converted into the bladder, while the rectum is formed from the dorsal part.

The mesodermal sheath which surrounds the entodermic diverticulum extends beyond it to the inner surface of the chorion; the part which extends beyond the diverticulum is at first extremely short, indeed it is only recognisable as a layer of mesoderm uniting the body-stalk and chorion, but as development proceeds and the body-stalk is folded forward to form the ventral wall of the body of the embryo, posterior to the umbilicus, this portion of the mesoderm is elongated, and it forms the **allantoic stalk** by which the embryo retains its connexion with the chorion, and along which pass the allantoic or umbilical arteries to, and the corresponding veins from, the chorionic villi.

After the separation of the cloaca into bladder and rectum, that portion of the allantois which lies in the body of the embryo, between the apex of the bladder and the umbilical orifice, is gradually converted into a fibrous cord, the **urachus**. The entodermal diverticulum disappears, and after birth, when the placental circulation ceases, the umbilical arteries are transformed into fine fibrous strands. The remainder of the allantois which lies outside the body of the embryo, and which takes part in the formation of the umbilical cord and placenta, is separated from the embryo at birth.

Umbilical Cord.—The umbilical cord is essentially a mesodermal structure which connects the embryo with the placenta, serving as a passage for the allantoic vessels to and from the fœtal portion of the latter organ. It replaces, functionally, the body-stalk and the allantoic stalk, which were earlier provisions for the same purpose, and it is formed by the fusion of the allantoic stalk with part of the vitello-intestinal duct and the remains of the yolk-sac.

The vitello-intestinal duct is at first a relatively wide channel which connects the primitive gut with the yolk-sac; it passes through the umbilical orifice. In later stages, as the body-stalk is swung round into the ventral wall of the body, the allantoic stalk, which projects from the end of the body-stalk, is brought into close relation with the distal end of the vitello-intestinal duct and the remains of the yolk-sac: the mesodermal constituents of the three structures then fuse together, and the whole is surrounded by the expanding amnion. In this way the umbilical cord is formed. It includes, therefore, the allantoic stalk and its blood-vessels, together with the remains of the yolk-sac and its stalk, the vitello-intestinal duct, all of which are invested and bound together by the amnion.

The mesodermal core of the cord forms a fibro-mucoid tissue known as "Wharton's jelly," which consists of stellate and irregular cells embedded in a gelatinous matrix. The blood-vessels of the cord are situated in the core, and include two allantoic or umbilical arteries which run spirally round a single umbilical vein. The terminal portion of the allantoic divert[illegible]ects into

the embryonic end of the cord, and at first a loop of intestine protrudes into it a short distance; the gut, however, soon recedes into the abdominal cavity.

The umbilical cord, which extends from the umbilical orifice to the centre of the placenta, is at first short and straight. As the amnion expands the length of the umbilical cord increases until, at the time of birth it measures, on an average, about 20 inches. This increase in the length of the cord allows the fœtus to float freely in the amniotic fluid, and prevents traction on the placenta.

After the middle of the second month the umbilical cord is twisted spirally, usually from right to left. It is suggested that this is due either to the greater elongation of the allantoic arteries or to muscular movements of the fœtus, and it involves a rotation of the fœtus in the amniotic fluid.

Chorion.—The chorionic area, by far the largest of the areas into which the blastoderm is divisible, lies external to the amniotic area. In most mammals it consists at first of ectoderm and entoderm, but after the extension and cleavage of the mesoderm has taken place, it is formed by ectoderm and somatic mesoderm. In man, however, it consists in the earliest stages of ectoderm alone, but on the formation and extension of the mesoderm it also acquires an inner layer of somatic mesoderm. In all cases, therefore, it eventually consists of the same two layers.

The ectoderm of the chorionic area which immediately surrounds the amniotic area thickens to form the annular placental area, and in this way the chorionic area becomes divisible into placental and non-placental regions.

When the blastodermic vesicle enters the uterus numerous ectodermal villous processes grow from the surface of the chorionic area, both in its placental and non-placental parts, and attach themselves to the uterine mucous membrane. As already pointed out in the description of the formation of the amnion, the embryonic and amniotic areas do not become attached to the uterus, but remain free from it, whilst by the approximation and fusion of its inner margins, the rapidly growing ring-like placental area is converted into a disc which intervenes between the amnion and the uterine wall.

The chorionic area after the separation of the amnion is known as the chorion or chorionic membrane.

The chorion forms the outer wall of a vesicle, the chorionic vesicle, which is the modified remains of the blastodermic vesicle, and which contains the embryo, the yolk-sac, the amnion, and the allantois. It consists of an outer layer of ectoderm and an inner layer of somatic mesoderm.

The cavity of the chorion is the extra-embryonic portion of the cœlom. For a time it remains distinct, and is traversed by the allantoic stalk which unites the embryo to the inner or mesodermal layer of the placental area. The cavity is ultimately obliterated by the growth of the amnion, the latter sac expanding rapidly till its outer surface is in contact and intimately blended with the inner surface of the chorion.

Chorionic Villi. — The villous processes which begin to grow from the surface of the chorionic area before it is separated from the amnion continue to develop after the separation of the two membranes is completed. They penetrate the surrounding uterine tissues. At first each consists of ectoderm only, but a core of vascular mesoderm is soon acquired. The villi increase in size and in complexity also, but ultimately only those in the placental area persist and continue to grow; the remainder atrophy and disappear.

Thus the placental region of the chorion eventually constitutes the main bond of union between the ovum and the mother, and it forms the fœtal part of the placenta.

THE PLACENTA.

The placenta is the organ of fœtal nutrition and respiration.

In it the blood-vessels of the fœtus and those of the uterus are brought into such close relationship with one another that free interchanges readily take place between the blood of the mother and that of the fœtus. In the simplest form of placenta the fœtal villi are merely embedded in the maternal mucous membrane and the relationship between fœtal and maternal blood is not very close. In other

forms, *e.g.* the human placenta, the relation of fœtal to maternal blood is much more intimate; this involves marked complications in the elements of the placenta, and its structure becomes correspondingly more complex. In all forms, however, the placenta consists of fœtal and maternal portions.

Before the impregnated ovum reaches the uterine cavity the mucous membrane of the uterus undergoes certain changes in preparation for its reception and reten-

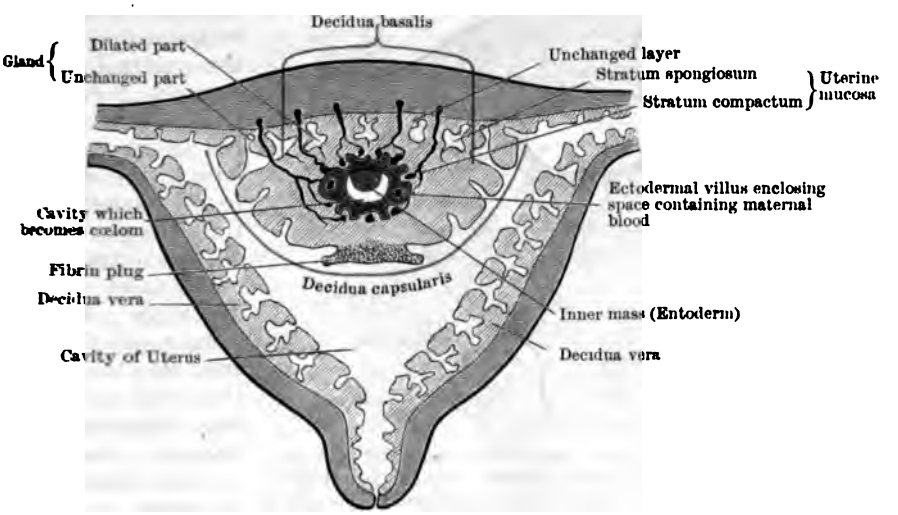

FIG. 39.—DIAGRAM representing a very young human ovum almost immediately after its entrance into the decidua, and whilst the place of its entrance is still covered with a plug of fibrin. The ectoderm has already proliferated and embraced spaces which contain maternal blood and are continuous with the maternal blood-vessels.

ion, and the modified mucous membrane is known as the uterine decidua. These hanges are, for the most part, hypertrophic; the vascularity of the mucous membrane is increased mainly by the dilatation of its veins and capillaries, the tubular terine glands become longated, irregular, and rtuous, and they dilate oth at their orifices and the deeper part of the ucous membrane; at the me time the interlandular connective tisue proliferates, and as a sult the decidua is icker, softer, and more pongy than the unaltered ucous membrane.

After the developing vum enters the uterus comes into contact ith the decidua, into hich it forces its way stroying the surface pithelium, and destroyor pushing aside, the perficial portions of the lands. In this way it comes embedded in the vascular interglandular tissue. The orifice which it makes in the superficial surface of the decidua is plugged, for a time, by a mass of fibrin, but all traces of the aperture which the fibrin closes eventually disappear and the ovum is entirely encapsuled in the decidua, which again presents an unbroken surface towards the uterine cavity.

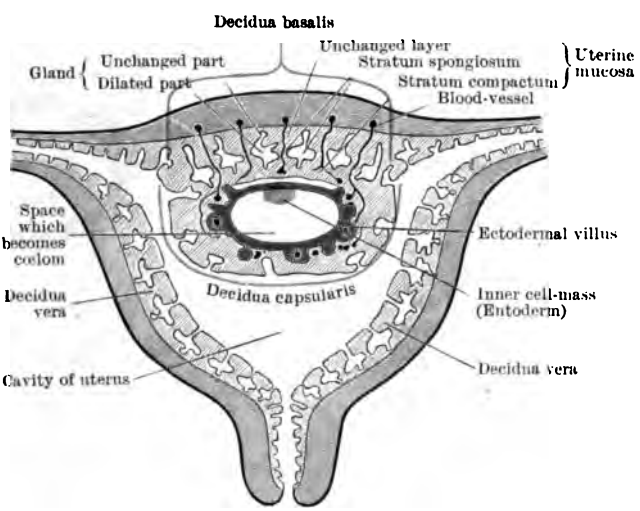

FIG. 40.—DIAGRAM, showing the relation of the young human ovum to the decidua.

The ectoderm is distinct from the inner cell-mass, but as yet there is no entodermal cavity in the latter.

Immediately after the ovum becomes embedded the superficial ectoderm its surface proliferate rapidly and form numerous branching processes or vill invade the surrounding decidua, destroying its cells and gradually enclosi maternal blood with which they into relation. time the maternal which at first surr the maternal blood entirely disappea from this period o the maternal blood lates in the spaces fœtal ectoderm. time the prolifera the ectodermal vi comes most mark mediately aroun margin of the ar area of the ovu thus a placental the chorion is entiated. FIG. 41.—DIAGRAM, showing a further stage of development of the human ovum and its relation to the decidual tissues. The entodermal cavity or yolk-sac has appeared in the inner cell-mass, and the mesoderm has commenced to extend from the primitive streak in two layers, splanchnic on the yolk-sac and somatic on the ectoderm.

uterus, and at this period three areas of the decidua can be distinguished part outside the ovum, that is between the ovum and the muscular the uterus, is known as the **decidua basalis**; the part pushed into the cavity of the uterus around the growing ovum is the **decidua capsularis**; and the remainder of the decidua is the **decidua vera.**

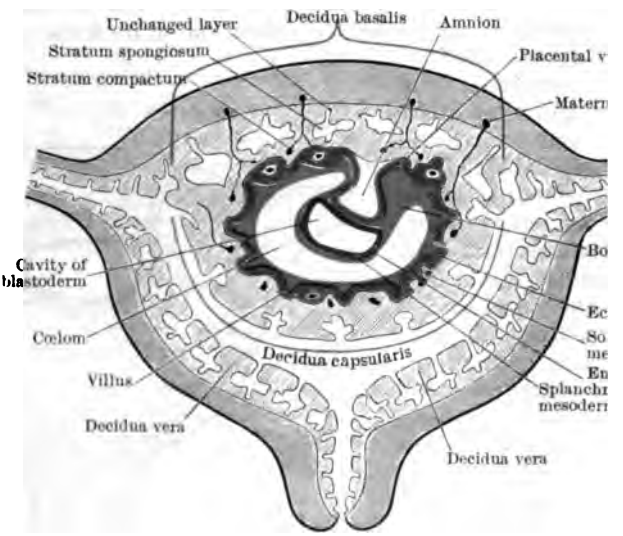

FIG. 42.—DIAGRAM, showing the completion of the decidua capsu enlargement of the maternal blood-vessels in the stratum comp the decidua basalis, the increase of the placental villi, the for the amnion folds, and the appearance of the allantoic diverticulu

The **decidua capsularis** is not formed, as was formerly believed, by folds of the decidua which have grown up and surrounded an ovum merely attached to the surface of the decidua basalis. On the contrary it is merely the superficial part of that portion of the decidua into which the ovum has penetrated, therefore it may contain glands or the rem glands which open on its superficial surface into the uterine cavity, but no open on its inner surface.

The **decidua basalis** lies in contact with the placental area of the chori the fœtal part of the placenta, and it forms the maternal part of the orga the fully developed human placenta, the fœtal and maternal tissues of w

Changes in the Decidua.—The occurrence of further changes in the decidu the developing ovum enters the uterus, is dependent upon the retention ovum in the substance of the decidua. These changes only occur, there what may be termed the decidua of pregnancy. They are intimately ass with and essential to the development of the maternal part of the placen a more detailed and complete account of the decidua and the modification several parts is therefore necessary.

The **decidua** is formed by the mucous membrane of the uterus, which is a thick-walled muscular organ, situated in the pelvic cavity. The mucous me contains numerous tubular glands embedded in an interglandular tissue for round and irregular cells. The uterine glands are lined by a columnar or epithelium, and they open into the cavity of the uterus on a surface which covered by columnar cells. The whole of the mucous membrane is ple supplied with blood-vessels which pass into it from the surrounding m walls, and it is transformed into the decidua by proliferation and hypertr all its parts. The interglandular tissue increases in amount and its blood- dilate, especially near the surface of the membrane; but the most striking early changes occur in the glands—they become longer, more tortuou

s enlarge and assume a funnel-like appearance, and they dilate a short
from their terminations into large irregular spaces. The increase of
rglandular tissue is most marked in the intervals between the dilated
of the glands and their apertures, and when all the changes are fully
ied it is possible to recognise three layers of the decidual tissue. (1) A
al relatively thick layer in which the interglandular tissue preponderates,
tum compactum; (2) A layer formed principally by the dilated portions
lands, the **stratum spongiosum**; and (3) a thin deep part of the membrane
ntains the outer extremities of the glands which are practically unchanged,
anged layer.

lecidua capsularis differs from the other portions of the decidua in that
ents only the superficial portion of the other parts of the decidua, and
contains no spongy layer or deep unchanged layer. This is obviously the
after the ovum has penetrated through the surface epithelium it becomes
d in the stratum compactum of that portion of the decidua which it has
and consequently the portion of the stratum which closes over it cannot
nore than the outer parts of some of the uterine glands with their orifices
intervening interglandular tissue.

changes which occur in the decidua capsularis are due, first, to its
n with and invasion by the chorionic villi; and, secondly, to the pressure
ıpon it by the enlarging ovum. The former influence is brought to bear
he decidua is still increasing; the latter after it has reached its full
ıent.

:hanges which result from its union with the chorion are the destruction
rption of some of the interglandular tissue; they are due to the activity
todermic cells of the chorion, which attack and invade the uterine tissues.

:hanges due to pressure exerted by the enlarging ovum are diminution of
ty, disappearance of the lumina of such portions of the glands as remain in
ua capsularis, and the removal of their epithelium, together with the co-
ıtrophy of the fœtal villi which have penetrated this portion of the placental
All these changes result in the reduction of the decidua capsularis to a
ıbrane in which no traces of the original structure are recognisable, in the
the altered decidua capsularis with the decidua vera, and the consequent
on of the uterine cavity.

the fifth month the decidua vera also undergoes atrophic changes, but they
roceed so far as in the decidua capsularis; nevertheless the stratum com-
is greatly reduced, the superficial epithelium and the superficial parts of
ds entirely disappear from it, the interglandular tissue becomes less
and it diminishes very considerably in thickness. The epithelium dis-
from the spaces in the spongy layer, and the spaces themselves are
out into long slit-like clefts, in which condition they remain till
d of pregnancy is completed. The decidua vera is thus reduced to the
ı of a relatively thin membrane, and its inner surface is fused with
ins of the decidua capsularis.

lua Basalis.—This portion of the decidua is constituted by the deeper
:he stratum compactum in which the ovum is embedded together with
externally situated spongy and unchanged layers, and, apart from the
lue to the invasion of the fœtal villi, the most important transformations
art of the decidua occur in the stratum compactum. The alterations in
gy layer are similar to those which occur in the same layer of the decidua
the lining epithelium disappears and the spaces are flattened out into a
:left-like slits.

e stratum compactum, however, much more striking changes occur; all
the glands disappear, but the blood-vessels become greatly dilated, and,
ntly, the layer increases considerably in thickness. The small blood-vessels
in the immediate neighbourhood of the ovum become converted into
ı blood sinuses, but in the deeper part of the stratum a thin layer, which
the stratum spongiosum, remains relatively unchanged; this deeper part
the basal layer, and through it the blood-vessels pass to and from the

blood sinuses in the more superficial portion of the membrane. When is completed, therefore, the maternal portion of the placenta, which is t transformed decidua basalis, no longer consists of the stratum compactum, t stratum spongiosum, and the unchanged layer, but it is formed from with outwards of—(1) a layer of blood sinuses, (2) the basal layer, (3) the modifi spongy layer, and (4) the unchanged layer. The difference between the decid basalis and the maternal part of the placenta may be tabulated as follows:—

Decidua basalis.	**Maternal placenta.**
Deep part of stratum compactum	Layer of blood sinuses. Basal layer.
Stratum spongiosum	Modified stratum spongiosum.
Unchanged layer	Unchanged layer.

It must not be forgotten, however, that whilst the changes which result in t formation of the maternal placenta out of the decidua basalis are taking place t stratum compactum has been invaded by the placental villi.

The first result of this invasion is the destruction of much of the decidual tissue l the ectoderm the fœtal vil Gradually the e toderm of the vil always in advan of the main bod reaches and su rounds the dilat decidual vesse destroys the i tervening tissu and ultimately places the end thelial walls of t vessels, which this time ha dilated into enc mous spaces. In these spaces t ramifications the villi proje and, as the enc thelial walls a destroyed, they directly with the cavities of t spaces, and a surrounded on sides by matern blood. The m peculiar feature this part of t placenta, wh fully developed that the whole the maternal p tion of it, exce the blood, h

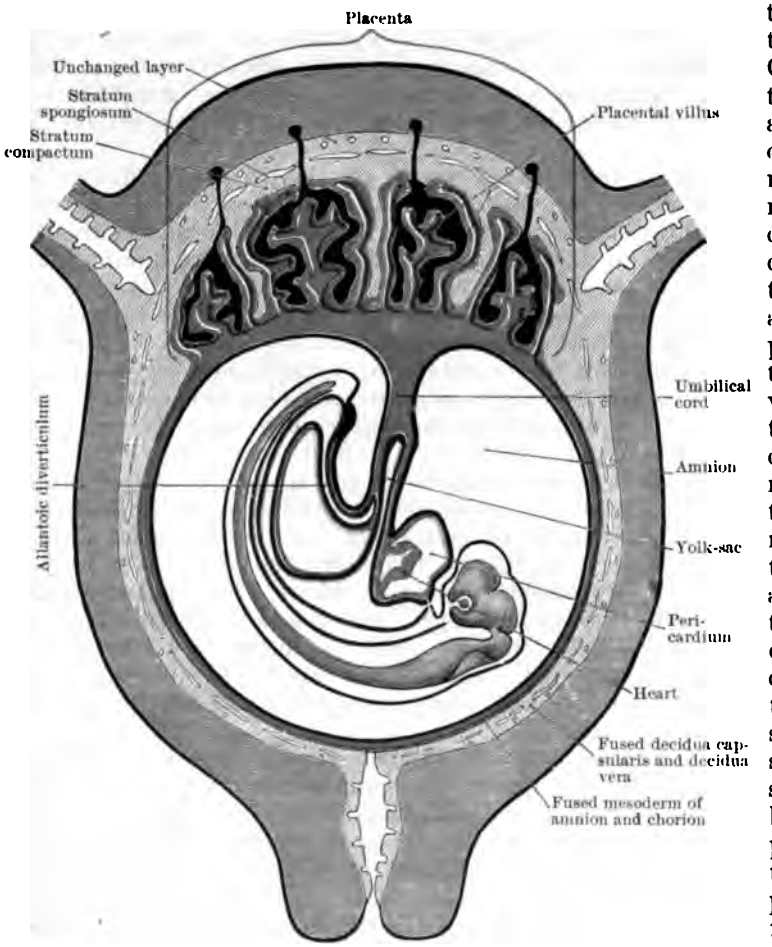

FIG. 46.—DIAGRAM. Later stage in the development of the placenta, showing the relations of the fœtal villi to the placental sinuses, the fusion of the amnion with the inner surface of the chorion, and the thinning of the fused decidua (capsularis and vera).

been removed and replaced by fœtal tissues, so that, although the matern blood continues to circulate in the same spaces which it has occupied from t first, viz. the blood sinuses in the more superficial part of the stratum compactum the maternal decidua, yet the walls of these spaces have been replaced more or l

mpletely by fœtal ectoderm, and, consequently, the spaces now lie in the midst of e fœtal tissues.

The invasion of the maternal by the fœtal part of the placenta proceeds as far the basal layer, and in this region the fœtal ectoderm is directly continuous with he walls of the maternal blood-vessels at the points where they enter the sinuses.

Although the invasion of the decidua basalis is so complete, some portions of he maternal tissues persist; thus the basal layer and many strands of the stratum ompactum escape destruction. The latter extend from the basal layer to the outer rface of the chorion, and they are eventually converted into fibrous strands, which ivide the superficial part of the completed placenta into lobular areas.

The **completed placenta** consists, therefore, of closely intermingled and fused tal and maternal tissues, through which both the fœtal and maternal blood reams circulate. It is well adapted, on account of its peculiarities of structure, to lfil the nutritive and respiratory requirements of the embryo. The fœtal blood tream which flows through the placental villi and the maternal blood stream in he placental sinuses are only separated from each other by two layers of fœtal ctodermal epithelium and a small amount of fœtal mesoderm, the latter being ractically reduced to the single layer of endothelial cells which form the walls of he fœtal vessels. Through these layers, by osmosis, and possibly by secretion, aterials are passed both from mother to embryo and from embryo to mother, the lacenta serving not only for purposes of nutrition and respiration, but also as an cretory organ.

Whilst the placenta is attaining its full development the amnion is expanding, nd finally its outer surface fuses with the inner surface of the chorion, consequently, he innermost portion of the placenta is provided with a covering of amnion.

The full-time placenta is a discoid mass about 20 or 25 inches (50 to 60 cm.) in circumference and 1¼ in thickness at its centre; it is much thinner, however, at its margins, where it is continuous with the membranes formed by the fused chorion, decidua vera, and decidua capsularis. Its weight is about one pound, and it consists from within outwards of the following layers:—

Fœtal	Amnion	Ectoderm. Mesoderm.
	Allantois with fœtal vessels	Mesoderm.
	Chorion	Mesoderm. Ectoderm.
Maternal	Layer of maternal blood sinuses and remains of the interglandular tissue of the stratum compactum.	
	Basal layer.	
	Modified spongy layer.	
	Unchanged layer.	

When the period of intrauterine life is completed the muscular walls of the uterus contract and the lower orifice of the uterine cavity is dilated, the fused chorion and amnion, which close the upper part of the orifice, rupture and the amniotic fluid escapes, the fœtus is then expelled, but it remains attached to the placenta by the umbilical cord. The cord is divided artificially, and after a short period the placenta and membranes are expelled. The membranes attached to the placenta consist of the fused amnion, chorion, decidua capsularis, and also the decidua vera internal to the altered spongy layer; therefore both the placenta and the membranes consist of maternal and fœtal tissues. Before the placenta and membranes are expelled the uterine decidua is separated into two parts by a cleavage which takes place in the modified stratum spongiosum. The inner portion which includes the placenta and membranes is cast off. The outer portion remains in the uterus; it consists almost entirely of the deep unchanged layer of the decidua, and from it the uterine mucous membrane is reconstructed.

THE PRIMITIVE VASCULAR SYSTEM AND THE FŒTAL CIRCULATION.

It has already been said that the ovum during its passage down the Fallopian tube lives either on its own yolk particles or upon substances absorbed from the fluids by which it is surrounded. For a time after it enters the uterus its nutrition must be provided for in a similar manner, but as soon as the chorionic villi are formed it is probable that the ectodermal cells, of which in the earliest stages the ovum entirely consist, and which cover their surfaces in the later stages, actually eat away the decidual tissues which they invade and use them for food. This source of nutrition, however, is only sufficient for the short period during which the ovum remains relatively small, and substances absorbed through the surface cells can be readily transmitted to all its parts.

In addition to the solid decidual tissues devoured by the ectodermal cells it is evident that fluids from the mother are also absorbed, for the yolk-sac and cœlom enlarge and are filled with fluid. The only sources from which this can have been derived are the uterine glands or the blood and lymph vessels of the decidua.

In all probability the fluids absorbed into the ovum contain nutritive material, and so long as the embryo is constituted by the thin layers of the early blastoderm sufficient food material can easily be absorbed. When, however, the various parts of the embryo increase in thickness and become moulded into the form of organs they are no longer in such intimate relation with the surrounding nutritive fluids whilst, further, as their development progresses they require a greater amount of food and oxygen than they can obtain from these fluids. There is, therefore, an imperative necessity for a further supply of nutritive material by which their requirements may be satisfied, failing which, development must cease and death ensue.

To meet this necessity the vascular system is formed. It is essentially an irrigation system consisting of a propulsive organ, the heart, and of tubular vessels, the blood-vessels, all of which contain blood. The heart propels the blood through the blood-vessels to all parts of the embryo, but the blood which is at first formed from the mesoderm of the ovum must, at least so far as its fluid part is concerned, be supplemented largely from maternal sources. It is necessary, therefore, that the fœtal blood-vessels be brought into close relation with the maternal blood-vessels at an early period. It is for this purpose, amongst others, that the large blood sinuses are formed in the maternal portion of the placenta, and that they are surrounded and invaded by the fœtal villi, carrying in their interior branches of the fœtal blood-vessels, and as previously shown, the fœtal blood vessels in the placenta are only separated from the maternal blood in the sinuses by their own thin mesodermal walls, and by one or two layers of ectodermal cells. When the placenta is fully formed fluids can readily pass from the maternal to the fœtal vessels, and there can be no doubt that both food and oxygen pass from the maternal blood to the fœtal blood through and by the agency of the intervening cells, whilst at the same time the waste products which are formed in the embryo pass outwards to the maternal blood.

Obviously, however, a system of vessels filled with fluid would be of little use in the general economy unless there were some means by which the fluid could be kept in constant movement. In the first instance this is accomplished by rhythmical contractions of the vessel walls, but in a short time portions of the two primitive stem-vessels which appear in the embryo are modified into a single propulsive organ, the heart, which forces the fluid, or blood, in a definite direction both through the body of the embryo, along the body-stalk or umbilical cord, according to the age of the embryo, and through the vessels in the placental villi.

We have now to consider how the blood-vessels and blood are formed.

Where, or how, the first blood-vessels appear in the human subject is not definitely known, but in other mammals they are first seen outside the body of the embryo in the wall of the yolk-sac. The outer layer of the wall of the yolk-sac consists of splanchnic mesoderm, and in that part of this layer which lies nearest the primitive alimentary canal a large number of the cells proliferate

rapidly and, fusing together, form multi-nucleated masses of protoplasm, the "**blood islands**" of Pander.

Soon after their appearance the blood islands anastomose together by means of nucleated processes which they throw out on all sides, and thus a nucleated protoplasmic reticulum is formed in the substance of the splanchnic mesoderm. The region in which this occurs is known as the **vascular area**. The solid nucleated reticulum is soon converted into a system of anastomosing canals, the primitive blood-vessels, by the appearance within it of numerous vacuoles which soon fuse together, whilst at the same time the nucleated protoplasm is transformed into cells. The cells which lie nearest the interior separate from each other and form the primitive blood-corpuscles, whilst those situated externally remain connected by their margins and form the endothelial walls of the embryonic vessels. The fluid which fills these first-formed vessels in the vascular area is probably derived either from the cœlom or from the yolk-sac.

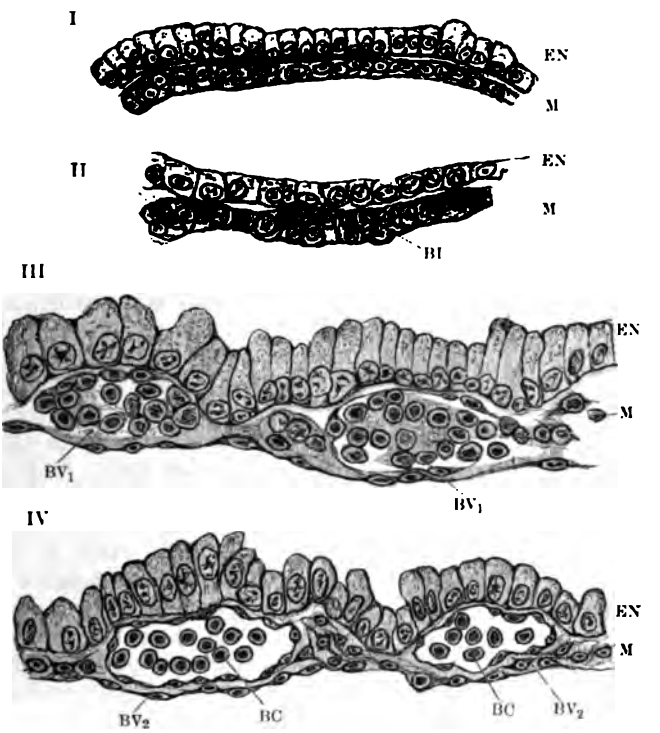

FIG. 47.—DEVELOPMENT OF BLOOD-VESSELS IN THE VASCULAR AREA OF THE RAT.

I. Entoderm and splanchnic mesoderm.

III. Commencing differentiation of islands to form blood-vessels and blood-corpuscles.
IV. Completed vessels.

BC Blood-corpuscles.	BV_2 Blood-vessels.
BI Blood islands.	
BV_1 Blood islands being transformed into blood-vessels.	EN Entoderm. M Mesoderm.

The primitive blood-corpuscles are nucleated cells of a reddish colour; white or colourless blood-corpuscles appear later, and it is stated that those first formed are developed in the thymus gland.

Nucleated red corpuscles persist and increase in number till the end of the second month of intrauterine life; they are then gradually replaced by non-nucleated red corpuscles. The majority of the nucleated red corpuscles disappear long before birth, but a few can usually be found in the blood of the new-born child. There is some doubt about their ultimate fate, but it is generally believed that their nuclei disappear, and that they are converted into non-nucleated corpuscles.

Directly after the appearance of the blood islands in the vascular area of the yolk-sac, and just as the folding off of the embryo commences, two short tubular vessels appear in the splanchnic layer of the pericardial mesoderm. These vessels at once extend forwards and outwards into the extra-embryonic region where they become connected with the vessels of the vascular area; they also extend backwards in the body of the embryo beneath the protovertebral somites. In the majority of mammals they at first terminate behind, as in front, on the wall of the yolk-sac, but after a time the main stems appear to be continued along the allantoic stalk to the placenta, whilst they give off branches to the yolk-sac. It is probable that in the human embryo also, though this has not apparently been actually observed, these main stem vessels, the primitive aortæ, end at first on the wall of

the yolk-sac, but on the fourteenth day of intrauterine life, before the heart is formed, the two primitive stem vessels pass backwards along the body-stalk to the chorion, their terminal branches entering the chorionic villi. As they pass backwards the primitive aortæ give off branches to the wall of the yolk-sac. Thus, at this period the vascular system of the human embryo consists of two longitudinal vessels which run parallel with each other, one on each side of the middle line throughout the whole length of the embryo. They communicate anteriorly with the vessels on the yolk-sac, and terminate posteriorly in the chorion. When the circulation commences the blood flows from the anterior part of the vascular area into the anterior ends of the primitive aortæ, and passes backwards through the embryo. Some of it is returned to the vascular area by the branches which are given off to the walls of the yolk-sac; but the greater part is carried to the chorion, whence it returns by venous channels, the allantoic veins, which have been developed in the meantime, to the anterior ends of the primitive aortæ.

As the cephalic and caudal folds are developed the anterior and posterior parts of the primitive aortæ are carried into the ventral wall of the body of the embryo, and thus each primitive vessel is divisible into three parts: (1) a dorsal part, the primitive dorsal aorta, which extends from the dorsal end of the mandibular arch to the cloaca, and runs beneath the protovertebral somites; (2) an anterior ventral part, situated in the dorsal wall of the pericardium and extending from the umbilicus to the ventral end of the mandibular arch; and (3) a posterior ventral part, which at first runs in the ventral wall at the side of the cloaca, and then turns backwards in the body-stalk to the placenta, but afterwards, when the posterior part of the ventral wall of the body is completed, it extends forwards from the pelvic region to the umbilical orifice, through which it passes to the umbilical cord.

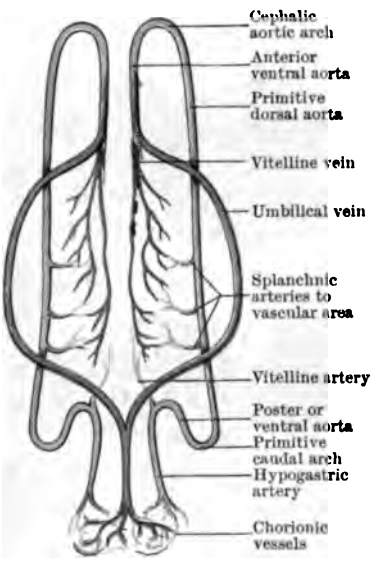

FIG. 48.—THE PRIMITIVE BLOOD-VESSELS OF THE EMBRYO.

The three sections are united together by two arches—an anterior arch, the first cephalic aortic arch, which passes through the mandibular arch and a posterior arch, the caudal arch, which lies at the side of the cloaca.

In a short time four additional communications are formed between the anterior ventral and the dorsal part of each primitive aorta; they are the second, third, fourth, and fifth cephalic aortic arches, each of which lies in the substance of the corresponding visceral arch.

As soon as the last cephalic aortic arch is developed the rudiments of the main vessels of the embryo are established; and by a series of transformations, for a full account of which the chapter which deals with the Vascular System must be consulted, there are formed from the vessels which have been mentioned the heart, the aorta, the main vessels of the head and neck, the pulmonary artery and its primary branches, the common and internal iliac arteries, and the hypogastric arteries.

The blood distributed by the various arteries is returned to the heart by vessels called veins, which are developed in the substance of the mesoderm in the same manner as the arteries. From the yolk-sac the blood returns by the vitelline veins; from the alimentary canal and its appendages, through the portal and hepatic veins; from the head and neck, by the jugular veins and the superior vena cava; and from the body and lower limbs, first by the cardinal veins, and afterwards by the inferior vena cava and the azygos veins.

The heart is formed by the fusion of portions of the anterior ventral sections of the primitive aortæ behind the origins of the cephalic aortic arches, and, therefore, it is primitively a bilateral organ. Subsequently it possesses for a time a single chamber, but this is afterwards divided. During the greater part of fœtal life the

heart, as in the adult, possesses four chambers—two auricles or upper chambers, and two ventricles or lower chambers, right and left. The two auricles communicate with the corresponding ventricles through auriculo-ventricular apertures, and with each other through a foramen, the foramen ovale, in the septum between them.

In the adult the blood enters the right auricle by the superior and inferior venæ cavæ and the coronary sinus; from the right auricle it passes into the right ventricle, by which it is propelled through the pulmonary arteries and lungs; returning to the heart by the pulmonary veins it passes into the left auricle, and then into the left ventricle, by the contraction of which it is forced into the systemic aorta. From the aorta, by various branches, it traverses the organs and tissues of the body, and is returned again to the right auricle.

The course of the fœtal circulation differs from that of the adult; the blood passes out of the body into the placenta, to be oxygenated and purified, the lungs of the fœtus remaining functionless until the time of birth. Very little of the blood which is ejected from the right ventricle at every contraction of that chamber reaches the lungs; the greater part is transferred from the pulmonary

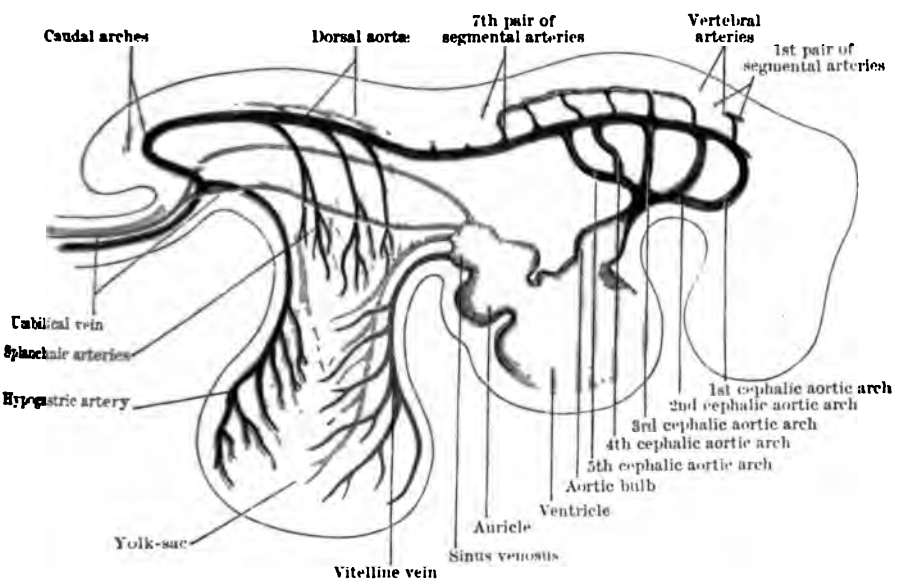

FIG. 42.—DIAGRAM OF THE BLOOD-VESSELS OF A MAMMALIAN EMBRYO AFTER THE FORMATION OF THE HEART.

artery to the aorta by an anastomosing channel, the ductus arteriosus, which disappears after the pulmonary circulation is established.

During the later months of fœtal life, blood enters the right auricle by the superior and inferior venæ cavæ and through the coronary sinus; only a small amount of blood, viz. that returning from the walls of the heart, enters the right auricle through the coronary sinus. The blood poured into the right auricle by the superior vena cava is returned from the head, neck, upper extremities, and the thoracic walls; passing from the auricle by the right auriculo-ventricular opening it enters the right ventricle; from the right ventricle it is forced into the pulmonary artery, and a small part of it traverses the lungs and returns to the left auricle by the pulmonary veins; the main part, however, is conducted by the ductus arteriosus into the aorta at a point beyond where the main vessel of supply to the left upper extremity, the left subclavian artery, rises.

The blood which enters the right auricle by the inferior vena cava is mixed; it consists partly of purified blood from the placenta, and partly of impure blood returning from the abdomen and lower extremities. The blood from the placenta is returned to the embryo by the umbilical vein. From the umbilical vein it passes along a channel called the ductus venosus, which terminates in the upper part of the inferior vena cava. The mixed blood from the inferior vena cava passes through the right auricle, traverses the foramen ovale in the interauricular septum, and

enters the left auricle; from the left auricle it is transferred to the left ve through the left auriculo-ventricular opening, and the left ventricle ejects the aorta. From the first part of the aorta some of the blood passes in vessels which supply the head and neck and upper extremities, the rem

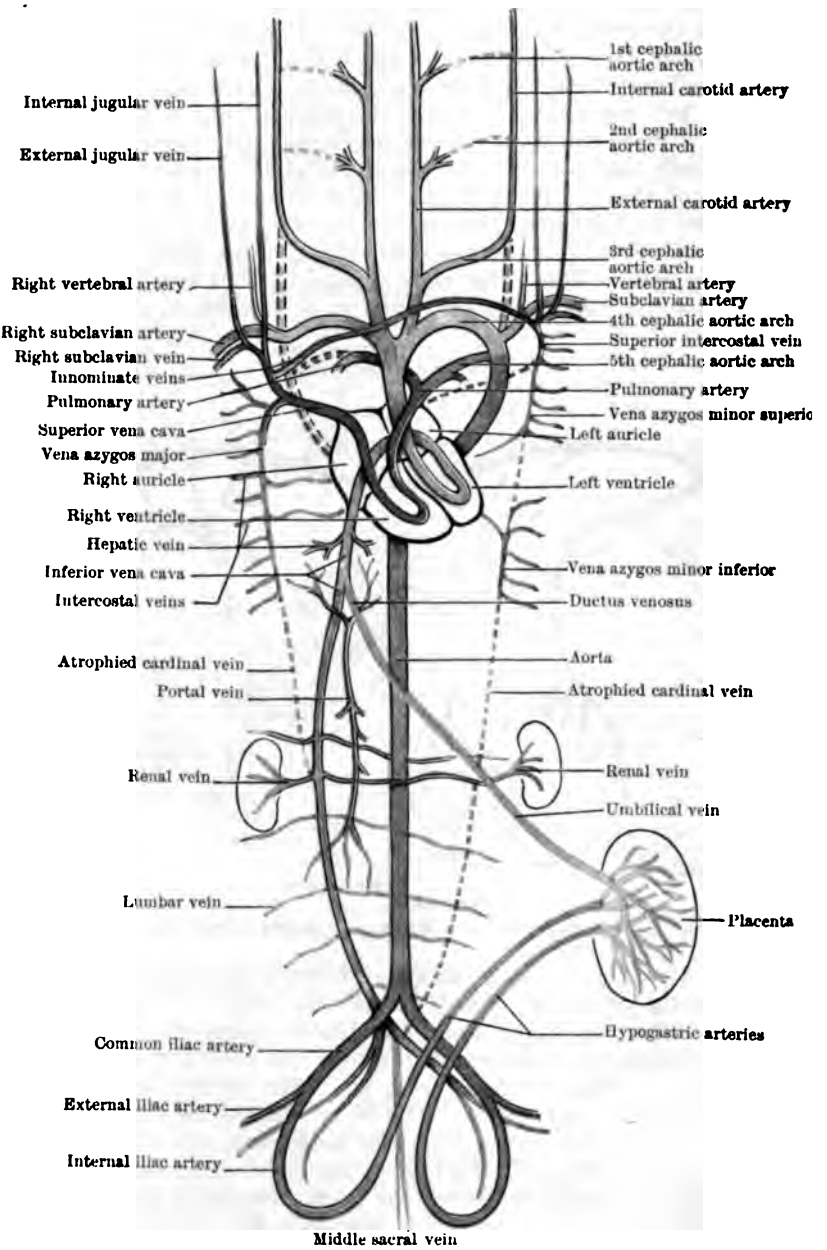

FIG. 50.—DIAGRAM OF THE FŒTAL CIRCULATION.

mixes with the blood conveyed to the aorta by the ductus arteriosus, a blood, thus further mixed, is in part distributed to the walls of the thora abdomen to the abdominal viscera and to the lower extremities, and in passes to the placenta.

Before birth, therefore, there is no pure arterial or fully oxygenated bl the arteries of the fœtus. The blood entering the heart by the superior ven is venous blood from the head, neck, upper extremities, and thorax; that en by the inferior vena cava is mixed blood, consisting of venous blood from the

part of the body and the lower extremities, and arterial blood from the placenta. The two streams do not mix in the right auricle, but the mixed or more arterial stream passes directly through the right into the left auricle, thence into the left ventricle, and from the left ventricle into the aorta or main systemic vessel, which conveys it to all parts of the body. The different parts of the body do not, however, receive equally oxygenated blood, for the venous stream which enters the right auricle by the superior vena cava, passes through that cavity into the right ventricle; by the right ventricle it is forced into the pulmonary artery, from which some small part passes into the lungs, and so back to the left auricle by the pulmonary veins, but by far the greater part is carried by the ductus arteriosus to the aorta, which it enters beyond the origins of the vessels which supply the head, neck, and upper extremities; therefore the blood in the lower part of the aorta, which is distributed to the abdomen, the abdominal viscera including the liver, the lower limbs, and the placenta, is much more mixed or impure (less oxygenated) than that which is distributed to the head, neck, and upper extremities from the upper part of the aorta.

SUMMARY OF THE EXTERNAL FEATURES OF THE HUMAN EMBRYO AT DIFFERENT PERIODS OF DEVELOPMENT.

First week.—The phenomena of fertilisation and segmentation have not been observed in the human ovum, but there is no reason to believe that they differ in any essential respect from those met with in the ova of other mammals. Fertilisation probably occurs in the upper part of the Fallopian tube, and segmentation is completed in the lower part of the same canal by the sixth or eighth day, when, presumably, the ovum becomes a morula, and passes, either as such or as a blastula, into the cavity of the uterus.

Second week.—At the **twelfth day** the ovum is embedded in the uterine wall; it is a lenticular vesicle, which measures 5·5 mm. ($\frac{1}{4}$ of an inch) in length and 3·3 mm. ($\frac{1}{8}$ of an inch) in breadth. Its upper and lower surfaces are smooth and convex, the latter being somewhat flatter than the former, and it is surrounded equatorially by a broad band of villi, some of which are slightly branched. The wall of the vesicle and the villous processes which project from it consist of ectodermal cells, and in the embryonic area, which is clearly marked on the upper surface, there is an inner layer of granular nucleated corpuscles.

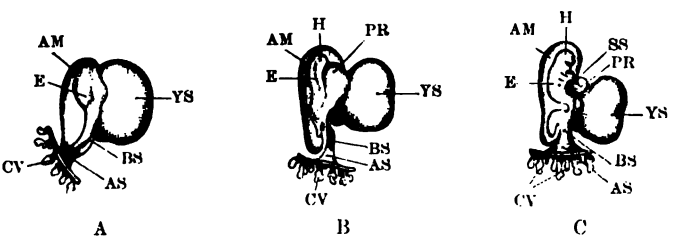

FIG. 51.

AM. Amnion; AS. Allantoic stalk; BS. Body-stalk; CV. Chorionic villi on a segment of the chorion; E. Embryo; H. Head of embryo; PR. Pericardial region; SS. Stomatodæal depression; YS. Yolk-sac.

By the end of the twelfth or the beginning of the thirteenth day the length of the ovum has increased to 6 mm. ($\frac{1}{4}$ inch), and its breadth to 4·5 mm. ($\frac{1}{6}$ inch). The embryonic area is no longer on the surface of the ovum, for the amnion folds have closed. The yolk-sac is formed, and the rudiment of the allantoic duct projects backwards from the upper and posterior part of the embryonic area. Mesoderm has formed, and it has extended round the yolk-sac and over the inner surface of the chorion. The embryonic area, with the yolk-sac and the amnion, are enclosed within the blastoderm, but they remain attached to the inner surface of the chorion by a relatively thick stalk of ectodermal and mesodermal tissue, the body-stalk, which is subsequently replaced by the umbilical cord. The outer surface of the ovum, which now consists entirely of chorion, is covered with small villi into some of which mesodermal cores are projecting.

Obviously the ovum of the latter part of the twelfth day differs considerably from that of the earlier part of the same day, but the transitional stages which intervene between the two have not yet been observed. Probably, however, the inner granular layer of cells in the embryonic area, which represent the entoderm, increase and form a solid mass in which a cavity soon appears. Directly after the formation of the cavity in the entoderm the primitive streak appears, and the mesoderm, growing from it, rapidly

covers the entodermal sac and spreads over the inner surface of the chorionic area. At the same time the amniotic folds form and separate from the chorion, but this separation is not effected till the mesoderm, extending backwards from the posterior end of the embryonic area, has reached and becomes connected with the inner surface of the chorion. Consequently, when the amniotic folds fuse together and separate from the remainder of the blastoderm, the embryonic area with the yolk-sac and amnion still remain attached to the inner surface of the chorion.

During the **thirteenth day** the embryonic area is elevated, the cephalic and caudal folds are developed, and the pericardial region becomes prominent between the head extremity of the embryo and the upper and anterior part of the yolk-sac. The neural groove and the neural folds appear; the posterior ends of the folds embrace the anterior extremity of the primitive streak on which the primitive groove is formed. At the anterior end of the primitive groove a neurenteric canal appears, forming a communication between the neural groove and the posterior end of the primitive alimentary canal

On the **fourteenth day** the embryo is more distinctly separated from the yolk-sac; the head increases considerably in size, and its anterior part is bent downwards. The posterior part of the neural canal is completed, except at the extreme end, by the meeting and fusion of the neural folds, but it is still open anteriorly, where traces of the cerebral vesicles are present. The two halves of the heart fuse together; the single tube thus formed is slightly bent upon itself, and its outline is visible from the exterior. The pericardial region increases in size, and a distinct stomatodæal space appears between it and the anterior part of the head. The outlines of fourteen protovertebral somites are visible on the outer surface of the body.

Yolk-sac.

Third week.—On the **fifteenth day** the auditory pits and two visceral clefts appear. The head and pericardial region enlarge, and the stomatodæal space, which increases simultaneously, becomes more defined laterally by the forward growth of the maxillary processes.

By the end of the third week Wolffian ridges appear below the ventral ends of the protovertebral somites; they are most marked in the thoracic and pelvic regions, where bud-like projections form the rudiments of the limbs. Four visceral clefts are visible, and there is a distinct tail.

Fourth week.—The embryo is curved upon itself, and its outline is almost circular. The visceral arches begin to overlap each other. The rudiments of the external ear are just visible as small nodules. The limb rudiments are flat, oval buds.

Fifth week.—The curvature is diminished, and the head and neck form about half the embryo. The eye is recognisable externally. The nose begins to grow forwards, but it is still broad and flat, and the nostrils are widely apart. The nodular elements of the external ear fuse together. The segments of the limbs are defined, but the digits do not project beyond the ends of the limb-buds. The genital tubercle, the rudiment of the external generative organs, is formed.

Sixth week.—During the sixth week the increase in size is less rapid than in previous stages, but the embryo begins to assume a more distinctly human form. The

l remains relatively large and it is bent at right angles to the body. The neck is er defined and appears as a constricted region between the head and trunk. The

limbs commences, and the fingers reach the extremity of the hand: the tail is inning to disappear as an external projection.

Seventh week.—The flexure of the head upon the body is reduced. The nose jects more than in the preceding stage, and the chin appears. The toes reach the rgins of the feet, and the projecting portion of the tail is still further reduced in length.

Eighth week.—The flexure of the head disappears. The forehead projects.

The nose narrows and becomes more prominent, but the anterior nasal orifices s directed forwards. The upper lip is completed by the fusion of the globular pr The thumb is widely separated from the fingers, and the hand assumes a di human appearance. The tail is reduced tc nodule, and the umbilical cord is attache lower part of the abdominal wall. At th the second month the total length of th excluding the legs, is 28 mm. ($1\frac{1}{8}$ in.).

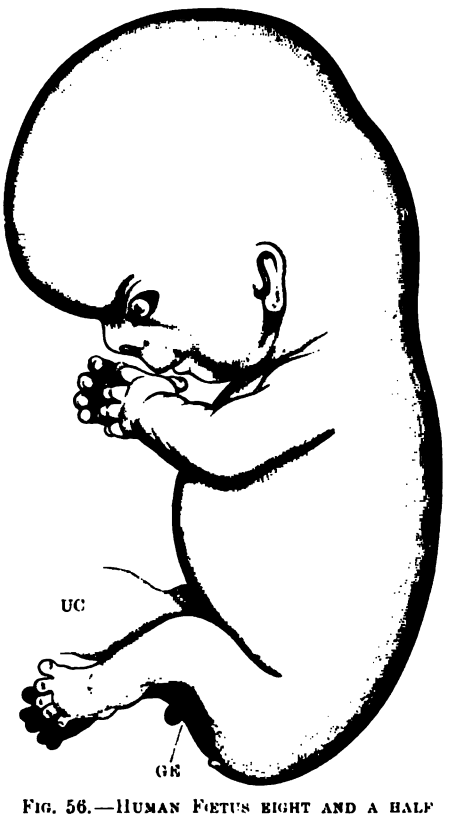

FIG. 56.—HUMAN FŒTUS EIGHT AND A HALF WEEKS OLD. (After His.)

GE. Genital eminence; UC. Umbilical cord.

Third month. — The head gro rapidly and, though it is still large, it is re smaller in proportion to the whole body eyelids close, and their margins fuse t The neck increases in length. The vario of the limbs assume their definite proporti nails appear on the fingers and toes. The dæum is formed and the external generativ are differentiated, so that the sex can b guished on external examination. The s rosy colour, thin and delicate, but more co than in the preceding stages. By the en third month the total length of the fœ cluding the legs, is 7 cm. ($2\frac{4}{5}$ in.), inclu legs, 9-10 cm. ($3\frac{3}{5}$-4 in.), and it weigh 100-125 grammes ($3\frac{1}{2}$-$4\frac{1}{2}$ oz.).

Fourth month. — In the fourth the skin becomes firmer, and fine hairs veloped. The disproportion between t and hind limbs disappears. If the fœtus at this period it may live for a few hou total length from vertex to heels is 16-20 c in.), from vertex to coccyx 12-13 cm. ($4\frac{4}{5}$ and it weighs from 230-260 grammes ($8\frac{1}{8}$

Fifth month.—The skin becomes the hairs are more developed, and se matter appears on the surface of the body legs are longer than the arms, and the ur is farther from the pubis. At the end month the total length of the fœtus, fron to heels, is 25-27 cm. (10-$10\frac{4}{5}$ in.), from vertex to coccyx 20 cm. (8 in.), and its weight is about half a kilogramme ($1\frac{1}{10}$ lbs.).

Sixth month.—The skin is wrinkled and of a dirty reddish colour. Th are stronger and darker. The deposit of sebaceous matter is greater, especially axillæ and groins. The eyelashes and eyebrows appear. At the end of the mo total length of the fœtus, from vertex to heels, is from 30-32 cm. (12-$12\frac{4}{5}$ in.), average weight is about one kilogramme ($2\frac{1}{5}$ lbs.).

Seventh month. — The skin is still a dirty red colour, but it is lighte in the previous month. The body is more plump on account of a greater deposit cutaneous fat. The eyelids reopen, and the fœtus is capable of living if born period. Its total length at the end of the month, measured from vertex to heels, i cm. (14-$14\frac{4}{5}$ in.), and its weight is about one and a half kilogrammes ($3\frac{1}{3}$ lbs.).

Eighth month.—The skin is completely covered with sebaceous deposit is thickest on the head and in the axillæ and groins, and its colour changes to a flesh tint. The umbilicus is farther from the pubis, but it is not yet at the centre body. The total length of the fœtus, from vertex to heels, is 40 cm. (16 in.), and its varies from 2 to $2\frac{1}{2}$ kilogrammes ($4\frac{1}{2}$-$5\frac{1}{2}$ lbs.).

Ninth month. — The hair begins to disappear from the body, but it long and abundant on the head. The skin becomes paler, the plumpness increas the umbilicus reaches the centre of the body. At the end of the ninth month, w fœtus is born, it measures about 50 cm. from vertex to heels (20 in.), and it weig 3-$3\frac{1}{2}$ kilogrammes ($6\frac{6}{10}$-$7\frac{7}{10}$ lbs.).

The age of a fœtus may be estimated approximately by Hasse's rule, viz. Up to t month the length in centimeters, the lower limbs being included, equals the square of in months, and after the fifth month the length in centimeters equals the age multiplied

OSTEOLOGY.

THE SKELETON.

By ARTHUR THOMSON.

THE term **skeleton** (from the Greek, σκελετός, dried) is applied to the parts which remain after the softer tissues of the body have been disintegrated or removed, and includes not only the bones, but also the cartilages and ligaments which bind them together. In the restricted sense of the word the skeleton denotes the osseous framework of the body. It is in this sense that it is generally employed in human anatomy.

The skeleton serves to support the softer structures which are grouped around it, and also affords protection to many of the delicate organs which are lodged within its cavities. By the articulation of its several parts, its segments are converted into levers which constitute the passive portion of the locomotory system. Recent research has also proved that certain cells found in bone-marrow are intimately associated with the development and production of some of the corpuscles of the blood.

Bone may be regarded as white fibrous tissue which, having become calcified, has undergone subsequent changes, so as to be converted into true osseous tissue. Most probably all bone is of membranous origin, but it may pass through a stage in which cartilage plays an important part in its development. In many instances the cartilage persists, and is not converted into bone, as in the case of the articular cartilage which clothes the joint surfaces, the nasal septum, the cartilages of the nose, and the cartilages of the ribs. A persistence of the membranous condition is met with in man in the case of the tentorium cerebelli, which in some groups of animals (Carnivora) is converted into a bony partition.

Skeletal structures may be derived from each of the three layers of the trilaminar blastoderm. The **exo-skeleton** includes structures of ectodermal, and some of mesodermal origin in the shape of hair, nails, feathers, teeth, scales, armour-plates, etc., whilst the **endo-skeleton**, with which we are more particularly concerned, is largely derived from the mesoblastic tissue, but also includes the notochord, an entodermal structure which forms the primitive endo-skeleton, around which the axial skeleton is subsequently developed in the Vertebrata. The endo-skeleton is divisible into an axial portion, appertaining to the trunk and head, and an appendicular part associated with the limbs. It also includes the **splanchnic skeleton**, which comprises certain bones developed in the substance of some of the viscera, such as the os cordis and os penis of certain mammals. In man, perhaps, the cartilaginous framework of the trachea and bronchi may be referred to this system.

The number of the bones of the skeleton of man varies according to age. Owing to a process of fusion taking place during growth, the number in the adult is less than the number in the child. The following table does not include the sesamoid bones which are frequently developed in tendons, the most constant ossicles of this description being those in relation to the metacarpo-phalangeal joint of the thumb, and the metatarso-phalangeal joint of the great toe.

The table represents the number of bones distinct and separable during adul life:—

		Single Bones.	Pairs.	Total.
Axial skeleton	The vertebral column	26	...	26
	The skull	6	8	22
	The sternum	1	...	1
	The ribs	...	12	24
	The hyoid bone	1	...	1
Appendicular skeleton	The upper limbs	...	32	64
	The lower limbs	...	31	62
The ossicles of the ear		...	3	6
		34	86	206

Bones are often classified according to their shape. Thus **long bones**, th is to say, bones of elongated cylindrical form, are more or less characteristic the limbs. **Broad** or **flat bones** are plate-like, and serve as protective coverings the structures they overlie; the bones of the cranial vault display this particul form. Other bones, such as the carpus and tarsus, are termed **short bones**; whil the bones of the cranial base, the face, and the vertebræ, are frequently referred as **irregular bones.**

Various descriptive terms are applied to the prominences commonly met wit on a bone, such as *tuberosity, eminence, protuberance, process, tubercle, spin ridge, crest,* and *line.* These may be articular in their nature, or may serve points or lines of muscular and ligamentous attachment. The surface of the bo may be excavated into *pits, depressions, fossæ, cavities, furrows, grooves,* a *notches.* These may be articular or non-articular, the latter serving for the rece tion of organs, tendons, ligaments, vessels, and nerves. In some instances t substance of the bone is hollowed out to form an *air space, sinus,* or *antru* Bones are traversed by *foramina* and *canals*; these may be for the entrance and ex of nutrient vessels, or for the transmission of vessels and nerves from one region another. A *cleft, hiatus,* or *fissure* serves the same purpose. Channels of this kir are usually placed in the line of a suture, or correspond to the line of fusion of t primitive portions of the bone which they pierce.

Composition of Bone.—Bone is composed of a combination of organic a inorganic substances in about the proportion of one to two.

Organic matter (Fat Collagen)		31·04
Mineral matter—		
Calcic phosphate	58·23	
Calcic carbonate	7·32	
Calcic fluoride	1·41	68·97
Magnesic phosphate	1·32	
Sodic chloride	·69	
		100·00

The animal matter may be removed by boiling or charring. According to t completeness with which the fibrous elements have been withdrawn, so the britt ness of the bone increases. When subjected to high temperatures the earth matter alone remains. By soaking a bone in acid the salts may be dissolved o leaving only the organic part. The shape of the bone is still retained, though has now become soft, and can be bent about in any direction.

Bone may be examined either in the fresh or dry condition. In the form state it retains all its organic parts, which include the fibrous tissue in and arou it, the blood-vessels and their contents, together with the cellular elements fou within the substance of the bone itself, and the marrow which occupies the lacun spaces and marrow cavity. In the dried or macerated bone most of these ha disappeared, though a considerable portion of the organic matter still remai even in bones of great antiquity and in a more or less fossil condition. Co sidering its nature and the amount of material employed, bone possesses a remar

able strength, equal to nearly twice that of oak, whilst it is capable of resisting a greater crushing strain; it is stated that a cubic inch of bone will support a weight of over two tons. Its elasticity is remarkable, and is of the greatest service in enabling it to withstand the shocks to which it is so frequently subjected. In regions where wood is scarce the natives use the ribs of large mammals as a substitute in the construction of their bows. Its hardness and density vary in different parts of the skeleton, and its permanency and durability exceed that of any other tissue of the body, except the enamel and dentine of the teeth. The osseous remains of a race over eighty centuries old is now being excavated in Egypt.

Structure of Bone.—The structure of the bone varies with the form of the bone examined. If a long bone be studied in section, the **shaft** or **diaphysis** is seen to be hollow, displaying a cavity of elongated shape, which contains the soft cellular marrow. Around this, the bone is deposited in spicules so as to form a loose osseous meshwork, which becomes denser as it reaches the circumference, and gradually merges with the compact layer which forms the outer investing envelope. The extremities of the bone, usually developed from separate or secondary centres called **epiphyses**, are composed of cancellous tissue, usually finer in the grain and not, as a rule, displaying any medullary cavity. Here the confining shell of bone is thin, and displays none of the stoutness which is so characteristic of the outer layers in the shaft. In the recent condition, the extremities are cartilage-covered where they enter into the formation of joints. In flat bones the osseous tissue is disposed in two compact layers, with a layer of softer cancellous bone, here called the **diploe**, sandwiched in between. There is no medullary cavity, although in certain regions the substance of the diploe may be absorbed, thus forming **air-spaces** or **air-sinuses**.

True bone differs from calcified cartilage or membrane in that it not merely consists of the deposition of earthy salts within its matrix, but displays a definite arrangement of its organic and inorganic parts. Dense bone merely differs from loose or cancellous bone in the compactness of its tissue, the characteristic feature of which is the arrangement of the osseous lamellæ to form what are called **Haversian systems**. These consist of a central or **Haversian canal** which contains the vessels of the bone. Around this the **osseous lamellæ** are arranged concentrically, separated here and there by interspaces called **lacunæ**, in which the bone corpuscles are lodged. Passing from these lacunæ are many fine channels called **canaliculi**. These are disposed radially to the Haversian canal, and pass through the osseous lamellæ. They are occupied by the slender processes of the bone corpuscles. Each Haversian system consists of from three to ten concentric rings of osseous lamellæ.

In addition to the lamellæ of the Haversian systems there are others which are termed the **interstitial lamellæ**; these occupy the intervals between adjoining Haversian systems, and consist of Haversian systems which have undergone a process of partial absorption. Towards the surface of the bone, and subjacent to the periosteal membrane which surrounds the shaft, there are lamellæ arranged circumferentially; these are sometimes referred to as the outer **fundamental lamellæ**. The **periosteal membrane** which surrounds the bone, and which plays so important a part in its development, sends in processes through the various Haversian systems, which carry with them vessels and cells, thus forming an organic meshwork around which the earthy salts are deposited.

The interior of the bone, viz. the **marrow cavity**, and the interspaces within the cancellous tissue, as well as some of the larger Haversian canals, are occupied by the **marrow** or **medulla** of the bone. This varies considerably in its composition in different bones. In the medullary cavity of the shafts of the long bones it consists mainly of fat cells, together with a few marrow cells proper, supported by a kind of retiform tissue, and is known as the **yellow marrow**. In other situations, viz. in the diploe of the cranial bones, in the cancellated tissue of the epiphyses of the long bones, the vertebræ, the sternum, and the ribs, the marrow is more fluid in its consistence, contains less fat, but is characterised by the presence of marrow-cells proper, which resemble in some respects colourless blood corpuscles. In addition to these, however, there are smaller reddish coloured cells, akin to the nucleated red

corpuscles of the blood of the embryo. It is these cells (erythroblasts) which are concerned in the formation of the coloured corpuscles of the blood. Marrow which displays these characteristic appearances is distinguished from the yellow variety already described by being called the **red marrow**. In the diploe of the cranial bones of aged individuals the marrow, which has undergone degenerative changes, is sometimes referred to as the **gelatinous marrow**.

Apart from the adaptation of form rendered necessary by the use to which the bone is put, external influences are seen to react upon the intimate structure of the bone itself. Thus, if sections of different bones be made, the structural arrangement of their cancellous and dense tissue is seen to vary. In long bones the walls of the shaft are thick and strong, more particularly towards the concave side if the shaft happens to be bent. The marrow cavity—largest towards the centre—gradually tapers towards the extremities, being encroached upon by the surrounding cancellous tissue, which is disposed in lines converging towards the extremities like the sides of a vaulted arch, thereby forming platforms on which the epiphyses are supported. The surfaces of these platforms are not smooth, but so arranged as best to withstand the strain to which the epiphyses are habitually subjected. Such provision is necessary in order to obviate the tendency to separation, which might otherwise occur prior to the complete osseous union of the diaphysis with the epiphysis. In the epiphysis itself the arrangement of the fibres of the cancellous tissue is determined by the disposition of the articular surfaces. The osseous lamellæ, as a rule, are disposed at right angles to the planes of the articular facets, whilst they are bound together by other lamellæ arranged conformably with these articular planes. The former correspond to the direction of greatest pressure whilst the latter agree with the lines of greatest tension. In cases where there is an outstanding process projecting from the shaft, as, for example, the head and neck of the femur, a section of the bone displays a bracket-like arrangement of the osseous fibres of the cancellous tissue, which assists materially in strengthening the bone.

Ossification and Growth of Bones.—For an account of the earlier development of the skeleton the reader is referred to the section on Embryology. Concerning the subsequent changes which take place, these are dependent on the conversion of the sclerotogenous tissue into membrane and cartilage. A characteristic of this tissue is that it contains elements which become formed into bone-producing cells, called **osteoblasts**. These are met with in the connective tissue from which the membrane bones are formed, whilst they also appear in the deeper layers of the investing tissue of the cartilage (perichondrium), and so lead to its conversion into the bone-producing layer or periosteum. All true bone, therefore, may probably be regarded as of membranous origin, though its appearance is preceded in some instances by the deposition of cartilage; in this case calcification of the cartilage is an essential stage in the process of bone formation, but the ultimate conversion into true bone with characteristic Haversian systems, leads to the absorption and disappearance of this primitive calcified cartilage.

Membrane bones are such as have developed from fibrous tissue without having passed through a cartilaginous stage. Of this nature are the bones of the cranial vault and the majority of the bones of the face, viz. the superior maxillæ, malars, nasals, lachrymals, and palate bones, as well as the vomer. The internal pterygoid plate is also of membranous origin.

Cartilage bones are those which are preformed in cartilage, and include most of the bones of the skeleton. Their growth is often described as endochondral and ectochondral, the former term implying the deposition of membrane bone in the centre of the cartilage, while the latter signifies a deposit of membrane bone on the surface of the cartilage, the osteogenetic layer on the surface of the cartilage being called the perichondrium till once bone has been formed, when it is called the periosteum.

In the course of the development of a bone from membrane, as, for example the parietal bone, the fibrous tissue corresponding to the position of the primary centre becomes osteogenetic, because here appear the bone-forming cells (osteoblasts) which rapidly surround themselves with a bony deposit more or less spicular in

arrangement. As growth goes on these osteoblasts become embedded in the ossifying matrix, and remain as the corpuscles of the future bone, the spaces in which they are lodged corresponding to the lacunæ and canaliculi of the fully developed osseous tissue. From the primary centre ossification spreads eccentrically towards the margins of the bone, where ultimately the sutures are formed. Here the growth rendered necessary by the expansion of the cranium takes place through the agency of an intervening layer of vascular connective tissue rich in osteoblasts; but in course of time the activity of this is reduced until only a thin layer of intermediate tissue persists along the line of the suture; this may eventually become absorbed, leading to the obliteration of the suture by the osseous union of the contiguous bones. Whilst the expansion of the bone in all directions is thus provided for, its increase in thickness is determined by the activity of the underlying and overlying strata. These form the periosteum, and furnish the lamellæ which constitute the inner and outer compact osseous layers.

In a cartilage bone changes of a similar nature occur. The cartilage, which may be regarded histologically as white fibrous tissue + chondro-sulphuric acid and a certain amount of lime salts, undergoes the following changes:—**First**, the cartilage cells being arranged in rows, become enlarged; **secondly**, the matrix between the cartilage cells becomes calcified by the deposition of an additional amount of lime salts; **thirdly**, the rows of cells become confluent; and, **fourthly**, into the spaces so formed extend the blood-vessels derived from the vascular layer of the periosteum. Accompanying these vessels are osteoblasts and osteoclasts, the former building up true bone at the expense of the calcified cartilage, the latter causing an absorption of the newly-formed bone, and leading to its conversion into a marrow cavity, so that in due course all the cartilage or its products disappear. At the same time that this is taking place within the cartilage, the perichondrium is undergoing conversion into the periosteum, an investing membrane, the deeper stratum of which, highly vascular, furnishes a layer of osteoblast cells which serve to develop the circumferential lamellæ of the bone. It is by the accrescence of these layers externally, and their absorption internally through the action of the osteoclast cells, that growth takes place transversely. A transverse section of the shaft of a long bone shows this very clearly. Centrally there is the marrow cavity, formed primarily by the absorption of the calcified cartilage; around this the cancellous tissue produced by the partial erosion of the primary periosteal bone is disposed, whilst externally there is the dense envelope made up of the more recent periosteal growth.

Such a description, whilst explaining the growth of bone circumferentially, fails to account for its growth in length; hence the necessity in long bones for some arrangement whereby ossification may take place at one or both extremities of the shaft. This zone of growth is situated where the ossified shaft becomes continuous with the cartilaginous epiphysis. In addition, within these epiphysial cartilages calcification of the cartilage takes place centrally, just as in the diaphysis. The two parts of the bone, viz. the diaphysis and epiphysis, are thus separated by a layer of cartilage, as yet uncalcified, but extremely active in growth owing to the invasion of vessels and cells from a vascular zone which surrounds the epiphysis. The nucleus of the epiphysis becomes converted into true bone, which grows eccentrically. This arrangement provides for the growth of the shaft towards the epiphysis, and the growth of the epiphysis towards the shaft; so that as long as the active intervening layer of cartilage persists, extension of growth in a longitudinal direction is possible. Subsequently, however, at variable periods the intervening layer of cartilage becomes calcified, and true bony growth occurs within it, thus leading to complete osseous union between the shaft and epiphysis. When this has taken place all further growth in a longitudinal direction ceases. In cases where the epiphysis enters into the formation of a joint, the cartilage over the articular area persists and undergoes neither calcification nor ossification. In long bones the ossific nucleus for the shaft or diaphysis is the first to appear, and is hence often called the primary centre of ossification. The centres for the epiphyses appear subsequently at variable periods, and are referred to as the secondary centres of ossification.

From what has been said it will be gathered that the vascular supply of the bone is derived from the vessels of the periosteum. These consist of fine arteries

which enter the surface of the shaft and epiphysis; but in addition there larger trunk which enters the diaphysis and reaches the medullary cavity. Th called the **nutrient artery** of the bone. The direction taken by this vessel vari different bones. In the upper limb the artery runs downwards in the case of humerus and upwards in the radius and ulna; in the lower limb the nutr vessel of the femur is directed towards the upper extremity of the shaft, w in the tibia and fibula it follows a downward course. It is difficult to account this difference in the arrangement of the vessels; but it has been pointed out when all the joints are flexed, as in the position occupied by the fœtus in u the direction taken by the vessels is the same, and corresponds to a line pas from the head towards the tail-end of the embryo. Consequently, in the u limb the vessels flow towards the elbow, whilst in the lower limb they pass the knee.

The attention of anatomists has long been directed to the elucidation of the which regulate bone-growth. Our present knowledge of the subject may be br summarised in the following generalisations:—

1. In bones with a shaft and two epiphyses, the epiphysis towards which nutrient artery is directed is the first to unite with the shaft.

2. In bones with a shaft and two epiphyses, as a rule the epiphysis which mences to ossify latest unites soonest with the shaft. (The fibula is a not exception to this rule. See p. 239.)

3. In bones with a shaft and one epiphysis the nutrient artery is dire towards the end of the bone which has no epiphysis. (This arrangement l good in the case of the clavicle, the metacarpus, metatarsus, and phalanges.)

4. When an epiphysis is ossified from more than one centre, coalescence t place between the separate ossific nuclei before the epiphysis unites with the s

Highly suggestive, too, are the following propositions—That ossification commences in the epiphysis which ultimately acquires the largest relative pro tion to the rest of the bone, and that the ossification of the epiphysis is correlated with its functional importance. In cases of long bones with only epiphysis, the epiphysis is placed at the end of the bone where there is movement.

The **veins** which permeate the cancellous texture of the bone are large and t walled. They do not accompany the arteries, and, as a rule, in long bones escape through large openings near the articular surface. In flat bones they oc channels within the diploe, and drain into an adjacent sinus, or form commu tions with the superficial veins of the scalp.

The **lymphatics** are mainly periosteal, but enter the bone along with the ve and become perivascular.

The **nerves** which accompany the arteries are probably destined for the su of the coats of these vessels. Whether they end in the bony tissue or n unknown.

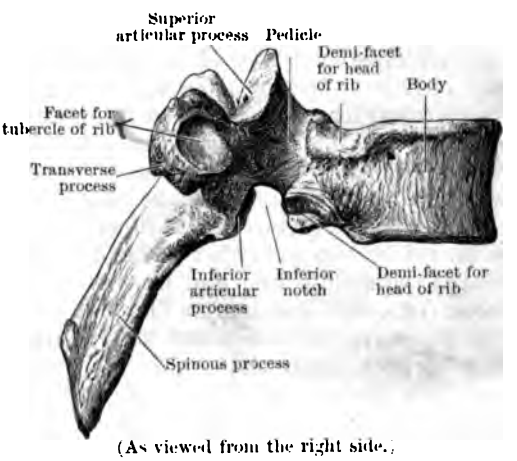
THE VERTEBRAL COLUMN.

The **vertebral column** (columna vertebralis) of man consists of thirty-segments or **vertebræ**, placed one on the top of the other. In the adult, certa these vertebræ have become fused together in the process of growth to form t the segmental arrangement of which is somewhat obscured, though even in fully-developed condition sufficient evidence remains to demonstrate their pound nature. The vertebræ so blended are termed the **fixed** or **false vert** whilst those between which osseous union has not taken place are described a **movable** or **true vertebræ**. This fusion of the vertebral segments is met wi either extremity of the vertebral column, more particularly below, where the co is modified to adapt it for union with the girdle of the lower limb, and al the region of man's degenerated caudal appendage. But a partial union o vertebral segments also takes place above, between the two highest vertebr association with the mechanism necessary to provide for the movements o head on the column.

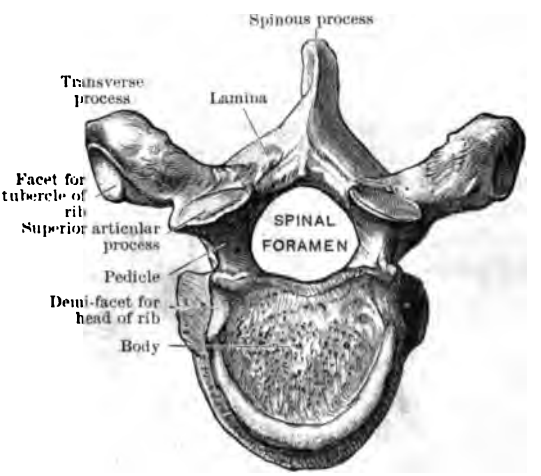
r descriptive purposes the vertebral column is subdivided according to the s through which it passes. Thus the vertebræ are described as **cervical** ræ cervicales), **dorsal** or **thoracic** (vertebræ thoracales), **lumbar** (vertebræ les), **sacral** (vertebræ sacrales), and **coccygeal** (vertebræ caudales), according · lie in the regions of the neck, back, loins, pelvis, and tail. The number of ·e met with in these regions is fairly constant, though, as will be hereafter l out, variations may occur in the number of the members of the different The vertebræ in man are thus apportioned—7 cervical, 12 dorsal, 5 lumbar, l, and 4 or 5 coccygeal; the three former groups comprise the **true** or **mov**rtebræ, the two latter the **false** or **fixed** vertebræ. The **vertebral formula** thus expressed:—

Movable or **True Vertebræ.**			**Fixed** or **False Vertebræ.**		
rvical.	Dorsal.	Lumbar.	Sacral.	Coccygeal.	
7	12	5	5	4	= 33.

tebræ of which the column is built up, though displaying great diversity of ers in the regions above enumerated, yet preserve certain features in ı. All possess a solid part, ı or **body** (corpus vertebræ): · **articular processes** by which ticulate with their fellows; ıave **muscular processes** de- ı in connexion with them; the majority display a **verte- spinal foramen** (foramen verte- ormed by the union of a bony rcus vertebræ) with the body. common characters may best lied by selecting for descrip- ı intermediate member of the For this purpose one of the · or lower thoracic vertebræ · chosen.



(As viewed from the right side.)



(As viewed from above.)

FIGS. 57, 58.—FIFTH THORACIC VERTEBRA.

typical vertebra may be de- ı as consisting of a **body** or ı (corpus vertebræ) composed ass of spongy bone, more or lindrical in form. The size ape of the body is liable to erable variation according to rtebra examined. The upper wer surfaces of the body are lightly concave from before ards and from side to side, · the thickening of the bone lits margins. In the recent con- these surfaces afford attach- for the intervertebral discs are placed like pads between dies of the movable members series. The circumference of dy, formed as it is of more ct bone than the interior, is · slightly concave from above ards, though it becomes flat l, where the body forms the anterior boundary of the spinal or vertebral n, at which point it is usually slightly concave from side to side. The l surfaces of the body are pierced here and there by foramina for the

passage of nutrient vessels, more particularly on the posterior surface, depression of considerable size receives the openings of the canals throu some of the veins which drain the body of the bone escape. Connected body posteriorly there is a bony **arch** (arcus vertebræ), which, by its u the body, encloses a foramen of variable size, the **spinal** or **vertebral** (foramen vertebrale). When the vertebræ are placed on the top of e these foramina form with the uniting ligaments a continuous canal— **neural canal**—in which the spinal cord with its coverings is lodged. which is formed by the union of the **pedicles** and **laminæ**, besides encl spinal foramen, also supports a certain number of processes; of these, outstanding, and may be regarded as a series of levers to which mu attached, whilst others are **articular** and assist in uniting the different together by means of a series of movable joints. The **pedicles** are th bone which pass from the back of the body of the vertebræ on eithe the points where the articular processes are united to the arch. The are compressed laterally, and have rounded superior and inferior border the vertical breadth of the pedicles is not as great as the thickness of th which they are attached, it follows that when the vertebræ are placed the other a series of intervals is left between the pedicles of the different These spaces, enclosed in front by the bodies of the vertebræ and th vertebral discs, and behind by the coaptation of the articular processes series of holes communicating with the neural or spinal canal; these are **intervertebral foramina** (foramina intervertebralia), and allow of the transm spinal nerves and vessels. As each intervertebral foramen is bounded a below by a pedicle, the grooved surfaces in correspondence with the u lower borders of the pedicles are called the **upper** and **lower intervertebra** or **notches** (incisura vertebralis superior et inferior). Posteriorly, the two are united by two somewhat flattened plates of bone—the **laminæ**, which towards the middle line, and become fused with the root of the projectin **process** (processus spinosus). The breadth of the laminæ and their sloping ment are such, that when the vertebræ are articulated together they le space between them, thus enclosing fairly completely the neural canal, they form the posterior wall. The edges and inner surfaces of the la rough for the attachment of the ligaments which bind them together.

The **muscular processes** are three in number, viz. two **transverse proce** on either side—and one central or median, the **spinous process.** Th (processus transversus) project outwards on either side from the arch at t where the pedicle joins the lamina. The latter (processus spinosus) exte wards in the middle line from the point of fusion of the laminæ. Th processes display much variety of length and form.

The **articular processes** (zygapophyses), four in number, are arranged i one superior, the other inferior; the former are placed on the upper surfa arch where the pedicles and laminæ join, the latter below the arch in corres with the superior. Whilst differing much in the direction of their surfaces, the upper have generally a backward tendency, whilst the low forwards.

THE TRUE OR MOVABLE VERTEBRÆ.

The Cervical Vertebræ.

The **cervical vertebræ** (vertebræ cervicales), seven in number, can b distinguished from all the other vertebræ by the fact that their transv cesses are pierced by a foramen. The two highest, and the lowest, requi description; the remaining four conform to a common type.

Their **bodies**, the smallest of all the true vertebræ, are oblong in s transverse diameter being much longer than the antero-posterior width. T surface, which slopes from behind forwards and downwards, is concave fro side, owing to the marked projection of its lateral margins. Its anter rounded off, whilst its posterior edge is sharply defined.

ferior surface, which is more or less saddle-shaped, is directed downwards ·ards. It is convex from side to side, and concave from before backwards, ght rounding off of the projecting anterior lip. The vertical diameter of is small in proportion to its width. The anterior surface is flat in the ıe, but furrowed laterally. The posterior surface, which is rough and r many small foramina, is flat from side to side and above downwards; it its entire extent the anterior wall of the spinal foramen. The lateral the body, particularly in their upper parts, are fused with the costal he transverse processes, and form the inner wall of the vertebrarterial foramen transversarium).

edicles which spring from the posterior half of the lateral aspects of the ut equidistant from their upper and lower margins, are directed hori- ackwards and outwards. The **superior** and **inferior notches** are nearly lepth.

uminæ are long, and about as wide as the body of the bone is thick.

pinal foramen is larger than in the thoracic and lumbar regions; its shape ılar, or more nearly semilunar.

ransverse processes, so called, are pierced by the vertebrarterial foramen

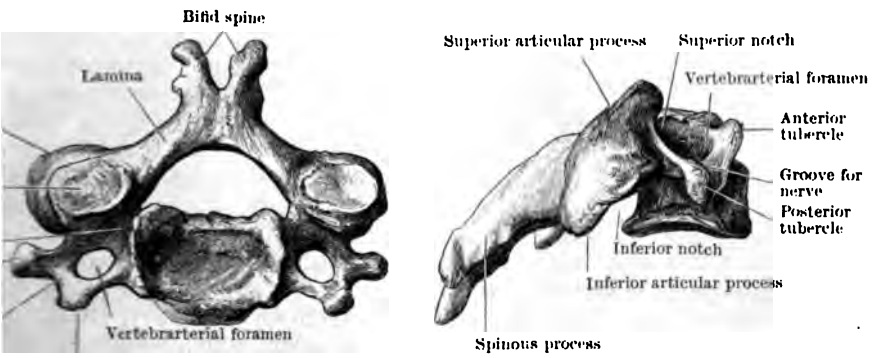


FIG. 59.—FOURTH CERVICAL VERTEBRA FROM ABOVE AND FROM THE RIGHT SIDE.

transversarium). They consist of two parts—the part behind the foramen, rings from the neural arch and is the true transverse process, and the ront, which is homologous with the ribs in the thoracic portion of the These two processes, united externally by a bridge of bone, which thus the interval between them into a foramen, terminate in two tubercles, spectively as the **anterior** and **posterior tubercles**. The general direction rocesses is outwards, slightly forwards, and a little downwards, the anterior lying internal to the posterior. The two tubercles are separated above by directed outwards, downwards, and forwards; along this the spinal nerve sses. The **vertebrarterial foramen** (foramen transversarium), often sub- by a spicule of bone, is traversed by the vertebral artery and vein in the r vertebræ. The **spinous processes**, which are directed downwards, are short, ed vertically, and bifid. The **articular processes** are supported on cylindrical of bone fused with the arch where the pedicles and laminæ join. These s are sliced away obliquely above and below, so that the superior articular ore or less circular in form, are directed upwards and backwards, whilst sponding inferior surfaces are turned downwards and forwards.

tions.—Szawlowski records the presence of an independent rib element in the trans- ss of the fourth cervical vertebra. (*Anat. Anz. Jena*, vol. xx. p. 306.)

t Cervical Vertebra or **Atlas.**—This bone may be readily recognised by ence of the body and spinous process. It consists of two **lateral masses**, support the articular and transverse processes. The lateral masses are ves united by two curved bars of bone, the **anterior** and **posterior arches**, of he former is the stouter and shorter. Each **lateral mass** is irregularly six- nd so placed that it lies closer to its fellow of the opposite side in front than

behind. Its upper surface is excavated to form an elongated **oval facet**, cc from before backwards, and inclined obliquely inwards; not infrequently articular surface displays indications of division into two parts. These face for the reception of the condyles of the occipital bone.

The **inferior articular facets** are placed on the under surfaces of the l masses. Of circular they display a slight to-side concavity, tl flat in the antero-pos direction. Their dispo is such that their su incline downwards slightly inwards. The on the superior art processes of the secon vical vertebra. Spri from the anterior and aspects of the lateral m and uniting them in is a curved bar of the **anterior arch** (anterior); compresse either side, this is t ened centrally so as to on its anterior aspec rounded **anterior tu**

10. Posterior tubercle.

(tuberculum anterius). In correspondence with this on the posterior surfa this arch is a **circular facet** (fovea dentis) for articulation with the odontoid pr of the second cervical vertebra (axis).

The inner surface of the lateral mass is rough and irregular, displaying a **tubercle** for the attachment of the tranverse ligament which passes across the included between the two lateral masses and the anterior arch, thus holdin odontoid process of the axis in position. Behind each tubercle there is usu deep pit, opening into the bottom of which are the canals for the nutrient ves

External to the lateral mass, and principally from its upper half, the trans process arises by two roots which include between them the vertebrarterial for The **transverse process** is long, obliquely compressed, and down-turned; the an and posterior tubercles are no longer distinguishable, as they have fused to one mass.

The **posterior arch** arises in part from the posterior surface of the lateral and in part from the posterior root of the transverse process. Compressed above downwards anteriorly, where it bounds a groove which curves aroun posterior aspect of the superior articular process, which groove is also conti externally with the vertebrarterial foramen, the posterior arch becomes th mesially, at which point it displays posteriorly a rough irregular **projection-posterior tubercle** (tuberculum posterius), the feeble representative of the sp process. A prominent little tubercle, arising from the posterior extremity o superior articular process, overhangs the groove above mentioned, and no frequently becomes developed so as to form a bridge of bone across it, conve the groove into a canal through which the vertebral artery and the first cervi suboccipital nerve pass—a condition normally met with in many animals. noteworthy that the grooves traversed by the two highest spinal nerves lie b the articular processes, in place of in front, as in other parts of the column.

The **ring** formed by the lateral masses and the anterior and posterior arc of irregular outline. The anterior part, cut off from the rest by the trans ligament, serves for the lodgment of the odontoid process of the axis; the l part behind corresponds to the upper part of the neural or spinal canal.

Variations.—The vertebrarterial foramen is often deficient in front. Imperfect ossifi occasionally leads to the anterior and posterior arches being incomplete. The superior art

casionally partially or completely divided into anterior and posterior portions.
ces the extremity of the transverse process has two tubercles. The transverse
n rare cases, articulate with a projecting process (paroccipital) from the under
jugular process of the occipital bone (see p. 113). An upward extension from the
the anterior arch, due probably to an ossification of the anterior occipito-atlantal
articulate with the anterior surface of the summit of the odontoid process of
n has noticed the articulation of the superior border of the posterior arch with
order of the foramen magnum. Cases of partial or complete fusion of the atlas
ital bone are not uncommon (see p. 113).

Cervical Vertebra, Axis, or **Epistropheus.**—This is characterised by
of the tooth-like **odontoid process** (dens) which projects upwards from
surface of the body. Slightly constricted where it joins the body, the
ocess tapers to a blunt point superiorly, on the sides of which there are
the attachment of the odontoid or check ligaments. When the atlas
articulated together this process lies behind the anterior arch of the
isplays on its anterior surface an oval or circular facet which articu-
hat on the posterior surface of the anterior arch of the atlas. On the

o the persistence of the primitive condition in which it is developed from two
sionally the odontoid process fails to be united with the body of the axis, forming
ideum comparable to that met with in the crocodilia (Giacomini, Romiti, and

Turner). The vertebrarterial foramen is not infrequently incomplete, owing to the imper ossification of the posterior root of the transverse process.

The **seventh cervical vertebra**, or **vertebra prominens**, receives the latter na from the outstanding nature of its **spinous process**, which ends in a single broad tube This forms a well-marked surface projection at the back of the root of the n The **transverse processes** are broad, being flattened from above downwards; t project considerably beyond those of the sixth. The maximum width betw their extremities agrees with that between the transverse processes of the a these two constituting the widest members of the cervical series. The v **brarterial foramen** is small. Not infrequently the costal element is separate f the true transverse process, thus constituting a **cervical rib.**

Variations.—The vertebrarterial foramen may be absent on one or other side.

Thoracic Vertebræ.

The **thoracic** or **dorsal vertebræ** (vertebræ thoracales), twelve in num are distinguished by having facets on the sides of their bodies for the heads o ribs, and in most instances also articular surfaces on their transverse process the tubercles of the ribs (Figs. 57 and 58, p. 75).

The **body** is described as characteristically heart-shaped, though in the u and lower members of the series it undergoes transition to the typical forms o cervical and lumbar vertebræ respectively. Its antero-posterior and trans widths are nearly equal; the latter is greatest in line with the facets for the h of the rib. The bodies are slightly thicker behind than in front, thus adap themselves to the anterior concavity which the column displays in this re The bodies of the second to the ninth thoracic vertebræ inclusive, each possess **costal demi-facets**—a superior pair placed on the upper margin of the body, clo the junction of the pedicle with the centrum, and an inferior pair situated o lower edge, close to and in front of the inferior intervertebral grooves.

When contiguous vertebræ are articulated, the upper pair of demi-facets of the l vertebra coincide with the lower demi-facets of the higher vertebra, and, together wit intervening intervertebral disc, form an articular cup for the reception of the he a rib. Of these facets on the body the upper pair are the primary articular su for the head of the rib; the lower are only acquired secondarily. Moreover, these though apparently placed on the body, are in reality developed on the sides of the p behind the line of union of the pedicles with the centrum (neuro-central synchondro will be explained hereafter.

The **pedicles** are short and thick, and directed backwards and slightly up The superior notch is faintly marked; the inferior notch is deep. The lamin broad, flat, and sloping, having sharp upper and lower margins. When vertebræ are superposed the latter overlap the former so as to form imbricated arrangement. The **spinal foramen** is smaller than in the cervic lumbar regions, and nearly circular in shape.

The **spinous processes** vary in length and direction, being shorter and horizontal in the upper and lower members of the series, longest and most ob in direction towards the middle of this part of the column. Nearly all have a d ward inclination, and are so arranged that they overlap one another. Triangul section where they spring from the neural arch, they become laterally compr towards their extremities, which are capped by more or less distinct tubercles. **transverse processes** are directed backwards and outwards, and a little upw They gradually decrease in size and length from above downwards. Each h somewhat expanded extremity, the anterior surface of which, in the case of the u ten vertebræ, is hollowed out in the form of a circular facet for articulation w the tubercle of the rib which rests in the upper demi-facet of the vertebra to wh the transverse process belongs. The **superior articular processes** are vertical; have their surfaces directed backwards, slightly upwards, and a little outwa the **inferior**, correspondingly forwards, downwards, and inwards.

Certain of the thoracic vertebræ display characters by which they can rea

ıised. These are the first, tenth, eleventh, and twelfth, and sometimes the

irst thoracic verte- embles the seventh in the shape of its ıd the length and ı of its spine. twelfth thoracic vertebra may usually be distinguished from the eleventh by arrangement of its inferior articular processes, which resemble those of the lum series in being out-turned; but the eleventh occasionally displays the s arrangement, in which case it is not always easy to distinguish between them.

Variations.—Barclay Smith (*Journ. Anat. and Physiol.* Lond. 1902, p. 372) records five c in which the superior articular processes of the twelfth thoracic vertebra displayed thoracic lumbar characteristics on the opposite sides.

Lumbar Vertebræ.

The **lumbar vertebræ** (vertebræ lumbales), five in number, are the largest the movable vertebræ. They have no costal articular facets, nor are their tra verse processes pierced a foramen. In this v they can be readily d tinguished from the me bers of the cervical a thoracic series.

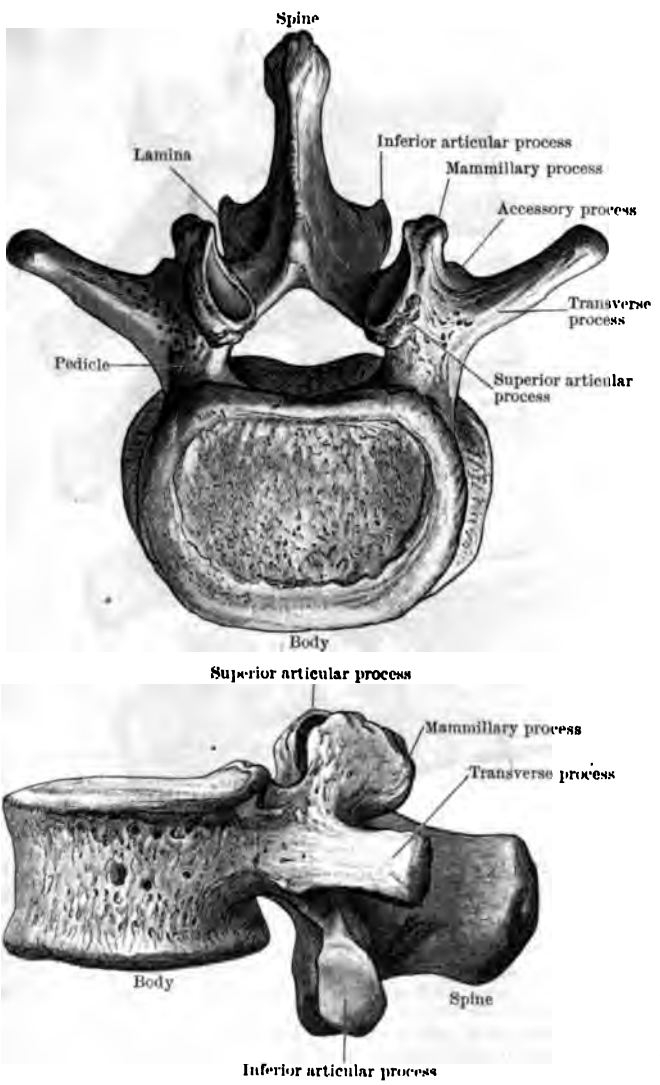

Fig. 64.—Third Lumbar Vertebra from Above, and from the Left Side.

The **body** is kidn shaped in outline, and large size. The transve diameter is usually ab a half greater than t antero-posterior wid The anterior thickness slightly greater than t posterior, being th adapted to the anter convex curve of t column in this regi The **pedicles**, direct horizontally backwar are short and stout; t superior notches a shallow, but deeper th in the thoracic region; t inferior grooves are de The **laminæ** are broad a nearly vertical, slopi but little. They suppo on their lower margi the inferior articular p cesses. The **spinal foram** is large and triangular.

The **spinous process** spatula shaped, with thickened posteri margin, project backwa and slightly downwar The **transverse process** more slender than in t dorsal region, pass ho zontally outwards, with slight backward inclin tion. Arising from the junction of the pedicles with the laminæ in the high members of the series, they tend to advance so as to become fused with the ou side of the pedicle and back of the body in the two lower lumbar vertebræ. these latter vertebræ the superior intervertebral grooves are carried obliquely acr the upper surfaces of the bases of the transverse processes. The transverse proces

line with the external tubercles of the lower thoracic vertebræ, with which re serially homologous, and are to be regarded as representing the costal it. Placed on their base posteriorly, and just external to and below the or articular processes, are the small **accessory tubercles** (processus accessorii) are in series with the inferior tubercles of the lower thoracic vertebræ. The r **articular processes** are stout, oval, curved plates of bone, fused in front with dicles and laminæ, and having their concave articular surfaces vertical and ned. Externally, and on their posterior edge, the bone rises in the form of an ted oval tubercle, the **mammillary process** (processus mammillaris); these are respondence with the superior tubercles of the lower thoracic transverse pro-

e **inferior articular processes** lie on either side of the root of the spinous s, supported on the inferior margin of the laminæ. Their articular surfaces, n outline, convex from side to side, and plane from above downwards, are rned. The inferior articular processes are much closer together than the or; so that when the vertebræ are articulated the superior articular processes e lower vertebra embrace the inferior articular processes of the higher ra.

e **fifth lumbar vertebra** is characterised by the size of its body, which is rgest of all the vertebræ. Further, the under surface of the body is cut at the expense of its posterior part: hence the thickness of the centrum in much exceeds that of the vertical diameter behind. The **transverse process** ramidal in form, and stouter than those of the other lumbar vertebræ. It by a broad base from the side of the back of the body, as well as from the le, and is directed outwards and a little backwards and upwards. Its upper e is slightly grooved by the superior intervertebral notch. A deep notch ates it posteriorly from the superior articular processes, which are less rned than in the other members of the series, their articular surfaces being ed more backwards than inwards, and displaying less concavity. The inferior lar processes are further apart than is the case with the other members of eries, they lie in line with the superior. The spinous process is shorter and wer than the other lumbar spines, particularly so in the female.

riations.—The mammillary and accessory processes are sometimes unduly developed. The l arch of the fifth lumbar vertebra is occasionally interrupted on either side by a synchon- which runs between the upper and lower articular processes. In macerated specimens the rts of the bone are thus separate and independent. The anterior includes the centrum, to- with the pedicles, transverse and superior articular processes; the posterior comprises the r articular processes, the laminæ, and the spine. (Turner, *Challenger Reports*, vol. xvi.) owski and Dwight record instances of the occurrence of a foramen in the transverse of the V. lumbar vertebra (*Anat. Anz. Jena*, vol. xx.), and Ramsay Smith describes a case in the right transverse process of the IV. lumbar vertebra of an Australian sprang from the f the body in front of the pedicle, being unconnected either with the pedicle or articular a.

THE FALSE OR FIXED VERTEBRÆ.

The Sacrum.

he **sacrum** (os sacrum), of roughly triangular shape, is formed by the fusion ally, of five vertebræ. The **anterior surface** of the bone is slightly hollow from to side and concave from above downwards, the curve being usually most unced opposite the third sacral segment. The central part corresponds to odies of the sacral vertebræ, the lines of fusion of which are indicated by a s of four parallel ridges which cross the central part of the bone at gradually nishing intervals from above downwards; externally, these ridges disappear ither side on the inner walls of the four **anterior sacral foramina** (foramina lia anteriora). The size of these holes decreases from above downwards. The r and under border of each foramen is formed by a stout bar of bone, of which are five on each side, corresponding in number with the vertebræ present. e unite externally so as to form the **lateral mass** (pars lateralis), and thus se the foramina to the outer side, though here the edge is not abrupt, but

sloped so as to pass gradually into the canal. The large anterior divisions o sacral nerves pass through these foramina and occupy the shallow grooves. bone is broadest across the first sacral vertebra, tends to narrow opposit second, and again usually increases in width opposite the third. When condition is well marked, the edge has a notched appearance (sacral notch) v assists in the interlocking of the sacro-iliac joint; this feature is common i Simiidæ and some of the lower races of mankind (Paterson). The surface of between and external to the first, second, third, and fourth foramina a attachment to the fibres of origin of the pyriformis which may in some inst extend on to the bodies of the II. and III. segments (Adolphi), whilst on the external to and below the fourth foramen the coccygeus is inserted.

The **posterior surface** is rough and irregular. Convex from above downwa displays mesially a **crest** (crista sacralis media) whereon are seen four elon

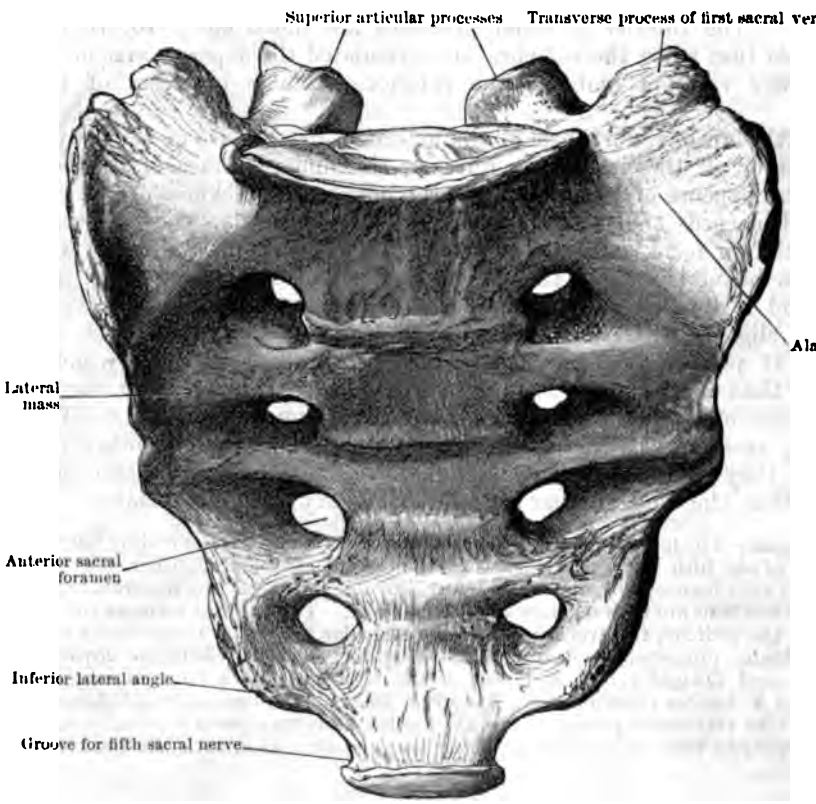

FIG. 65.—THE SACRUM (anterior view).

tubercles—the spines of the upper four sacral vertebræ. External to thes bone forms a groove—the **sacral groove**—the floor of which is made up of the fluent laminæ of the corresponding vertebræ. In line with the intervals bet the spines, and wider apart above than below, another series of tubercles is seen. These are due to the fusion of the **articular processes** of the sacral vert and together they form faint irregular ridges on the bone (cristæ sacrales articul Normally, the spine of the lowest sacral segment is absent, and the laminæ d coalesce mesially, thus leaving a gap in which the spinal canal is exposed (h sacralis); whilst inferiorly the tubercles corresponding to the inferior arti processes of the last sacral vertebra form little down-projecting processes **sacral cornua** (cornua sacralia)—by means of which the sacrum is in part unit the coccyx. Just wide of the articular tubercles are the **posterior sacral for** (foramina sacralia posteriora), for the transmission of the posterior divisions o sacral nerves. These are in correspondence with the anterior foramina, so t

e can be passed directly through both openings; but it is to be noted that the rior are much smaller, and their margins much sharper, than is the case with anterior. The surface of the lateral mass external to the posterior sacral nina is rough and irregular, owing to the presence of four more or less elevated rcles, which constitute the lateral ridges on either side of the bone (cristæ les laterales), and which are serially homologous with the true transverse sses of the lumbar vertebræ.

he posterior surface of the bone furnishes an extensive surface for the origin e erector spinæ muscles, whilst the edge of the bone external to the third and h foramen gives attachment to the gluteus maximus.

he **base** of the bone displays features more in accordance with a typical

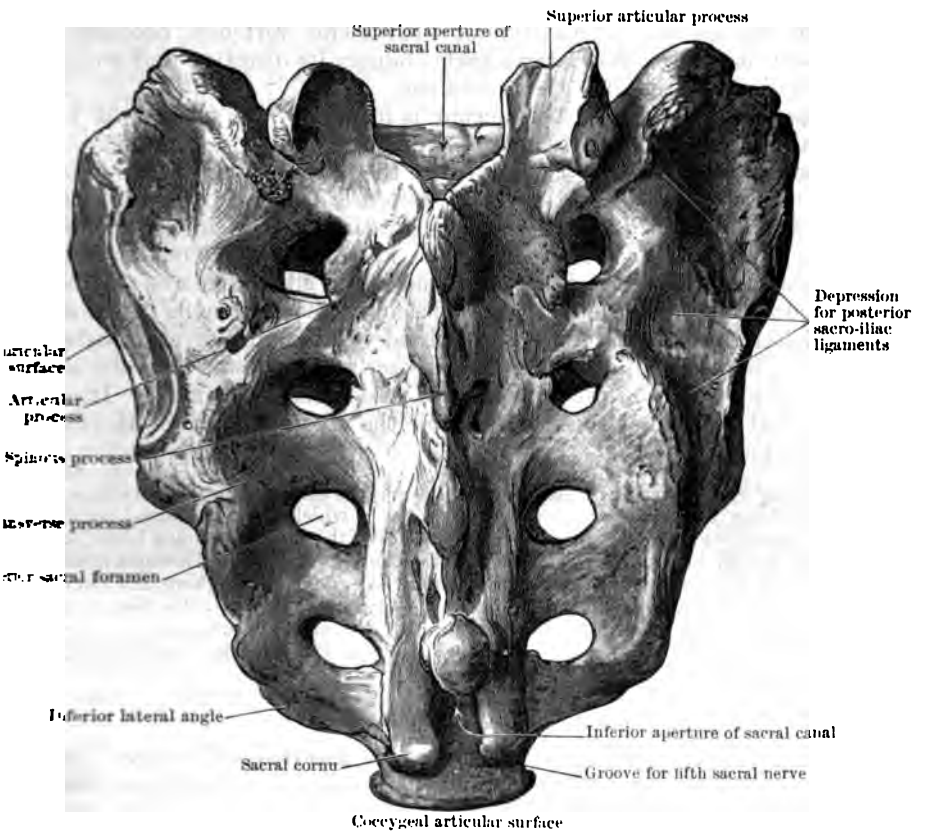

FIG. 66.—THE SACRUM (posterior view).

bra. Centrally, and in front, is placed the **body**, the upper surface of which ulates with the last lumbar vertebra through the medium of an intervertebral

The anterior margin is thin and projecting, overhanging the general con- y of the front of the bone, and forming what is called the **promontory** (promon- m). Behind the body, the spinal canal, of triangular form with slightly ssed sides, is seen, whilst posteriorly is the short spinous process forming the est tubercle of the median crest. Spreading out from the sides, and partly from back of the body on either side, is a fan-shaped mass of bone, the upper surface hich is slightly concave from side to side, and convex from above and behind nwards and forwards. This, the **ala** (ala sacralis), corresponds to the thick upper ler of the **lateral mass**, and is formed, as will be explained hereafter, by elements ch correspond to the pedicles and transverse processes of the sacral vertebræ, ther with superadded structures—the sacral ribs. The external margin of the ral mass, as seen from above, is sharp and outwardly convex, terminating behind a prominent tubercle—the highest of the series of elevations seen on the posterior face of the bone, which have been already described as serially homologous with

the true transverse processes of the lumbar vertebræ. Fused with the back of t lateral mass, and separated from it externally by a narrow but deep **notch**, is **superior articular process**. This supports a vertical articular surface, which i circular or oval form, and concave from side to side, having a general direc backwards and a little inwards.

The borders of the bone are thick above, where they articulate with the thin and tapering below, where they furnish attachments for the powerful sa sciatic ligaments. The **iliac articular surfaces** are described as auricular in sh (facies auriculares), and overlie the lateral masses formed by the first three sa vertebræ, though this arrangement is liable to considerable variation. **Behind** auricular surface the bone is rough and pitted by three distinct depressions for attachment of the strong sacro-iliac ligaments. Inferiorly, the edge formed the lateral masses of the fourth and fifth sacral vertebræ becomes gradu thinner, and at the **inferior lateral angle** changes its direction and sweeps inw towards the body of the fifth sacral segment.

The **apex**, or lower end of the sacrum, is formed by the small oval body of fifth sacral vertebra, which articulates with the coccyx.

The **sacral canal** follows the curve of the bone; more or less triangular shape above, it becomes appressed and flattened below. Inferiorly, its poster wall is deficient owing to the imperfect ossification of the laminæ of the fifth, a it may be, of the fourth sacral segments. Passing obliquely outwards and do wards from this canal into the lateral masses on either side are the four pair intervertebral foramina, each of which is connected externally with a V-sha canal which terminates in front and behind in the anterior and posterior sa foramina. The hinder limb of the V is shorter and narrower than the anterior.

The female sacrum is proportionately broader than the male. Its curves liable to great individual variation, though the absolute depth of the curve is than in the male.

Variations.—The number of sacral segments may be increased to six or reduced to four p. 90). Transition forms are occasionally met with in which the first sacral segment dis on one side purely sacral characters, *i.e.* it articulates with the innominate bone, whilst on opposite side it may present all the features of a lumbar vertebra. Through deficiency in development of the laminæ, the neural canal may be exposed throughout its entire leng to a greater extent than is normally the case. (Paterson, *Roy. Dublin Soc. Scientific T* vol. v. Series II.) Szawlowski and Barclay Smith record the occurrence of a foramen in lateral mass of the I. sacral vertebra (*Journ. of Anat. and Physiol.* Lond. vol. xxxvi. p. 372).

Coccyx.

The **coccyx** consists of four—sometimes five, less frequently three—rudimen vertebræ, which ten become fused. The piece is larger than others; it has an hollow facet on its u surface, which articul with the body of the sacral segment. I teriorly, two proce **cornua coccygea**, wh lie in series with articular processes the sacrum, extend wards and unite w the sacral cornua, t bridging over the no for the exit of the fi sacral nerve, and c verting it into a foramen, the last of the intervertebral series. From outer sides of the body project rudimentary **transverse processes** which m

r not, unite with the sacrum close to the lower lateral angles; in the ase the fifth anterior sacral foramina are enclosed. Inferiorly, the body of ne articulates with the succeeding vertebra. The second coccygeal vertebra s slight traces of a transverse process and the rudiments of pedicles. The ng segments are mere rounded or oval-shaped nodules of bone.

ion between the lower elements occurs normally in middle life, whilst union between : and second segments occurs somewhat later. It is not unusual, however, to find : first coccygeal vertebra remains separate from the others. Though very variable, e, fusion occurs more commonly in the male, and at an earlier age, than in the Szawlowski has recorded a case in which a curved process arose from the ventral of the first coccygeal segment. He regards this as possibly the homologue of a arch (*Anat. Anz. Jena*, vol. xx. p. 320).

m the posterior surface of the coccyx the gluteus maximus arises. To its l borders are attached the coccygei and levatores ani muscles, and from its ng the fibres of the sphincter ani.

VERTEBRAL COLUMN AS A WHOLE.

ien all the vertebræ are articulated together, the resulting column displays characteristic features. The division of the column into a true or movable mprising the members of the cervical, thoracic, and lumbar series, and a r fixed portion, including the sacrum and coccyx, can now be readily ised. The vertebræ are so disposed that the centra or bodies form an pted column of solid parts in front, which constitutes the axis of support head and trunk; whilst the neural arches behind constitute a canal for the nt and protection of the spinal cord and its membranes. In the movable f the column both the anterior supporting axis and the neural canal are to changes in their disposition owing to the movements of the head and

Like the bodies and neural arches, the spinous and transverse processes o superposed, and fall in line, forming three series of interrupted ridges— ne spinous) placed centrally and behind, the others (the transverse) placed ly. In this way two vertebral grooves are formed which lie between the l and lateral ridges. The floor of each groove is formed by the laminæ and lar processes, and in these grooves are lodged the muscles which serve to rt and control the movements of the column.

rther, the column so constituted is seen to display certain curves in an)-posterior direction. These curves are, of course, subject to very great ion according to the position of the trunk and head, and can only be satis- ily studied in a fresh specimen; but if care be exercised in the articulation vertebræ, the following characteristic features may be observed, assuming, of ; that the column is erect and the head so placed that the axis of vision is ed towards the horizon. There is a forward curve in the cervical region, gradually merges with the backward thoracic curve; this becomes con- ss below with an anterior convexity in the lumbar region, which ends more s abruptly at the union of the fifth lumbar with the first sacral vertebra, the sacrum slopes suddenly backwards, causing the column to form a d projection—the sacro-vertebral angle. Below this, the anterior concavity of vat of the sacrum is directed downwards as well as forwards. Of these four s, two—the thoracic and sacral—are primary, they alone exist during fœtal whilst the cervical and lumbar forward curves only make their appearance birth—the former being associated with the extension and elevation of the whilst the latter is developed in connexion with the use of the hind limb in yper-extended position, which in man is correlated with the assumption of rect posture; this curve, therefore, only appears after the child has begun to

For these reasons the cervical and lumbar curves are described as secondary mpensatory.

ot infrequently there is a slight lateral curvature in the thoracic region, the exity of the curve being usually directed towards the right side. This may

be associated with a greater use of the muscles of the right upper limb depend on the pressure exercised by the upper part of the thoracic aort

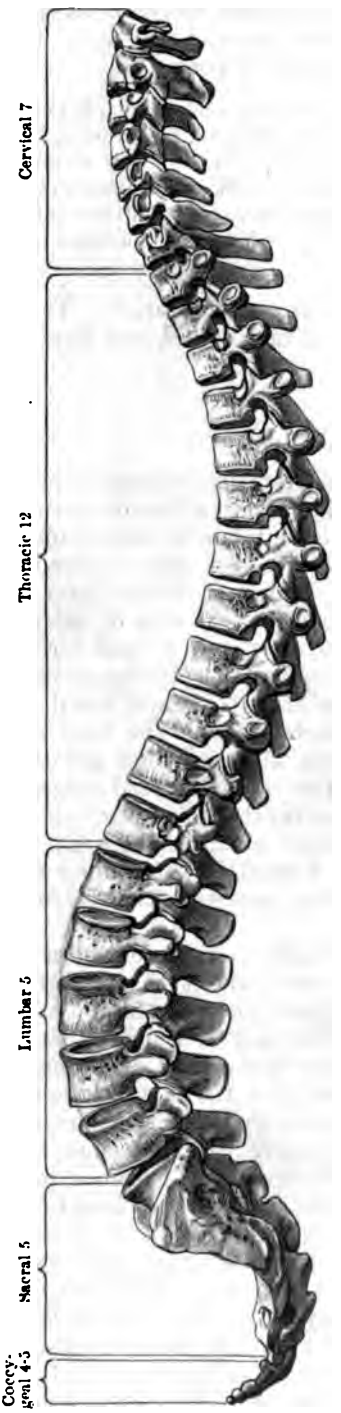

FIG. 68.—VERTEBRAL COLUMN FROM THE LEFT SIDE.

vertebræ of the thoracic region, thus causing lateral displacement, together with a flatteni side of the five thoracic vertebræ (impressio a was first pointed out by Wood (*Journ. Anat. & siol.* vol. iii.) Above and below this curve slight compensatory curves in the opposite d

The line which unites the tips of the not a repetition of the curves formed by th This is due to the fact that the length and of the spines vary much in different regions; the neck, with the exception of the second, si seventh, the spines are all short (absent in of the atlas). In the thoracic region th though long, are obliquely placed—a circu which much reduces their prominence; tha seventh thoracic vertebra is usually the lon most slanting. Below this point the lengt spines gradually decreases, and their positi nearly approaches the horizontal. In the l spines have all a slight downward direction.

Taken as a whole, the spines of the movable v man have a downward inclination—a character whicl with the anthropoid apes and a few other anim character serves to distinguish his column from thos mammals in which the spines of the lumbar ver directed headwards towards the "centre of motio is usually situated near the hinder extremity of t where a vertebra is placed the direction of whos vertical to the horizontally disposed column; thi is often referred to as the **anticlinal vertebra.**

The spines of the upper three or four sacr bræ form an osseous ridge with interrupted t The ridge formed by the vertebral spin important determinant of the surface form, responds to the median furrow of the back, the individual spines may be felt and coun the seventh cervical down to the sacral regio is best done when the back is well bent forw

As viewed from the front, the vertebr increase in width from the second cervica first thoracic; thence a reduction in bread place to the level of the fourth thoracic, belo there is a gradual increase in their transverse d until the sacrum is reached. Here a rapid r in width takes place, terminating inferiorly nodules of the coccyx.

The transverse processes of the atlas and outstanding. The succeeding four cervic bræ have transverse processes of nearly equa the seventh, however, displays a marked in its transverse diameter, and is about equal to the first thoracic vertebra. Below this a and regular diminution in width characte transverse processes of the thoracic vertebr in the case of the eleventh and twelfth they are merely represented by t external tubercles. In the lumbar region the transverse processes agai outstanding, and of nearly equal length.

The transverse diameter of the lateral mass of the first sacral vertebr

lest part of the column. Below this a decrease in width occurs until the f the third sacral segment is reached, at which point the transverse diameter ewhat abruptly diminished, a reduction in width is further suddenly accentuated opposite the fifth segment.

viewed from the side, the bodies display a gradual se in their antero-posterior width until the second r vertebra is reached, below which this diameter is y reduced. In the sacral region the reduction in liameter is great in the first and second sacral nts, more gradual and less marked in the last three nts.

e facets for the heads of the ribs in the upper thoracic lie on the sides of the bodies; those for the tenth, th, and twelfth are placed farther back on the es.

ie **intervertebral foramina** increase in size from above ards in the movable part of the column, being largest e lumbar region. In the sacral region they decrease e from above downwards. In the cervical region the ighest cervical nerves pass out behind the articular ses of the atlas and axis, and lie, therefore, behind orresponding transverse processes of these vertebræ. ucceeding cervical nerves pass out through the inter- ral foramina which are placed between the transverse ses and in front of the articular processes. In the ic and lumbar vertebræ the intervertebral foramina front of both the articular and transverse processes. rrangement of these foramina in the sacrum has been ly sufficiently explained.

he **neural canal** for the lodgment of the spinal cord and eninges is largest in the cervical and lumbar regions, th of which it assumes a triangular form; whilst it is w and circular in the thoracic region. These facts are ated with the movements of the column which are free in those regions where the canal is largest, *i.e.* the and loins.

he **average length** of the vertebral column is from 70 to ntimetres, or from $27\frac{1}{2}$ to $28\frac{3}{4}$ inches. Of this the cervical measures from 13 to 14 cm.; the thoracic, 27 to 29 cm.; ar, 17 to 18 cm.; and the sacro-coccygeal, 12 to 15 cm. ndividual differences in the length of the column are less one might expect, the variation in height of different iduals being often largely dependent on the length of the limbs. In the female the average length of the column out 60 centimetres, or $23\frac{3}{4}$ inches, and the curve in the ar region is usually more pronounced.

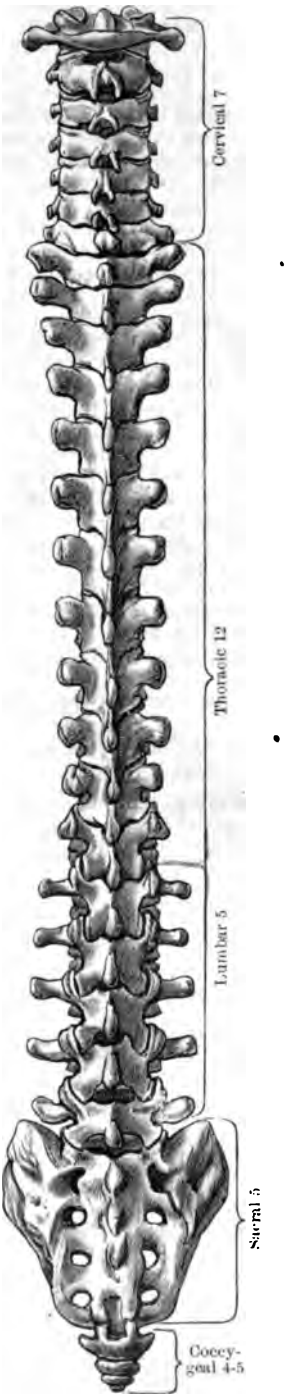

FIG. 69. VERTEBRAL COLUMN AS SEEN FROM BEHIND.

rchitecture.—The vertebræ are formed of spongy bone confined n a thin and dense envelope. In the bodies the arrangement of ancellous tissue, which is traversed by venous channels, is such display a vertical striation with lamellæ arranged horizontally. external, superior, and inferior walls are very thin that directed e neural canal being usually thicker and denser than the others. he pedicles and roots of the transverse processes the cancellous is much more open. The outer envelope is much thicker where unds the neural ring, and where it forms the bottom of the ior and inferior intervertebral notches. In the laminæ the gy tissue is confined between two compact layers, of which that directed to the spinal canal is hicker. In the spinous processes the upper edge is always the more compact.

Variations.—Numerical Variations of the Column as a Whole.- Increase in the number of ebral segments is usually due to differences in the number of the coccygeal vertebræ; these

may vary from four– which may be regarded as the normal number –to six. The numb presacral or movable vertebræ is normally 24 (7 C, 12 D, and 5 L). In which case the vertebra forms the first sacral segment (vertebra fulcralis of Welcker). The number of pres vertebræ may be increased by the intercalation of a segment either in the thoracic or lumbar re without any alteration in the number of the sacral or coccygeal elements: thus we may have 13 D, and 5 L, or 7 C, 12 D, and 6 L, or may be reduced by the disappearance of a vertebral ment –thus, 7 C, 12 D, and 4 L. Such an arrangement presupposes developmental errors ei of excess or default in the segmentation of the column. On the other hand, the total numb vertebral segments remaining the same (24 or 25), we may have variations in the number of t assigned to different regions due to the addition of a vertebral segment to one, and its conseq subtraction from another region. Thus, in the 24 presacral vertebræ, in cases of the occurren cervical ribs the formula is rearranged thus 6 C, 13 D, and 5 L, or, in the case of a thirte rib being present, the formula would be 7 C, 13 D, 4 L, as happens normally in the gorilla chimpanzee. Similarly, the number of the presacral vertebræ (24) may be increased by withdrawal of a segment from the sacral region – 7 C, 12 D, 6 L, and 4 S- or diminished b increase in the number of the sacral vertebræ, as in the formula 7 C, 12 D, 4 L, and 6 S. crease in the number of sacral segments may be due to fusion with a lumbar vertebræ, or by addition of a coccygeal element: the latter is more frequently the case. This variability in constitution of the sacrum is necessarily correlated with a shifting backwards and forward the pelvic girdle along the vertebral column. Rosenburg considers that the 26th, 27th, and vertebræ are the primitive sacral segments, and that the sacral characters of the 25th vert (the first sacral segment in the normal adult column) are only secondarily acquired. He supposes that during development there is a forward shifting of the sacrum and pelvic gi with a consequent reduction in the length of the presacral portion of the column. This vie opposed by Paterson (*Roy. Dublin Soc. Scientific Trans.* vol. v. Ser. II.), who found that ossifica took place in the alæ of the 25th vertebra (first adult sacral segment) before it made its app ance in the alæ of the 26th vertebra. He thus assumes that the alæ of the 25th vertebra be regarded as the main and primary attachment with the ilium. His conclusions, based large number of observations, are at variance with Rosenburg's views, for, according to his opi liberation of the first sacral segment is more common than assimilation with the fifth lu vertebra, and assimilation of the first coccygeal vertebra with the sacrum is more common liberation of the fifth sacral, thus leading to the inference that the sacrum tends to shift b wards more often than forwards. (See also T. Dwight, *Anat. Anz. Jena*, vol. xix. pp. 321, 3

THE CARTILAGINOUS VERTEBRAL COLUMN.

As has been already stated (p. 30), the neural tube and the notochord enveloped by a continuous sheath of mesodermal tissue which forms the **membra vertebral column**. It is by the chondrification of this that the cartilaginous col is developed. This process commences about the end of the first or the begin of the second month of fœtal life. In correspondence with each vertebral segm two symmetrical nodules of cartilage appear on either side of the notochord; t rapidly surround and constrict it. By their fusion they constitute the body cartilaginous vertebra, and are so disposed that they alternate in position with muscle plates which are lying on either side. In this way a vertebral body c sponds in position to the posterior half of the anterior myotome, and the ant half of the posterior myotome, the intermyotomic intervals, which contain connective tissue plates separating the muscle segments, lie in line late with the mid-points of the sides of the cartilaginous vertebræ. It is by chon fication of these intersegmental layers that in certain regions the ribs ultimately developed. Meanwhile, the scleratogenous tissue between the chon fying vertebral bodies undergoes little change and persists as the interverte disc. Here the embedded chorda undergoes but slight compression and enla so that if a length of the column be examined in longitudinal section the n chord displays a moniliform appearance, the constricted parts of the ch corresponding to the bodies, the enlarged portions to the discs. The fo disappear at a later stage when ossification begins, but the latter persist in adult as the pulpy core in the centre of the intervertebral disc.

The portions of the scleratogenous tissue which lie lateral to the ch have next to be considered; these extend dorsalwards around the neural c and ventralwards beneath the chorda. The former is sometimes called vertebral bow, the latter the hypochordal bow. The vertebral bow begin chondrify on either side, and forms the lateral portions of the cartilaginous ne arch, the extremities of which usually unite dorsally about the fourth mont fœtal life; if from defective development this union should fail to occ deformity known as spina bifida is the result.

From the cartilaginous neural arch so formed arise the chondrified rudiments the spinous, transverse, and articular processes.

The chondrification of the neural arch is variously described as being independent of the body or an extension from it; in any case, union between it and the body is rapidly effected.

The scleratogenous tissue between the cartilaginous neural arches which does not undergo chondrification persists as the ligaments uniting the neural laminæ.

As regards the so-called hypochordal bow, for the most part it disappears. By some it is regarded as being represented by a fibrous strand in the intervertebral disc in front of the vertebra to which it belongs. It is, however, noteworthy that in the case of the atlas vertebra there is an exception to this arrangement; for here the hypochordal bow chrondrifies and subsequently by ossification forms the anterior arch of that bone—an arch which lies ventral to, and embraces the odontoid process of the axis (*q.v.* p. 92).

It is only in the thoracic region that the ribs, developed as stated above by the chondrification of the intersegmental septa, attain their full dimensions. In the cervical, lumbar, and sacral regions they exist only in a rudimentary or modified form, as has been described elsewhere. In the construction of the chest wall the ribs are supported ventrally by the sternum, as to the development of which there is some difference of opinion. Ruge has described this bone as formed by the fusion of two cartilaginous bands produced by the coalescence of the expanded ends of the first five or seven cartilaginous ribs. Paterson, on the other hand, regards the sternum as arising independently of the ribs by the union of a right and left sternal bar in the median ventral line. There are also reasons for supposing that the presternum is intimately associated with the development of the ventral part of the shoulder girdle.

Ossification of the Vertebræ.—The vertebræ are developed by ossification of the cartilage which surrounds the notochord and which passes backwards over the sides of the neural canal. The centres for the bodies first appear in the lower thoracic vertebræ about the tenth week. An oval nucleus develops in each body. At first it is placed dorsal to the notochord, but subsequently surrounds and causes the disappearance of that structure. Occasionally, however, the primitive centre appears to be formed by the coalescence of two primary nuclei. Support is given to this view by the occasional occurrence of vertebræ in which the body is developed in two lateral halves, or in cases where only one-half of the body persists (Turner); normally, however, it is impossible to make out this division. From these single nuclei the bodies are developed, the process extending up and down the column until, by the fifth month, all the centra possess ossific deposits, except the coccygeal segments. About the seventh week a single centre appears in the neural arch on either side. These commence first to ossify in the upper cervical region and extend rapidly downwards throughout the column. They first appear near the bases of the superior articular processes, and extend backwards into the laminæ, outwards into the transverse processes, and forwards into the pedicles. These latter project anteriorly, and form a considerable portion of the postero-lateral aspects of the body, from which, however, they are separated by a cartilaginous strip—the neuro-central synchondrosis—which does not entirely disappear until about the fifth or sixth year. It is important to note that in the thoracic region the costal facets lie behind the neuro-central synchondrosis, and are therefore borne on the lateral aspects of the pedicles. Fusion of the laminæ in the dorsal plane behind begins, after birth, in the lumbar region and extends upwards, so that by the fifteenth month or thereabouts the arches in the cervical region are completed behind. In the sacral region ossification is slower, the spinal canal not being enclosed till the seventh to the tenth year. The spinous processes are cartilaginous at birth, but these become ossified by the extension into them of the bony laminæ.

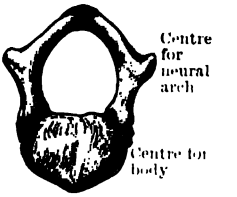

FIG 70. OSSIFICATION OF VERTEBRÆ.

At puberty certain **secondary centres** or **epiphyses** make their appearance; these are five in number. One caps the summit of the spinous process, except in the cervical region. A single epiphysis on either side appears at the extremity of the transverse process, and in the thoracic region assists in forming the articular surface for the tubercle of the rib. Two epiphysial plates are formed—one for the upper, and the second for the

lower surface of the body, including also that part which lies behind the neuro-c synchondrosis and formed by the pedicle ; from these the thickened circumference of upper and lower aspects of the body are derived. Fusion of these centres with th of the bone is not complete till the twenty-fifth year.

In the cervical region independent centres are described as occurring in the an roots of the transverse processes of the sixth and seventh vertebræ. These correspo the costal element, and may occasionally persist in the form of cervical ribs. Else they are formed by lateral extensions from the pedicle.

In the lumbar region the transverse process of the first lumbar vertebra is occasio associated with an independent costal centre, which may blend with it, or persist

Dorsal vertebra.

13. Centre for body.
14. Superior epiphysial plate, appears about puberty ; unites at 25th year.
15. Neuro-central synchondrosis does not ossify till 5th or 6th year.
16. Appears at puberty ; unites at 25th year.
17. Appears at puberty ; unites at 25th year.
18. Appears about 6th week.

Axis.

19. Centre for transverse process and neural arch ; appears about 8th week.
20. Synchondroses close about 3rd year.
21. Centre for summit of odontoid process ; a 3rd to 5th year, fuses 8th to 12th year.
22. Appears about 5th or 6th month ; unite opposite side 7th to 8th month.
23. Synchondrosis closes from 4th to 6th year.
24. Inferior epiphysial plate ; appears about pu unites about 25th year.
25. Single or double centre for body ; appears 5th month.

Atlas.

26. Posterior arch and lateral masses developed a single centre on either side, which a about 7th week.
27. Anterior arch and portion of superior art surface developed from single or double c appearing during 1st year.

Dorsal vertebra.

28. Epiphysis for transverse process ; appears puberty, unites about 25th year.
29. Epiphysis appears about puberty ; unites 25th or 27th year.
30. Centre for neural arch on either side ; a about 6th or 7th week, the laminæ unite birth to 15th month.
31. Centre for body ; appears about 6th week, with neural arch from 5th to 6th year.

lumbar rib. The mammillary processes are derived from separate epiphyses. The n arch of the fifth lumbar vertebra is occasionally developed from two centres on either as is demonstrated by the fact that the arch is sometimes divided by a synchondr joint running obliquely across between the superior and inferior articular processe either side. (See *ante*, p. 83 ; also *Fortschritte auf dem Gebiete der Röntgenstra* Ergänzungsheft i. ; "die Entwickelung des menschlichen Knochengerüstes während fötalen Lebens," von Lambertz.)

Atlas. —The lateral masses and posterior arch are developed from two centres—o either side —which correspond with the centres from which the neural arches of the members of the series are developed. These make their appearance about the sev week, and do not unite posteriorly till after the third year. Their point of unio sometimes preceded by the formation of a distinct spinal nucleus (Quain). The ant

eveloped from centres variously described as single or double, which appear in ne hypochordal arches of cartilage described by Froriep (*Arch. f. Anat. u. Anat. Abth.* 1886) which here persists. In this cartilage ossification commences ie first year of life. Union with the lateral masses is delayed till six or eight er birth. The external extremities of the anterior arch assist in forming the of the superior articular processes.

.—The axis ossifies from five primitive centres. Of these, two—one on either side about the seventh week, and form the articular and transverse processes, together laminæ and spine. One, or it may be two, nuclei appear in the lower part of the at the fifth month. The upper part of the body, including a small part of the rticular process, and the base of the odontoid process, are developed from two placed nuclei which appear shortly after, and fuse together at the seventh or onth, so that at birth the bone consists of four pieces. Fusion between these es place in the following order:—The odontoid unites with the body and lateral at the third or fourth year; union between the two lateral portions posteriorly ody and lateral parts in front, is complete at from four to six years.

summit of the odontoid process is developed from a separate centre, occasionally hich appears from the third to the fifth year, and fuses with the rest of the bone eighth to the twelfth year. About puberty an annular epiphysis is developed on r surface of the body, with which it is completely united during the twentieth to ty-fifth year. Some authorities state that a few granules between the base of the and the upper surface of the body represent the superior epiphysial plate; but between the odontoid and the body occurs before the time for the appearance of condary epiphysial plates, this can hardly be regarded as correct. The line of the odontoid with the body is defined by a small disc of cartilage which persists ie substance of the bone till an advanced period of life.

ir of epiphyses placed over the tubercles of the spine, if not always present, are frequent.

rum.—Each of the sacral segments is ossified from three centres: one for the d two for the neural arch—that for the body, which makes its appearance in the ee sacral vertebræ ie end of the third bout the fifth to the nonth for the last ients. From the two or the neural arches, ake their appearance e fifth or sixth month igher segments, the articular processes, posterior half of on either side are d. The spinal canal is not enclosed till the seventh to the tenth year, the usually failing to meet in the lowest segment, and occasionally, to a greater or nt, in some of the higher segments. The anterior part of the lateral masses is d from separate centres which represent the costal elements (Gegenbauer). These bout the sixth to the eighth month, and may develop in relation to the upper ral segments; more usually they are met with in connexion with the first three, ptionally they may be found only in the upper two. It is by fusion of these posterior arches that the lateral masses which support the innominate bones ed. The costal elements fuse about the second to the fifth year with the neural rior to their union with the centra; and the segments of the lateral masses unite h other sooner than the union of the bodies is effected. The latter only takes ter puberty by the fusion of the epiphysial plates, a pair of which make their ice between the centra of each segment. The lower segments begin to unite about the eighteenth year, but fusion between the first and second sacral verte- t completed till the twenty-fifth year or after. In addition to the foregoing, two ous laminæ are developed in the cartilage covering the outer surface of the alar The upper of these overspreads the auricular surface, whilst the lower forms the ge below. The extremities of the upper spinous processes are occasionally d from independent epiphyses. On making a mesial section of an adult bone stence of the intervertebral discs between the centra is indicated by a series of ties.

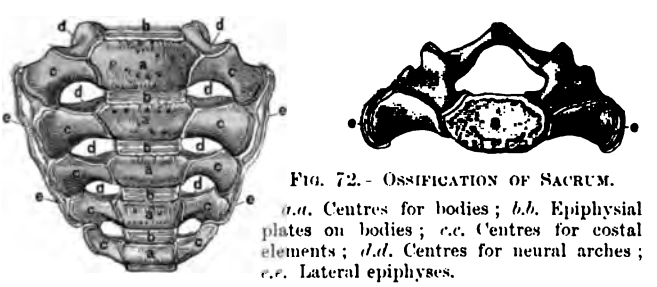

FIG. 72.—OSSIFICATION OF SACRUM.

a.a. Centres for bodies; *b.b.* Epiphysial plates on bodies; *c.c.* Centres for costal elements; *d.d.* Centres for neural arches; *e.e.* Lateral epiphyses.

Coccygeal Vertebræ.—These are cartilaginous at birth. Each has a s centre: the first appears from the first to the fourth year, the second from the s the tenth year, the third and fourth segments at or about puberty. Secondary for the coccygeal cornua and epiphysial plates for the bodies are also described. of the various segments begins below and proceeds upwards, but is liable to gre vidual variation. In advanced life the coccyx is often ossified to the sacrum.

SERIAL HOMOLOGIES OF THE VERTEBRÆ.

It is a self-evident fact that the vertebral column consists of a number of segments brae all possessing some characters in common. These vertebræ or segments undergo modi according to the region they occupy and the functions they are called upon to serve, their correspondence and identity is thereby obscured. There is no difficulty in recogni homology of the bodies and neural arches throughout the column. According anatomists the neural arch is the more primitive element in the formation of a vertebra others hold that the centra are the foundation of the column. Be that as it may, we find the higher vertebrates, at least, the bodies are the parts which most persist. They are, l subject to modifications dependent on their fusion with one another. This occurs in the part of the column where the centrum of the first cervical or atlas vertebra has for fu reasons become fused with the body of the second or axis vertebra to form the odontoid of that segment. For similar reasons, and in association with the union of the girdl hind-limb with the column, the bodies of the vertebræ which correspond to the sacral become fused together to form a solid mass. In the terminal portion of the cauda the centra alone represent the vertebral segments.

As regards the neural arch, this in man becomes deficient in the lower sacral region, an altogether in the lower coccygeal segments. The spinous processes are absent in the ca first cervical, lower sacral, and all the coccygeal vertebræ, and display characteristic di in the cervical, thoracic, and lumbar regions, which have been already described. The processes zygapophyses are secondary developments, and display great diversity of for mined by their functional requirements. It is noteworthy that, in the case of the u cervical vertebræ, they are so disposed as to lie in front of the foramina of exit of th two spinal nerves, and by this arrangement the weight of the head is transmitted to t column formed by the vertebral bodies, and not on to the series of neural arches. regard to the homology of the transverse processes, so called, that most difficulty arises. thoracic region they can best be studied in their simplest form; here the ribs—which Ow regards as a differentiation from the inferior or hæmal arches, in opposition to the view a by others that they are a secondary development from the fibrous intermuscular septa—a with the transverse processes and bodies of the thoracic vertebræ through the agene tubercular diapophysis, and capitular parapophysis processes respectively, the latte placed, strictly speaking, on the neural arch behind the line of the neuro-central synchon

An interval is thus left between the neck of the rib and the front of the transverse this forms an arterial passage which corresponds to the vertebrarterial canal in the tr processes of the cervical vertebræ, the anterior bar of which is homologous with the h tubercle of the thoracic rib, whilst the posterior part lies in series with the thoracic tr process. These homologies are further emphasised by the fact that in the case of the cervical vertebra the anterior limb of the so-called transverse process is developed independent ossific centre, which occasionally persists in an independent form as a cervic

In the lumbar region the external or transverse process is serially homologous w thoracic ribs, though here, owing to the coalescence of the contiguous parts, there is no channel between the rib element and the true transverse process, which is represented accessory processes anapophysis,, placed posteriorly at the root of the so-called tr process of human anatomy. Support is given to this view by the presence of a distin element in connexion with the transverse process of the first lumbar vertebra, which for the occasional formation of a supernumerary rib in this region. The cases of foramin transverse processes of the lumbar vertebræ (see p. 83) are also noteworthy as supporting t

In the sacrum the lateral mass of the bone is made up of combined transverse an elements, with only very exceptionally an intervening arterial channel (see p. 86). case of the upper three sacral segments the costal elements are largely developed, supporting the ilia, and are called the true sacral vertebræ; whilst the lower sacral s which are not in contact with the ilia, are referred to as the pseudo-sacral vertebræ.

The anterior arch of the atlas vertebra is, according to Froriep, developed from a hyp strip of cartilage (hypochordal spange).

THE STERNUM.

The **sternum** or **breast bone** occupies the middle of the upper part thoracic wall anteriorly. It is connected laterally with the cartilages of t seven ribs, and supports, superiorly, the clavicles. It consists of three parts, respectively the **manubrium** or **presternum**; the **body** (corpus sterni), **gladi mesosternum**; and the **ensiform** or **xiphoid cartilage** (processus xiphoideus)

rnum. Of these the body is formed by the fusion in early life of four
ts or sternebræ.

manubrium, usually separate throughout life from the rest of the bone, occasionally fused with it, is of a flattened triangular form. The anterior slightly saddle-shaped, affords attachment to the fibres of the pectoralis nd sterno-mastoid muscles. It is bounded above by a thick border, the lateral which are hollowed out obliquely the facets (incisuræ claviculares) sternal ends of the clavicles; the facets, which have an upward, l, and slightly backward direction, ie is faintly lipped. In the in- etween these two facets there is notch (incisura jugularis) which ne floor of the characteristic hollow the root of the neck anteriorly— rasternal notch, or pit of the neck. teral borders are excavated im- ely below the clavicular facets for ception of the cartilages of the s. Below this, the margin of the opes inwards, and is sharp, except ly, where it presents a facet which ts a part of the second costal ge. Around this the bone is usually anteriorly. The upper angles ond to the ridge separating the lar facets from the first costal whilst the lower angle, which e regarded as cut across trans- , forms the surface which is united ilage to the body of the sternum. terior edge of this surface is usually ient. The posterior aspect of the rium is smoother than the anterior, ved by numerous foramina, and htly concave from side to side and downwards. Here are attached of the fibres of the sterno-hyoid erno-thyroid muscles.

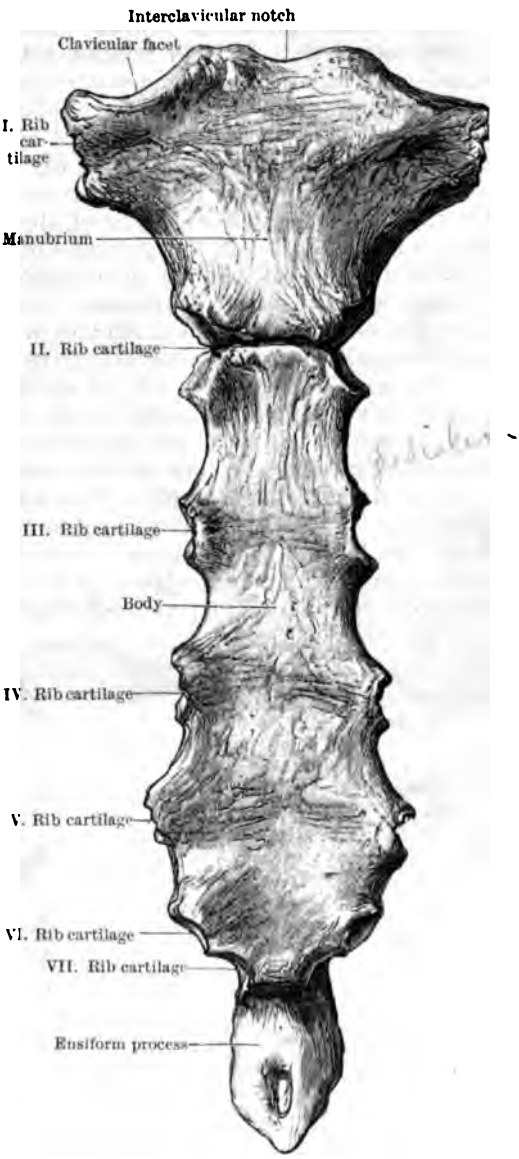

FIG. 73. -THE STERNUM (anterior view).

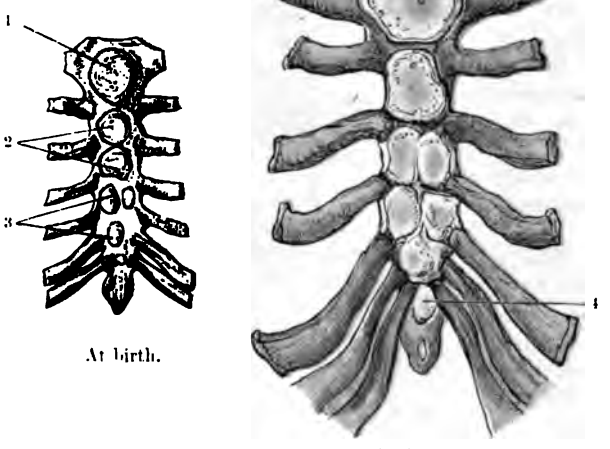
e **body** (corpus sterni), usually the length and from half to two- the width of the manubrium, dis- evidence of its composite nature. *anterior surface*, which is slightly from above downwards, and faintly e from side to side, be carefully ned, three ill-marked ridges may be rossing it transversely: these cor- d to the lines of fusion between the rimitive segments. To this surface of the bone the great pectoral muscles tensively attached on either side of the middle line. The *lateral borders* are and interrupted at points corresponding to the transverse lines already oned by U-shaped hollows, the edges of which are more or less projecting. are for the reception of the cartilages of the third, fourth, and fifth ribs. *pper border* is united to the manubrium above, and forms with it an angle iable degree—the **sternal angle** (angulus sterni). A small facet is formed at xpense of the outer extremity of this border, and in conjunction with the on the lower edge of the manubrium forms a recess on either side, in line with

the angle, into which the cartilage of the second rib fits. The *lower border* of body is curved, and is united in the middle line with the xiphoid cartilage, whilst either side it is pitted to receive the cartilages of the sixth and seventh ribs, latter being in part supported by the xiphoid cartilage. The middle line of the b of the sternum anteriorly corresponds to the floor of the median surface furrow, wh runs down the front of the chest in the interval between the two great pect muscles. The *posterior surface* is slightly concave from above downwards, a displays faint indications of three transverse lines in correspondence with th placed anteriorly. It is in relation with the pleura and pericardium, and affo attachment at its lower extremity to the triangularis sterni muscle.

The **xiphi-sternum** (processus xiphoideus) displays many varieties of form a structure. It is a pointed process of cartilage, supported by a core of bone c nected above with the lower end of the body of the sternum, and having its lo extremity, to which the linea alba is attached, free. It lies somewhat posterior t the plane of the anterior surface of the manubrium, and forms a floor to the V shaped interval between the cartilages of the seventh ribs. In this way a depressi is formed, the surface hollow in correspondence with which is called the pit of t stomach or **infrasternal depression**. To the sides of this process are attached t aponeuroses of the abdominal muscles, whilst posteriorly the fibres of the diaphrag and triangularis sterni muscles derive attachment from it. It remains part cartilaginous until middle life, at which time it generally undergoes ossificatio particularly at its upper part, which becomes fused with the body. Of vari form, it may be met with of spatula-shape, bifid, circular, pierced in the centre, twisted and deflected to one or other side, or turned forward.

The **sternum as a whole** is broadest above where the first rib cartilages a attached. It becomes narrow opposite the second rib cartilages, but again expand until the level of the fifth rib cartilage is reached, below which it is rapidly reduced in width and ends below in the pointed xiphoid cartilage. Its position in the body is oblique from above downwards and forwards; its axis, if prolonge upwards, would touch the column opposite the third or fourth cervical vertebra. Though liable to changes in position by the rising and falling of the chest wall, its upper extremity corresponds to the level of the lower border of the second dorsal vertebra, whilst the lower end of the xiphoid cartilage usually falls in line with the disc between the tenth and eleventh dorsal vertebræ.



At birth. At 3 years.

FIG. 74. OSSIFICATION OF THE STERNUM.

In this figure the second as well as the third segment of the body possesses two centres.

1. Appears about 5th or sixth month. 2. Appear about 7th month; unite from 20 to 25. 3. Appear about 8th or ninth month; III. segment unites with II. about puberty; IV. segment unites with III. in early childhood. 4. Appears about 3rd year or later.

In women the sternum is usually narrower and shorter than in men, and its position less oblique.

Architecture.—It consists of large-celled spongy bone, which is highly vascular, and is contained between two layers of thin compact tissue.

Ossification.—The cartilaginous sternum, developed from the fusion mesially of two cartilaginous bands uniting the anterior extremities of the cartilages of the first eight ribs, according to the researches of Ruge and more recently of Eggeling, begins to ossify about the sixth month of fœtal life. About this time a single centre appears in the manubrium; at birth this is well developed. Secondary epiphyses have been described in connexion with the clavicular facets; these do not unite with the rest of

rium till adult life is reached. The body formed by the fusion of four segments from independent centres, either single or double, for each segment. These he highest as early as the sixth month of intrauterine life—in some cases even manubrium has begun to ossify (Lambertz), the lowest towards the end of The common arrangement met with at birth is a single centre for the first, centres for each of the succeeding segments. Union between these segments ier irregularly, and is liable to much variation. The fourth unites with the ent in early childhood, the third with the second about puberty, whilst the he second with the first segment may not be complete till the twentieth or 1 year.

phi-sternum usually ossifies from a single centre, which may appear as early as ear, though often very much later. The xiphi-sternum usually unites with the forty or fifty, and in exceptional cases osseous union between the body and 1 may occur in advanced life.

ng to Paterson the presternum is developed in association with the shoulder becomes only secondarily associated with the ventrally growing ribs.

ons.—The sternum is liable to considerable individual variations affecting its length n. The majority of bones are asymmetrical, displaying irregularities in the levels of ar facets. The higher costal facets may be closer together on one, usually the right he other, whilst the pre-mesosternal joint is often oblique, sloping somewhat to the rding to Birmingham, these are the result of the strain thrown on the shoulder by her directly applied or through the pull of a weight carried in the hand.

es the sternum articulates with eight rib cartilages. This may happen on one or but when unilateral, much more frequently on the right side—a condition by some ith right-handedness. It is, however, more probably a persistence of the primitive f the cartilaginous sternum, in which each half is connected with the anterior of the first eight costal arches. In some rare cases only six pairs of ribs articulate f their costal cartilages with the sternum. Recently Lickley has brought forward show that the seventh rib is undergoing regressive changes. (*Anat. Anz.* vol. xxiv.

ally the presternum supports the first three ribs; in other words, the manubrium l the highest segment of the body. Keith has pointed out that this is the condition nly met with in the gibbon, and regards its occurrence in man as a reversion to the . As far as is at present known, its occurrence seems more common in the lower ugh errors of development the sternum may be fissured throughout, due to failure the cartilaginous hemisterna. The two ossified halves are usually widely separated nited together below by an arthrodial joint. The heart and pericardium are thus y the bone. Occasionally this condition is associated with ectopia cordis, under nstances life is rendered impossible. Through defects in ossification the mesosternum rced by a hole, usually in its lower part, or through failure of fusion of the lateral or more of the segments of the body may be divided longitudinally.

ally small ossicles are found in the ligaments of the sterno-clavicular articulation. ie so-called episternal bones, the morphological significance of which, however, has n satisfactorily determined. They are by some regarded as the homologues of the or episternal bone of monotremes.

THE RIBS.

bs (costæ) of which there are twelve pairs, form a series of curved osseous ich support the thoracic wall; posteriorly they articulate with the r dorsal vertebræ, anteriorly each rib is provided with a costal cartilage. seven ribs articulate with the sternum by means of their cartilages, and l the **true** (costæ veræ) or **vertebro-sternal ribs**. The lower five ribs are pported, and are described as the **false ribs** (costæ spuriæ). Of these the inth, and tenth are united by their cartilages to the cartilage of the ib, and are called the **vertebro-chondral ribs**, whilst the last two ribs are eir anterior extremities, and are named the **floating** or **vertebral ribs**.

ical rib consists of a **head** (capitulum costæ), a **neck** (collum costæ), a uberculum costæ), and a **shaft** (corpus costæ), on which, near its posterior **angle** (angulus costæ).

ead, placed on the posterior or vertebral end of the bone, is somewhat Internally its articular surface is wedge-shaped and divided into two upper and lower, by a ridge or crest (crista capituli), to which the inter- ligament is attached. Of these two facets the lower is usually the larger, ulates with the upper facet on the body of the vertebra in numerical lence with it, whilst the upper facet is for the corresponding area on the

lower part of the body of the vertebra above. The head is supported by a or less constricted bar of bone, the **neck**. This becomes continuous with the externally, at which point there is a well-marked tubercle on its posterior su The anterior surface of the neck is smooth; its posterior aspect is rough pierced by numerous small holes for vessels. Here is attached the middle costo-transverse ligament. Not uncommonly the upper border of the neck is lipped and ridged (crista colli costæ), and affords attachment to the anterior costo-transverse ligament.

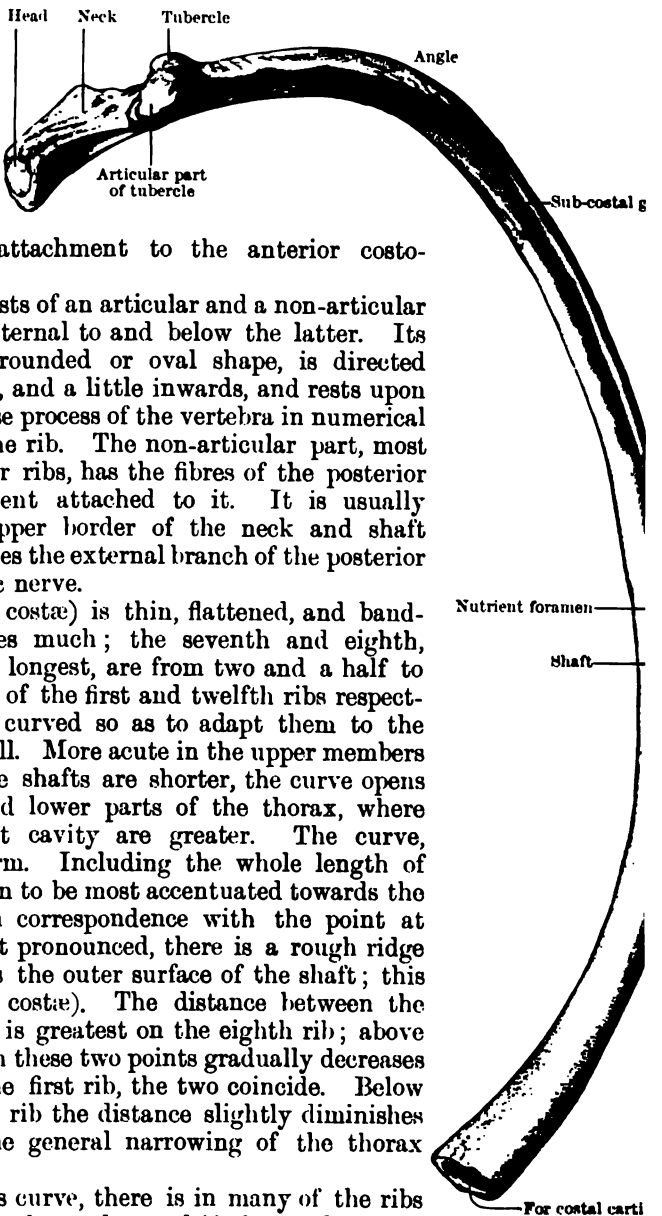


FIG. 75.—FIFTH RIGHT AS SEEN FROM BEL

The **tubercle** consists of an articular and a non-articular part; the former is internal to and below the latter. Its articular surface, of rounded or oval shape, is directed downwards, backwards, and a little inwards, and rests upon a facet on the transverse process of the vertebra in numerical correspondence with the rib. The non-articular part, most prominent in the upper ribs, has the fibres of the posterior costo-transverse ligament attached to it. It is usually separated from the upper border of the neck and shaft by a groove, in which lies the external branch of the posterior division of the thoracic nerve.

The **shaft** (corpus costæ) is thin, flattened, and band-like. Its length varies much; the seventh and eighth, which are usually the longest, are from two and a half to three times the length of the first and twelfth ribs respectively. The shafts are curved so as to adapt them to the form of the thoracic wall. More acute in the upper members of the series, where the shafts are shorter, the curve opens out in the middle and lower parts of the thorax, where the diameters of that cavity are greater. The curve, however, is not uniform. Including the whole length of the bone, it will be seen to be most accentuated towards the hinder part, where, in correspondence with the point at which the bend is most pronounced, there is a rough ridge placed obliquely across the outer surface of the shaft; this is the **angle** (angulus costæ). The distance between the angle and the tubercle is greatest on the eighth rib; above that, the width between these two points gradually decreases until, in the case of the first rib, the two coincide. Below the level of the eighth rib the distance slightly diminishes in conformity with the general narrowing of the thorax below that level.

Combined with this curve, there is in many of the ribs a twist. This may best be understood if the student will take a strip of stiff paper and bend it in the form of the curve of the rib. If, after he has done this, he pulls down the fore end and turns up the hind end of the strip, he will have imparted t strip of paper a twist similar to that met with in the rib. This appearan best seen in the middle members of the series, notably in the seventh and e ribs, above and below which it gradually becomes less marked. It is the occur of this twist which prevents the extremities of the ribs, together with the from resting on the same plane surface. To this rule there are certain no exceptions, viz. the first and second, the twelfth, and not infrequently the elev

The shaft has two surfaces, an internal and an external, and two bord

r and an inferior. The external surface, which is smooth, conforms to the vertical convexity of the thorax, being directed upwards in the first rib, s and outwards in her ribs, outwards in ddle series, and out- and slightly down- in the tenth, eleventh, elfth. The internal s are arranged con- and are covered by ietal pleura. Towards rnal end of the middle here the downward s most marked, there n an oblique line across ter surface. This is mes referred to as the anterior angle. The upper border of the shaft is thick unded behind, thinner and sharper in front; to it are attached the fibres of ternal and external intercostal muscles. The lower border is grooved behind expense of the inner surface, and is overhung externally by a sharp margin. iorly this **subcostal groove** (sulcus costalis) fades away, and its lips coalesce to form a rounded edge. The intercostal vessels and nerve are lodged in this groove, whilst its lips afford attachment to the external and internal intercostal muscles respectively. On the floor of the groove may also be seen the openings of the canals for the transmission of the nutrient vessels, which are directed towards the vertebral end of the rib.

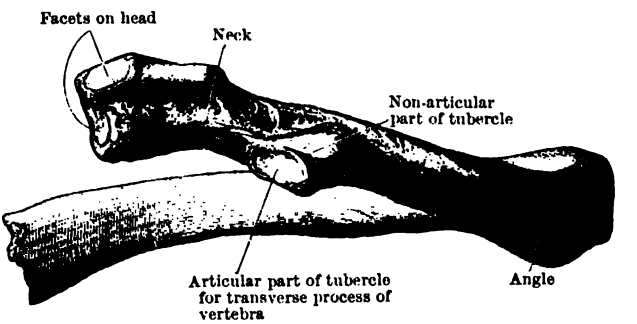

FIG. 76.—FIFTH RIGHT RIB AS SEEN FROM BEHIND.

The anterior or sternal extremity of the shaft, often slightly enlarged, displays an elongated oval pit into which the costal cartilage is sunk.

Peculiar Ribs.—The first, second, tenth, eleventh, and twelfth ribs all display characters by which they can be readily recognised.

. 77.—FIRST AND SECOND RIGHT RIBS AS SEEN FROM ABOVE.

The **first rib** can be easily distinguished from the others by its size, curvature, and flattened form. The **head**, which is of small size, has a single oval or circular facet, which is directed inwards and slightly backwards for articulation with the side of the body of the first thoracic vertebra. The **neck** is flattened from above downwards, and is slightly down-turned towards the end which supports the head. Its anterior border is rounded mooth; its posterior edge rough for the attachment of ligaments. At the where the neck joins the shaft posteriorly, a prominent **tubercle** curves rds and backwards. The inner and under surface of this process has a small ar facet which rests on a corresponding articular surface on the transverse s of the first thoracic vertebra. The **angle** coincides with the tubercle, and assists in emphasising its prominence. The surfaces of the body of the rib irected upwards and downwards, its borders inwards and outwards. If the be run along the thin inner border, a distinct spine or tubercle can be readily

felt about an inch or an inch and a quarter from its anterior extremity. Th is the **scalene tubercle** (tuberculum scaleni) for the attachment of the scalen anticus muscle. There is a shallow, oblique groove crossing the upper surfa of the shaft in front of this for the lodgment of the subclavian vein; whilst behi the tubercle there is another groove, usually better marked, and passing obliqu forwards for the subclavian artery (sulcus subclaviæ). The space on the upp surface of the rib between this latter groove and the tubercle posteriorly is som what rough, and affords attachment to the fibres of the scalenus medius musc The anterior extremity of the rib is thickened and often expanded for the receptio of its costal cartilage, which is not infrequently ossified. The under surface of th rib is smooth and is covered by pleura. The outer convex border, thin in fron is usually thick and rough behind the subclavian groove, where it has attached t it the fibres of the first digitation of the serratus magnus. Along this edge, al are attached the external and internal intercostal muscles of the first intercost space. The inner concave border is thin, and has connected with it the aponeuroti expansion known as Sibson's fascia.

The **second rib** may be distinguished by the size of its curve; the absence any twist on its shaft, so that it can be laid flat on the table; the oblique directio of the surfaces of its shaft, the outer being directed upwards and outwards, whil the inner is turned downwards and inwards; and the presence of a well-marke rough, oval area about the middle of its outer surface and lower border for pa of the first, and the whole of the second digitation of the serratus magnus musc The head has two facets, and the angle is close to the tubercle posteriorly.

The **tenth rib** has usually only a single articular facet on the head, and may may not have a facet on the tubercle.

The **eleventh** and **twelfth ribs** are recognised by their length. Their head usually large in proportion to their shafts, support a single facet for articulatio with the eleventh and twelfth dorsal vertebræ respectively. The tubercles are ill developed and have no articular facets. The angle is faintly marked on th eleventh, scarcely perceptible on the twelfth. Their anterior extremities are narro and pointed and tipped with cartilage. The subcostal groove is absent in th twelfth, and but slightly seen in the eleventh. The twelfth is considerably short than the eleventh rib.

Architecture.—Each rib consists of a curved and flattened bar of bone, the interior of whic is loose and cancellous, whilst the investing envelope is compact. The inner table is much th stronger, attaining its maximum thickness opposite the angle—in front and behind which becomes gradually reduced. The outer table, much thinner, is stoutest opposite the angle; o the posterior surface of the tubercle and neck it forms but a thin layer. The compact laye forming the upper and lower borders are not so thick as those forming the inner and out surfaces. The cancellous tissue, loose and open in the shaft, is most compact in the region of th head and towards the anterior extremity.

Variations.—The **number of ribs** may be increased or diminished. Increase may occur b the addition of a cervical rib due to the independent development of the costal element in th transverse process of the seventh cervical vertebra. This may happen on one or both sides. Th range of development of these cervical ribs varies; they may unite in front with the sternu or they may be fused anteriorly with the cartilage of the first rib, or the cervical rib may l free. It may in some instances be represented mainly by a ligamentous band, or its vertebr and sternal ends may be alone developed, the intermediate part being fibrous. At times th vertebral end only may be formed and may be fused with the first rib, thus leading to th formation of a bicipital rib such as occurs in many cetaceans. Increase in the number of rib may also be due to the ossification of the costal element which is normally present in the embry in connexion with the first lumbar vertebra. (Rosenberg, *Morph. Jahrb.* i.) Reduction in th number of ribs is less common. The twelfth rib rarely aborts; in some cases the first rib rudimentary. Cases of congenital absence of some of the ribs have been recorded by Hutchinso Murray, and Ludeke.

Fusion of adjacent ribs may occur. (Lane, *Guy's Hosp. Reports*, 1883.)

Variations in form may be in great part due to the occupation of the individual and the co stricting influence of corsets. Independently of these influences, the fore part of the shaft sometimes cleft so as to appear double; at other times the cleft may be incomplete so as to for a perforation. Occasionally adjacent ribs are united towards their posterior part by process having an intermediate ossicle between (Meckel), thus recalling the condition normally met wit in birds; more usually, however, the bony projections are not in contact.

The number of true or vertebro-sternal ribs may be reduced to six, or increased to eight (s *ante*, p. 97).

Ossification.—Ossification begins in the cartilaginous ribs about the sixth week, and rapidly extends along the shaft, so that by the end of the third month it has reached the permanent costal cartilage. The sixth and seventh ribs are the earliest to ossify; the first rib being the last (Lambertz). At puberty, or before, secondary centres appear. Of these there are three—an epiphysis for the articular surface of the tubercle, one for the non-articular part of the same process, and one for the head. By the twenty-fifth year fusion between these and the shaft is complete.

THE COSTAL CARTILAGES.

The **costal cartilages**, of which there are twelve pairs, are bars of hyaline cartilage united to the anterior extremities of the ribs, into which they are recessed and held in position by the periosteum. Through these cartilages the first seven ribs are connected directly with the sternum by means of synovial joints corresponding to the notches along the margins of the breast bone. To this there is an exception in the case of the first rib, the cartilage of which is directly blended with the manubrium sterni. The eighth, ninth, and tenth are connected indirectly with the sternum by their union with each other, and their articulation, through the medium of the eighth, with the seventh rib cartilage, whilst the eleventh and twelfth cartilages tip the ribs to which they belong, and lie free in the muscles of the flank. The costal cartilages increase in length from the first to the seventh, below which they become shorter. The first inclines obliquely downwards and inwards to unite with the upper angles of the manubrium. The second lies more or less horizontally. The third to the seventh gradually become more and more curved, inclining downward from the extremities of their respective ribs, and then turning upwards to reach the sternum. The tenth cartilage articulates by means of a synovial joint with the ninth, the ninth with the eighth, and the eighth with the seventh. There are also surfaces for the articulation of the seventh with the sixth, and sometimes for the sixth with the fifth.

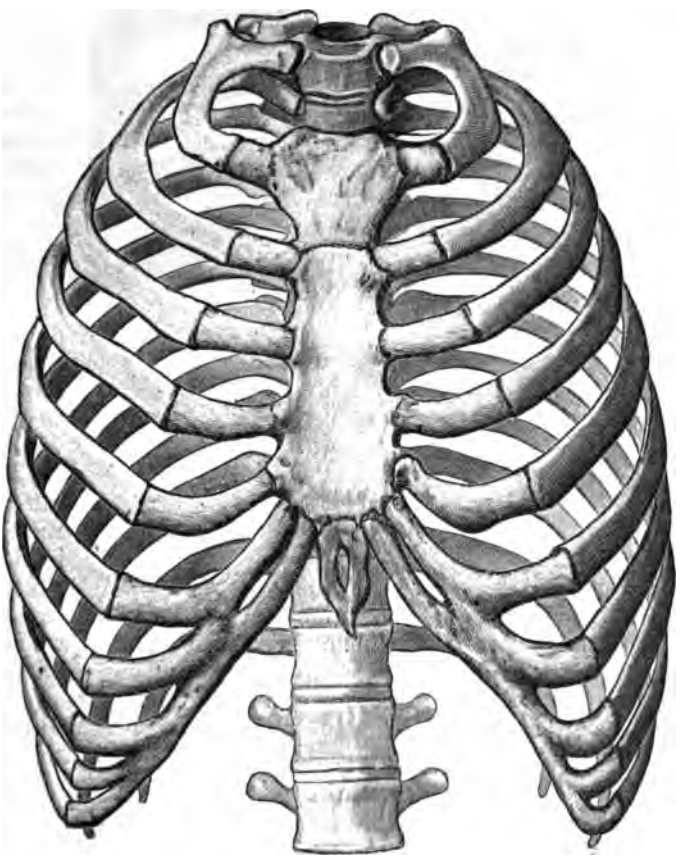

Fig. 78.—The Thorax as seen from the Front.

Variations. — Occasionally a costal cartilage is unduly broad, and may be pierced by a foramen. The number of costal cartilages connected with the sternum may be reduced to six or increased to eight (see p. 97). In advanced life there is a tendency towards ossification in the layers underlying the perichondrium, more particularly in the case of the first rib cartilage, in which it may be regarded as a more or less normal occurrence.

THE THORAX AS A WHOLE.

The bony and cartilaginous thorax is barrel-shaped, being narrower above than below, and compressed from before backwards. Its posterior wall is longer than its

anterior, and its transverse width, which reaches its maximum opposite the
or ninth rib, is much in excess of its sagittal diameter. This is largely
to the forward projection of the thoracic part of the vertebral column in
thoracic cavity.

The **anterior wall** is formed by the ribs and rib cartilages, togethe
the sternum. The **posterior wall** comprises the thoracic part of the vertebral c
and the ribs as far as
angles. Owing to the
ward curve of the rib
the projection forwards
vertebral bodies, the a
posterior diameter o
thoracic cavity is consid
greater on either side
middle line than in the
plane, thus allowing f
lodgment of the rounde
terior borders of the

The plane of the inlet is oblique from behind downwards and forwards, so t
expiration the upper border of the sternum lies on a level with the disc be
the second and third thoracic vertebræ.

The **lower aperture**, of large size, is bounded in the middle line behind
twelfth thoracic vertebra; passing thence the twelfth ribs slope outwards,
wards, and forwards. From these a line carried horizontally forwards from
tips touches the end of the eleventh rib, and then curving slightly upward
the cartilage of the tenth rib. Here it follows the confluent margins of th
tilages of the tenth, ninth, eighth, and seventh ribs, finally reaching the x
cartilage, where it forms with the costal margin of the opposite side the sub
angle, the summit of which coincides with the xiphi-sternal articulatio
expiration this joint usually lies on a level with the intervertebral disc be
the ninth and tenth thoracic vertebræ, and corresponds with the surface depr
familiarly known as the pit of the stomach. The inferior aperture of the tho
occupied by the vault of the diaphragm.

In the fœtal condition the form of the thorax differs from that of the adult. It is laterally compressed—in this respect resembling the simian type. Its antero-posterior diameter is relatively greater than in the adult. At birth changes in form take place dependent on the expansion of the lungs; during subsequent growth, the further expansion of the thoracic cavity in a transverse direction is correlated with the assumption of the erect posture, and the use of the fore-limbs as prehensile organs.

Sexual Differences.—The thorax of the female is usually described as being proportionately shorter and rounder than the male. It also tends to narrowness in the lower segment. It is hardly necessary to point out that the natural form is often modified by the use of tight or ill-fitting corsets.

THE BONES OF THE SKULL (Ossa Cranii).

The term skull (cranium) is commonly employed to signify the entire skeleton of the head. This comprises the bony envelope which surrounds the brain (cranium cerebrale), and the osseous structures which support the face (cranium viscerale, ossa faciei).

In catalogues of craniological collections the terms used are as follows:—
Skull = entire skeleton of head, including the mandible.
Cranium = the skull, minus the mandible.
Calvaria = that part of the skull which remains after the bones of the face have been removed or destroyed.

The cranium cerebrale is composed of the **occipital** (os occipitale), the **sphenoid** (os sphenoidale), the **ethmoid** (os ethmoidale), and the **frontal** (os frontale), the two **parietals** (ossa parietalia), and the two **temporals** (ossa temporalia)—eight bones in all.

The bones of the face (cranium viscerale, ossa faciei) include the following:—Two single, viz. the **vomer** (vomer), and the **inferior maxilla** or **mandible** (mandibula), and twelve bones, arranged in pairs, viz. the **superior maxillary** (maxillæ), **malar** (ossa zygomatica), **palate** (ossa palatina), together with the **lachrymal** (ossa lacrymalia), **nasal** (ossa nasalia), and **inferior turbinated** (conchæ inferiores)—fourteen bones in all.

According to the scheme of international nomenclature, the inferior turbinals, the lachrymals, the nasals, and the vomer are included under the cranium cerebrale, and not with the cranium viscerale.

The hyoid bone is usually described along with the skull. If, in addition, the bones of the middle ear, three on each side (malleus, incus, and stapes), be included, the skeleton of the head consists of twenty-nine bones.

The separate bones will first be described, and then the skull will be considered as a whole and in section.

THE SEPARATE BONES OF THE SKULL.

The Frontal Bone.

The **frontal bone** (os frontale), situated in the fore part of the cranium, is a single bone formed by the fusion in early life of two symmetrical halves. It consists of a **frontal part**, which corresponds to the region of the forehead; an **orbital part**, which enters in the structure of the roof of the orbits; and a **nasal part**, which assists in forming the roof of the nasal fossæ.

The **frontal part** (pars frontalis) is the shell-like portion of the bone which rises upwards above the orbital arches. Its external surface is rounded from side to side and from above downwards. This convexity is most pronounced about 1¼ inches above the orbital margins on either side of the middle line, constituting what are known as the **frontal eminences** (tubera frontalia). These mark the original sites of the centres from which the bone ossifies. The lower margin of this part is formed on either side of the middle line by the curved **orbital margins** (margines supraorbitales), the outer and inner extremities of which constitute the **external and internal angular processes** respectively. The latter descend to a lower level than the former, and articulate with the lachrymal

bones, being separated from each other by a rough articulate surface—the **notch** for the nasal and superior maxillary bones. The curve of the c margin varies in different individuals and races; towards its inner third crossed by a groove, not unfrequently converted into a foramen—the **supra notch** or **foramen** (incisura sive foramen supraorbitalis). Through this ther the supraorbital nerve and artery. Above the supraorbital margin the cha of the bone displays marked differences in the two sexes: in the male, abo interval between the two internal angular processes, there is usually a well-m prominence, called the **glabella**, from this the fulness extends outwards abo orbital margin, varying in degree and extent, and forming the elevations kno the **supraorbital** or **superciliary ridges** (arcus superciliares). The prominer these naturally reacts on the character of the supraorbital margins, which are t and more rounded in the male than in the female. Passing upwards over the gl the remains of the suture which originally separated the two halves of the fronta can usually be seen; above this point all trace of the suture is generally oblite

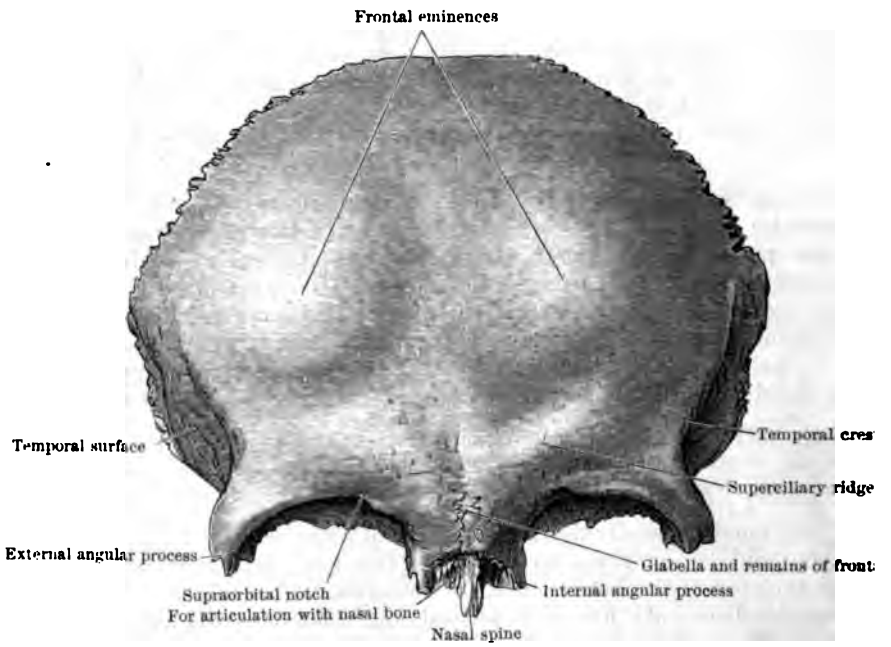

FIG. 80.—FRONTAL BONE (Anterior View).

Extending upwards from the external angular process is a well-marked which curves upwards and slightly inwards, then turning backwards it a across the lateral aspect of the bone. This is the **temporal ridge** or **crest** (lines poralis), which serves to separate the anterior surface of the **frontal portion** bone from its temporal aspect. The latter (facies temporalis) forms the **floor** upper and anterior part of the temporal fossa, and serves for the **attachment** temporal muscle.

The **orbital part** of the bone (pars orbitalis) consists of two **transversely-c** plates, each having the form of a sextant; their inner edges, which are **cellul** parallel to each other, and are separated in their posterior half by the **eth notch** (incisura ethmoidalis), in which the ethmoid bone is lodged. The ed the notch on either side are grooved in front and behind by the **anterior and po ethmoidal foramina**, which are completed when the ethmoid is *in situ*. The an transmits the internal branch of the nasal nerve and the anterior ethmoidal v the posterior, the posterior ethmoidal vessels. In front of the **ethmoidal notch** nasal notch, from the centre of which the **nasal process** projects downwards an wards to terminate in the **nasal spine** (spina nasalis), which lies between, and a lates with the nasal bones and perpendicular plate of the **ethmoid**. On eithe

the root of this process the bone is grooved obliquely from above downwards and rwards, and enters into the formation of the narrow roof (pars nasalis) of the al fossæ. Anteriorly the nasal notch is limited by a rough U-shaped articular face, the median part of which articulates with the nasal bones, whilst on either e the nasal processes of the superior maxillæ are united with it. Behind this, id the broken cells, the passages leading into the frontal sinuses are readily inguished, and here the inner edges of the orbital plates articulate with the rymal bones.

The orbital plate is thin and brittle. In front it is bounded by the superior tal margin, just within which, midway between the internal angular process the supraorbital notch there is a small shallow depression (fovea trochlearis), n displaying a spicule of bone arising from its edge (spina trochlearis), which rds attachment to the pulley of the superior oblique muscle of the eyeball. ernally the orbital plate is overhung by the orbital margin and the external ular process, and in the hollow so produced (fossa glandulæ lachrymalis) the rymal gland is lodged. The extremity of the **external angular process** (pro- is zygomaticus) articulates with the frontal process of the malar bone. Behind

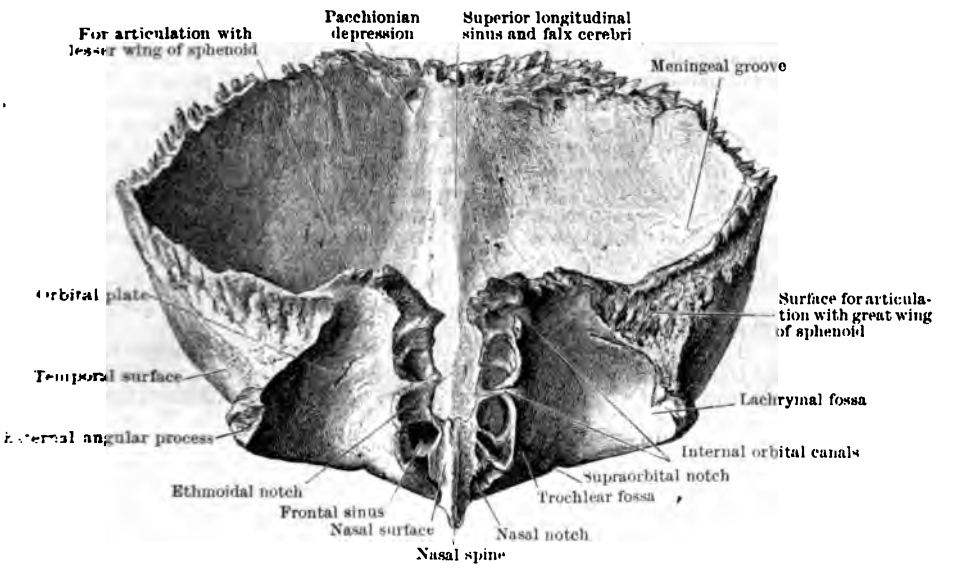

Fig. 81. -Frontal Bone as seen from Below.

the irregular edge of the orbital plate is united with the great wing of the noid by a triangular area, which also extends on to the inferior aspect of temporal surface of the frontal bone. The apex of the orbital plate, for the e of about half an inch, articulates with the lesser wing of the sphenoid.

The *cerebral surface* of the bone forms a fossa in which lie the fore and under s of the frontal lobes of the cerebrum, the convolutions of which impress their n on the inner aspect of the bone. Here, too, on either side of the middle line, be seen depressions for the lodgment of Pacchionian bodies. Descending from centre of the upper margin of the bone is a vertical groove, the **frontal sulcus**; rowing below, this ends in a ridge—the **frontal crest**—which nearly reached fore part of the ethmoidal notch, where it terminates in a small orifice, the men cæcum, placed usually in the suture between the fore part of the ethmois the frontal. This foramen may, or may not, transmit a small vein from the to the commencement of the superior longitudinal sinus. This sinus, which nterposed between the layers of the falx cerebri, is at first attached to the ital crest, but subsequently occupies the frontal sulcus. Deeply concave from to side and from above downwards, the lateral aspects of the fossa are seen to traversed by small grooves for the anterior branches of the middle meningeal ries. Below, the orbital plates bulge into the floor of the fossa, so that the

ethmoidal notch appears recessed between them. On either side of the notcl grooves for the meningeal branches of the ethmoidal vessels may be seen. circumference of the fossa is formed by the serrated edges of the bone articulate with the parietals above, and on either side below with the grea lesser wings of the sphenoid.

Connexions.—The frontal articulates with twelve bones, viz. posteriorly with the p and sphenoid; externally with the malars; inferiorly and internally with the nasals, s maxillæ, lachrymals, and ethmoid.

Architecture.—The frontal bone is composed, like the other bones of the cranial v two layers of compact tissue, enclosing between them a layer of spongy cancellous textu diploe. In certain definite situations, owing to the absorption of this intermediate la bone is hollow, forming the **frontal air sinuses**. The position and extent of these is t extent indicated by the degree of projection of the superciliary ridges, though this must taken as an absolutely reliable guide, for cases are recorded where the ridges were low a sinuses large, and *vice versa*. Of much surgical importance, these air-spaces only attain th development after the age of puberty, being of larger size in the male than in the fe circumstance which accounts for the more vertical appearance of the forehead in woman trasted with man. Usually two in number, they are placed one on either side of the line, and communicate by means of the infundibulum with the nasal fossa of the san It is exceptional to find the sinuses of opposite sides in communication with each other, are generally separated by a complete partition which, however, is occasionally much d to one or other side. Logan Turner ("On the Illumination of the Air Sinuses of the Skul some Observations upon the Surgical Anatomy of the Frontal Sinus," *Edin. Med. Jour.*, Ma gives the average dimensions of these sinuses as follows:—Height, 31 mm., *i.e.* from the nasal aperture upwards; breadth, 30 mm., *i.e.* from the septum horizontally outwards; de mm., from the anterior wall at the level of fronto-nasal suture backwards along the orbit Exceptionally large sinuses are sometimes met with extending backwards over the orbit form a double roof to that space. There is a specimen in the Oxford collection in wh sinus is so large, and extends so far back, that the optic nerve is carried through it in tube. Another point of some practical importance is that the sinuses are hardly eve metrical. It is rare to meet with cases of their complete absence, although sometimes th on one or other side may be wanting.

The external angular process, from the arrangement of its surfaces and the density structure, is particularly well adapted to resist the pressure to which it is subjected wh jaws are firmly closed.

Variations.—That most frequently met with is a persistence of the suture which uni two halves of the bone in the infantile condition: skulls displaying this peculiarity are **metopic**. The researches of various observers—Broca, Ranke, Gruber, Manouvrier, Anou and Papillault (*Rev. mens. de l'école d'Anthropol. de Paris*, année 6, n. 3)—point to th frequent occurrence of this metopic suture in the higher than in the lower races of ma Calmette asserts its greater frequence in the brachycephalic than the dolichocephalic Separate ossicles (Wormian bones) may occur in the region of the anterior fontanelle. The of these with one or other half of the frontal explains how the metopic suture is not alw line with the sagittal suture (Stieda, *Anat. Anz.* 1 227); they occasionally persist, however, and f their coalescence a bregmatic bone (G. Zoja, *Scientifico*, xvii. p. 76, Pavia). Turner (*Challenger* part xxix.) records an instance of direct articula the frontal with the orbital plate of the superior r in a Bush skull, and other examples of the same an which obtains normally in the skulls of the chim and gorilla, have been observed (*Jour. Anat. and* vol. xxiv. p. 349).

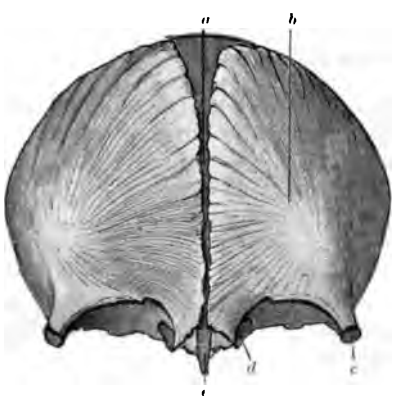

FIG. 82.—OSSIFICATION OF FRONTAL BONE.

a, Metopic suture still open. *b*, Position of primary centre. *c*, Centre for external angular process. *d*, Centre for region of trochlea. *e*, Centres for nasal spine.

Schwalbe (1901) records the presence of smal pendent ossicles (supranasal bones) in the anteri of the metopic suture. The same anatomist h recently directed attention (*Zeit. f. Morph. und* vol. iii. p. 93) to the existence of the metopic fon first described by Gerdy, and the occurrence of r ossicles (ossa interfrontalia) and canals.

Ossification.—Ossification begins in men from two centres, which appear about the si seventh week, one on either side immediately the orbital margin. From these the two ha the frontal part of the bone are developed, a extension inwards and backwards from their part the orbital plates are also formed. Serres, Rambaud, and Renault and v. I describe the occurrence of three pairs of secondary centres somewhat later: on for the nasal spine on either side of the foramen cæcum; a centre on either s

correspondence with the position of each trochlear fossa; and a centre for each external angular process. Fusion between these secondary and the primary centres is usually complete about the sixth or seventh month of fœtal life. At birth the two symmetrical halves of the bone are separated by the metopic suture, obliteration of which gradually takes place, so that about the fifth or sixth year it is more or less completely closed, traces only of the suture being left above and below. In about eight per cent of Europeans, however, the suture persists in the adult (see *ante*). At birth the supraorbital notches lie near the middle of the supraorbital arches.

Traces of the frontal sinuses may be met with about the second year, but it is only about the age of seven that they can be definitely recognised. From that time they increase in size till the age of puberty, subsequent to which time they attain their maximum development.

The Parietal Bones.

The **parietal bones** (ossa parietalia), two in number, are placed on either side of the vault of the cranium, articulating with the frontal anteriorly, the occipital

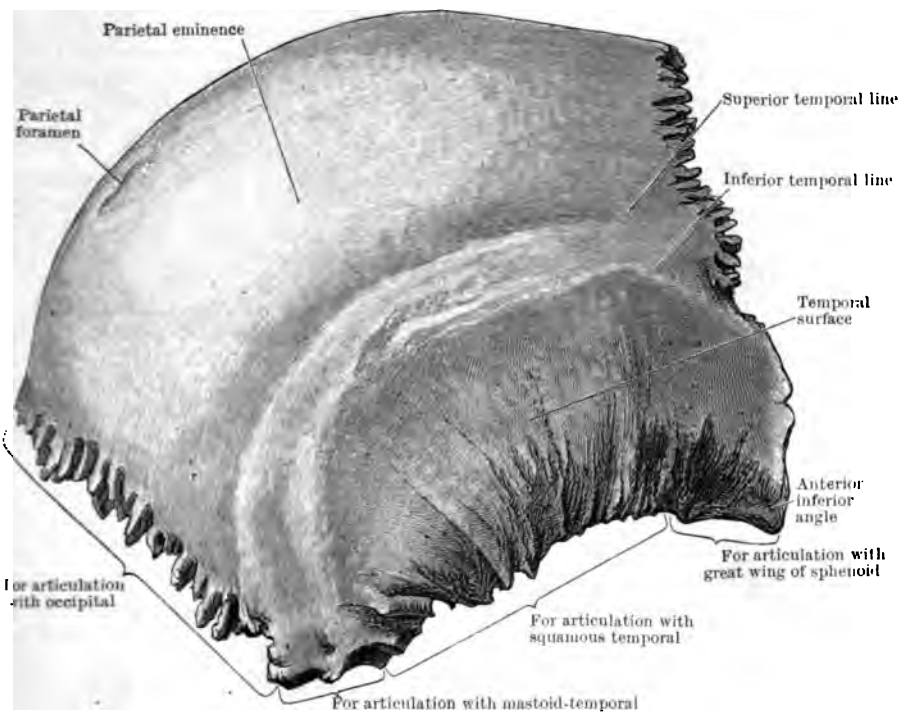

Fig. 83.—Right Parietal Bone (Outer Side).

posteriorly, and the temporals and sphenoid inferiorly. Each bone possesses an external and internal surface, four borders, and four angles.

The *external surface*, convex from above downwards and from before backwards, displays towards its centre a more or less pronounced elevation, the **parietal eminence** (tuber parietale). This marks the position of the primitive ossific centre, and not unfrequently corresponds to the point of maximum width of the head. At a variable distance from the lower border of the bone, and more or less parallel to it, two curved lines can usually be distinguished; these together constitute the **temporal crest**. The **superior temporal line** (linea temporalis superior) serves for the attachment of the temporal fascia; the **inferior temporal line** (linea temporalis inferior) defines the attachment of the temporal muscle, the extent and development of which necessarily determines the position of the crest. The surface below the crest enters into the formation of the floor of the **temporal fossa**, and is called the **planum temporale**; it also affords origin to the temporal muscle, and is often faintly marked by grooves which indicate the course of the middle temporal artery.

Above the superior temporal line the bone is covered only by the tissues of the scalp. Near its upper border, and about an inch from its posterior superior angle, is the small **parietal foramen** (foramen parietale), through which pass a small arteriole and an emissary vein.

The *inner* or *cerebral aspect* is concave from side to side and from above downwards, moulded over the surface of portions of the frontal, parietal, occipital, and temporal lobes of the cerebrum, it displays impressions corresponding to the arrangement of the convolutions of these portions of the brain. It also presents a series of well-marked grooves for the lodgment of the branches of the middle meningeal artery; these radiate from the anterior inferior angle of the bone, the best marked running upwards at some little distance behind and parallel to its anterior border. Within the upper margin are a series of depressions for Pacchionian bodies, and here also the bone is channelled so as to form a groove (sulcus sagittalis), which is completed by articulation with its fellow of the opposite side. Within

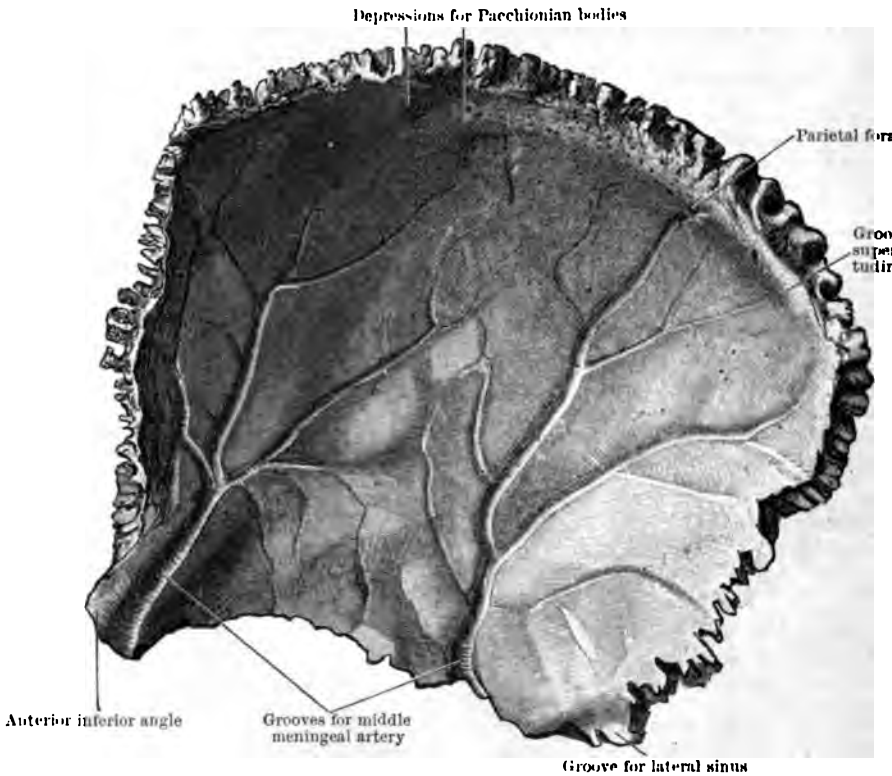

FIG. 84.—RIGHT PARIETAL BONE (Inner Surface).

this groove lies the superior longitudinal venous sinus, and to its edges the falx cerebri is attached. Close to the inferior posterior angle there is also a curved groove, the lateral sulcus, in which the lateral venous sinus is lodged.

The *anterior*, *superior*, and *posterior borders* are deeply serrated. The anterior articulates with the frontal bone, and constitutes the coronal suture; the posterior is united with the occipital bone, and forms the lambdoid suture. The superior border articulates with its fellow of the opposite side by means of the sagittal suture; in the interval between the two parietal foramina this suture is usually simple in its outline. The *anterior superior angle* (angulus frontalis) is almost rectangular, and corresponds to the site of the anterior fontanelle. The *posterior superior angle* (angulus occipitalis), usually more or less rounded, corresponds in position to the posterior fontanelle. The *inferior border* is curved, and shorter than the others; it lies between the anterior and posterior inferior angles. Sharp and bevelled at the expense of its outer table, it displays a fluted arrangement, and articulates with the squamous part of the temporal bone. The *anterior inferior angle* (angulus

oidalis), pointed and prominent, articulates with the great wing of the oid. It is wedged into the angle formed by the union of that bone with the d, and is bevelled at the expense of its inner table anteriorly, whilst inferiorly hinned at the expense of its outer table. The *posterior inferior angle* (angulus ideus) is a truncated angle lying between the inferior and posterior borders. deeply serrated, and articulates with the mastoid process of the temporal bone. nfrequently there is a channel in this suture which transmits an emissary vein.

nnexions.—The parietal bone articulates with its fellow, with the frontal, occipital, id and squamous temporal, and with the sphenoid. Occasionally the inferior angle may ach the great wing of the sphenoid, being separated from it by the articulation of the ous temporal with the frontal (see also p. 119).

chitecture.—Thin towards its lower part, where it enters into the formation of the al fossa, it is thickest along the superior border and in the neighbourhood of the posterior or angle.

riations.—A number of cases have been recorded in which the parietal is divided into an and lower part by an antero-posterior suture parallel to the sagittal suture. Coraini . *XI. Congr. Med. Internaz. Roma*, 1894, vol. v.) records a case in which the parietal was intely divided into an anterior and posterior part by a vertical suture. The parietal ia vary greatly in size, and to some extent in position. They are sometimes absent on one r side, or both. They correspond in position to the sagittal fontanelle. Sometimes the ion of this fontanelle is incomplete and a small transverse fissure remains. The parietal i represents the patent external extremity of this fissure after its edges have coalesced. nally in the region of the anterior fontanelle an ossicle of variable size may be met with. the so-called prae-interparietal bone. According to its fusion with adjacent bones it turb the direction of the sagittal suture.

sification.—Ossification takes place in membrane by the deposition of earthy the centre for which, most probably formed by the coalescence of two nuclei, over the parietal eminence about the sixth or seventh week of fœtal life; from this ds in a radial manner towards the edges of the bone, where, however, the mem- condition still for some time persists constituting the fontanelles. These corren position to the angles of the bone. Ossification is also somewhat delayed in ion of the parietal foramina, constituting what is known as the sagittal fontanelle, ranous interval which is not unfrequently apparent even at birth.

The Occipital Bone.

e **occipital bone** (os occipitale), placed at the back and lower part of the m, consists of three parts, arranged around a large oval hole, called the al foramen or foramen magnum. The expanded curved plate behind the n is the **tabular** or **squamous part**. The thick rod-like portion in front of the n is the **basilar process**. On either side the foramen is bounded by the . or **condylic portions**.

e **tabular** or **squamous part** (squama occipitalis) in shape somewhat resembles hic arch, and is curved from side to side and from above downwards. It forms rly a small portion of the middle of the posterior boundary of the foramen um, and unites on either side of that with the lateral parts of the bone. About ntre of the *external surface* of the squama there is a prominence—the **external al protuberance** (protuberantia occipitalis externa), which varies considerably distinctness and projection, and serves for the attachment of the ligamentum e. From the protuberance on either side two lines curve out towards ternal angles of the bone. These are known respectively as the **highest** and **or curved lines** (linea nuchæ suprema and linea nuchæ superior). To the of these the epicranial aponeurosis is attached, whilst the lower serves for rigin of the trapezius and occipitalis muscles and the insertion of the sterno- id and splenius capitis muscles. The two lines together serve to divide the nal surface of the tabular part into an upper or **occipital portion** (planum itale), covered by the hairy scalp and a lower or **nuchal part** (planum nuchale) ng for the attachment of the fleshy muscles of the back of the neck. As a rule cipital part bulges backwards beyond the external occipital protuberance; tionally, however, the latter process is the most outstanding part of the bone. he **nuchal plane**, irregular and rough, is divided into two lateral halves by a n ridge—the **external occipital crest** (linea nuchæ mediana), which stretches

from the external occipital protuberance above to the posterior border of the foram magnum below. Crossing the nuchal plane transversely, about its middle, is t **inferior curved line** (linea nuchæ inferior), which passes outwards and forwards either side towards the lateral margins of the bone. The areas thus marked o serve for the attachment of the complexus, obliquus superior, and rectus capi posticus major and minor muscles.

The *internal surface* of the squama, concave from side to side and from abo downwards, is subdivided into four fossæ by a crucial arrangement of ridges a grooves. The upper pair of fossæ lodges the occipital lobes of the cerebrum, t lower pair the lobes of the cerebellum. Near the centre of this aspect of the bo is the **internal occipital protuberance** (protuberantia occipitalis interna), an irregul elevation, the sides of which are variously channelled according to the disposition of the grooves. Leading from this to the hinder margin of the foramen magnum

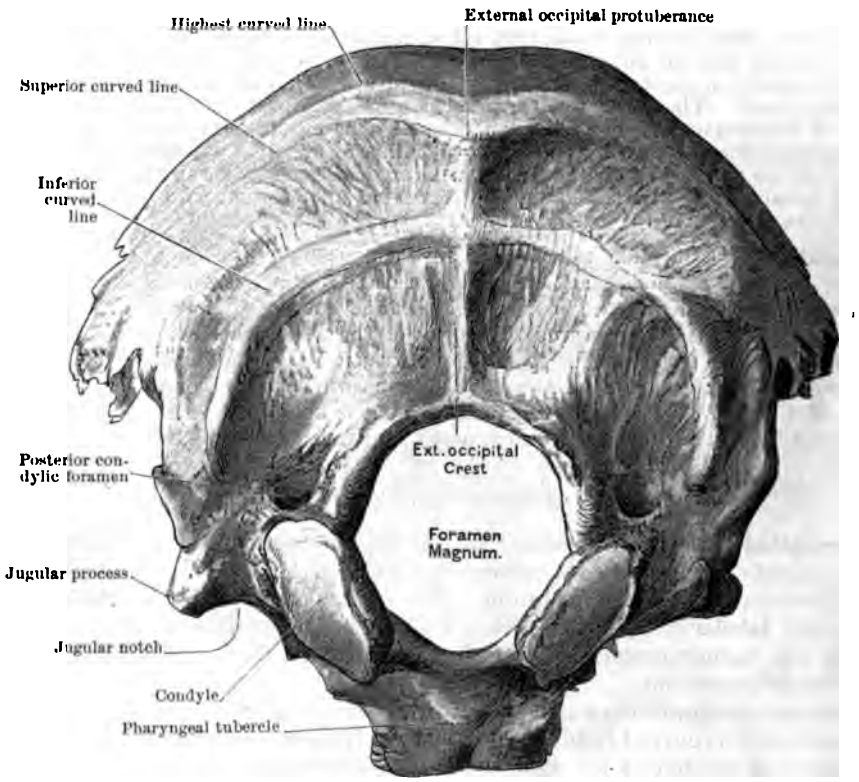

Fig. 85.—Occipital Bone as seen from Below.

is a sharp and well-defined ridge, the **internal occipital crest** (crista occipitalis interna), which serves for the attachment of the falx cerebelli, a process of dura mater which separates the two cerebellar hemispheres. Passing upwards from the internal occipital protuberance there is usually a well-marked ridge, to one or other side of which, more frequently the right (with the bone in the normal position and viewed from behind), there is a well-defined groove, the **sulcus sagittalis**, the outer lip of which is generally less prominent. Placed in this groove is the superior longitudinal venous sinus, and attached to the lips is the falx cerebri. At right angles to the foregoing, and at the level of the internal occipital protuberance, with which they become confluent, are two transverse grooves, the sulci transversi. These grooves, which have more or less prominent edges, lie between the upper and lower pairs of fossæ, and serve for the attachment of the tentorium cerebelli as well as the lodgment of the lateral blood-sinuses. Commonly the right lateral groove is confluent with the groove to the right side of the median ridge, but exceptions to this rule are not infrequent. The angle formed by the union of the venous sinuses

dged in these grooves constitutes the torcular Herophili, which may accordingly e placed to one or other side of the internal occipital protuberance, more frequently he right; in some cases, however, it may occupy a central position.

The *superior angle*, more or less sharp and pointed, is wedged in between the wo parietal bones, its position corresponding to the site of the posterior fontanelle. he *lateral angle* articulates on either side with the posterior extremity of the astoid portion of the temporal bone. The *superior borders*, much serrated, articuate with the parietal bones forming the **lambdoid suture**; and the *lateral edges*, xtending from the external angles to the jugular process inferiorly, are connected ith the inner sides of the mastoid portions of the temporals.

The **lateral or condylic parts** of the occipital bone (partes laterales) are placed

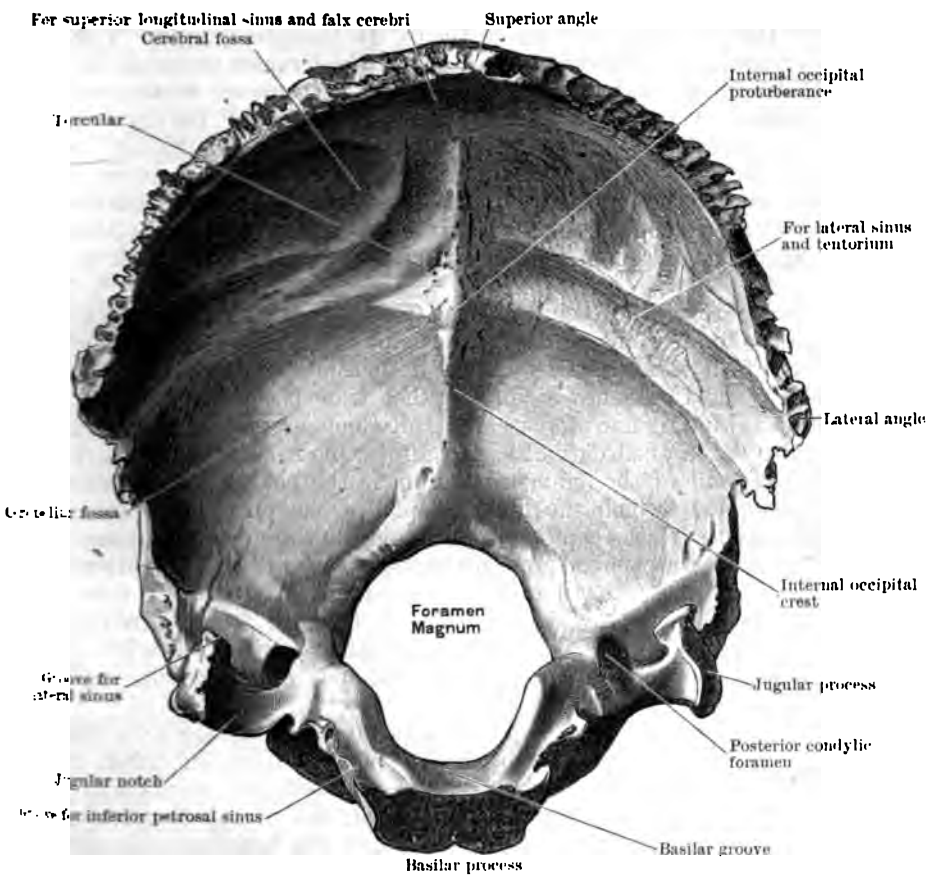

FIG. 86.—OCCIPITAL BONE (Inner Surface).

on either side of the foramen magnum; on their under surface they bear the condyles (condyli occipitales) by means of which the skull articulates with the atlas vertebra. Of elongated oval form, the condyles are so disposed that their anterior extremities, in line with the anterior margin of the foramen magnum, lie closer together than their posterior ends, which extend as far back as the middle of the external borders of the foramen. Convex from before backwards, they are skewed so that their surfaces, which are nearly plane from side to side, are directed slightly outwards. Each is supported on a boss of bone, pierced by the **anterior condylic foramen** (canalis hypoglossi), which opens obliquely from within outwards and forwards on the floor of a fossa called the **anterior condylic fossa**, situated just external to the fore part of the condyle. The foramen transmits the hypoglossal or XII. cranial nerve, together with a meningeal branch of the ascending pharyngeal artery and its companion veins. Behind the condyle is placed the **posterior condylic fossa**, in the floor of which the **posterior condylic foramen** frequently opens. Through

this a vein passes which joins the lateral sinus. The edge of the foramen magn immediately behind the condyle is often grooved for the passage of the verte artery around it. Jutting out from the posterior half of the condyle is a stout of bone, serially homologous with the vertebral transverse process—this is **jugular process** (processus jugularis); deeply notched in front, its anterior bo is free and rounded, and forms the posterior boundary of the jugular fora Curving outwards from this margin, in line with the anterior condylic fora there is often a small pointed projection, the **processus intra-jugularе**, which se to divide the jugular foramen into two compartments. Externally the jug process articulates by means of a synchondrosis with the jugular surface of petrous part of the temporal bone. Its posterior border is confluent with the lo and lateral portion of the occipital squama, and its under surface is rough tubercular for the attachment of the rectus capitis lateralis muscle. The *supe aspect* of the lateral part displays on either side of the foramen magnum an eleva surface of oval form, the **tuberculum jugulare**; this corresponds to the part of bone which bridges over the canal for the hypoglossal nerve. Its upper surface many instances displays an oblique groove running across it; in this are lodged glosso-pharyngeal, vagus, and accessory nerves. The jugular process is deep grooved superiorly for the lower part of the lateral blood sinus, which here tur round the anterior free edge of the process into the jugular foramen. Joining th close to its inner edge, is the opening of the posterior condylic foramen when th canal exists.

The **basilar part** of the occipital bone (pars basilaris) extends forwards a upwards from the foramen magnum. Its anterior extremity is usually sawn acro as, after adult life, it is necessary to sever it in this way from the sphenoid, t cartilage uniting the two bones having by that time become completely ossifi Broad and thin behind, it narrows laterally and thickens vertically in front, wh on section it displays a quadrilateral form. Projecting from its under surface so little distance in front of the foramen magnum is the **pharyngeal tubercle** (tub culum pharyngeum) to which the fibrous raphe of the pharynx is attached; either side of this the rectus capitis anticus major and minor muscles are inserte The *upper surface* forms a broad and shallow groove which slopes upwards a forwards from the thin anterior margin of the foramen magnum; in this rests t medulla oblongata. On either side its lateral edges are faintly grooved for t inferior petrosal venous sinuses, below which the lateral aspect of the bone is rou for the cartilage which unites it to the sides and apex of the petrous part of t temporal bone.

The **foramen magnum**, of oval shape, so disposed that its long axis lies in t sagittal plane, is of variable size and form. The plane of its outlet differs somewh in individual skulls; in most instances it is directed downwards and sligh forwards. In front the condyles encroach upon it, and narrow to some extent transverse diameter. To its margins are attached the ligaments which unite with the atlas and axis. Through it pass the lower part of the medulla oblonga where it becomes continuous with the spinal cord, the two vertebral arteries, t spinal accessory nerves, and the blood-vessels of the meninges of the upper part the cord.

Connexions.—The occipital bone articulates with the two parietals in front and above, wi the sphenoid in front and below, with the two temporals on either side, and with the at vertebra by means of its condyles.

Architecture.—The squamous part displays thickenings in the position of the various rid and crests, the stoutest part corresponding to the internal and external occipital protuberanc though it should be noted that the two protuberances do not necessarily coincide, the inter being, as a rule, placed at a higher level than the external. If the bone be held up to the lig it will be at once apparent that it is much thinner where it forms the floor of the inferior fos than in the upper part. The basilar portion consists of a spongy core surrounded by a m compact outer envelope, thickest on its lower surface. In the condyles the spongy tissue arranged radially to their convex articular surfaces, the hypoglossal canal being surrounded particularly dense and compact bone.

Variations.—The most striking of the many variations to which this bone is subject is t separation of the upper part of the occipital squama to form an independent bone—the int parietal bone, called also, from the frequency of its occurrence in Peruvian skulls, the os In

seen below (see Ossification), the occurrence of this anomaly is explained development- place of forming a single bone the interparietal is occasionally met with in two al halves, and instances have been recorded of its occurrence in three or even four the latter cases the two anterior parts form the pre-interparietals. Instances are f the presence of a separate epiphysis between the basi-occipital and the sphenoid, the um (Albrecht) or the os præ-basi-occipital. The articular surface of the condyles is divided into an anterior and posterior part. The so-called third occipital condyle is ding process rising from the anterior border of the foramen magnum, the extremity of culates with the odontoid process of the axis. Guerri has recorded a case, in which in ull, there were two outstanding tubercles in the position of the third occipital condyle, nt of the basi-occipital portions of the condyles (*Anat. Anz.* vol. xix. p. 42). This confirm the view of Macalister that there are two different structures included s name—one a mesial ossification in the sheath of the notochord, and the second, a ually paired process, caused by the deficiency of the mesial part of the hypochordal f the hindmost occipital vertebra, with thickenings of the lateral parts of the arch. from the under surface of the extremity of the jugular process, a rough or smooth urface, or else a projecting process, the extremity of which may articulate with the process of the atlas, is sometimes met with. This is the paroccipital or paramastoid Numerous instances of fusion of the atlas with the occipital bone have been recorded. no doubt, pathological in their origin; others are associated with errors in development. g anomalies are these in which there is evidence of the intercalation of a new vertebral etween the atlas and occipital, constituting what is termed a proatlas.

ification.—The major part of the bone ossifies in cartilage, the upper part of the interparietal), alone developing in membrane. The **basilar part** begins to ossify sixth week of fœtal life by the appearance of two centres, one in front of the ie anterior, according to Albrecht, constitutes the basiotic, the posterior the ital. These two centres—which there is some reason to believe—may themselves l by the fusion of pairs placed laterally, rapidly unite, so that the occurrence of e alone is frequently described. From this the fore part of the margin of the magnum is formed, together with a portion of the anterior end of the occipital n either side. It helps also to close up the front of the anterior condylic canal. ith the condylic parts is complete about h or fifth year. Ankylosis between the ital and the sphenoid takes place about the th year.

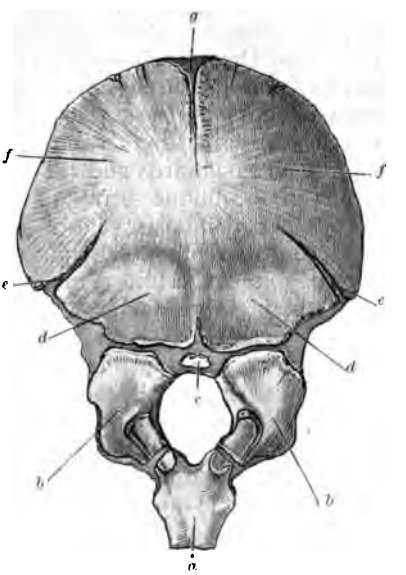

FIG. 87.—OSSIFICATION OF OCCIPITAL BONE.
a, Basilar centre; *b*, Exoccipital; *c*, Ossicle of Kerkring; *d*, Supra-occipital (from cartilage); *e*, Fissure between supra-occipital and interparietal; *f*, Interparietal (from membrane); *g*, Fissure between interparietals.

teral, condylic, or **exoccipital parts** begin from a single centre about the end of the onth of fœtal life. The notch for the al canal appears about the third month. s centre is formed the posterior three- f the occipital condyle. The exoccipital completely fused with the squama by year or earlier.

ready noted, the squama consists of two ie one above the occipital crest, the other ; the former develops in membrane, the cartilage. In a three-months' fœtus this is very characteristic. The cartilaginous ra-occipital) begins to ossify from two centres e sixth or seventh week, which rapidly join an elongated strip placed transversely in on of the occipital protuberance. The for the upper part (interparietal) appear According to Maggi (*Arch. Ital. Biol.* tome 2, p. 301), they are four in number, of vo placed on either side of the middle line bout the second month. The other pair, terally, are seen about the third month; etween these takes place early, but their on and arrangement explain the anomalies n this part of the bone is subject. The air may persist as separate ossicles, or fuse to form the pre-interparietals, whilst ral pair may remain independent of the supra-occipital as a single or double ietal bone. Union between the supra-occipital and the interparietal elements bout the third or fourth month; but evidence of their separation is frequently

met with even in the adult by the persistence of a transverse suture running inwa from each external angle of the squama, or, as above mentioned, there may be an Incæ. The supra-occipital forms a small part of the middle of the hinder border of foramen magnum, though here a small independent centre, known as the ossicl Kerkring, is occasionally met with. Other independent centres are sometimes f between the supra-occipital and the exoccipitals.

At birth the occipital consists of four parts—the interparietal and supra-occip combined, the basi-occipital, and the exoccipitals—one on either side.

The Temporal Bones.

The **temporal bone** (os temporale) lies about the centre of the lower half of eit side of the skull, and enters largely into the formation of the cranial base. I placed between the occipital behind, the parietal above, the sphenoid in front, a the occipital and sphenoid internally and below. At birth it consists of th parts—an upper and outer part, the **squamous** or **squamo-zygomatic portion**; an in and posterior portion, the **petro-mastoid**, which contains the parts specially associat with the sense of hearing, together with the organ associated with equilibratio and an under or **tympanic part**, from which the floor and anterior wall of t external auditory meatus is formed.

The **squamous part** (pars squamosa) consists of a thin shell-like plate of bo placed vertically, having an inner (cerebral) and an outer (temporal) surface and semicircular upper border. Inferiorly, behind, and internally it is fused in ear life with the petro-mastoid portion by means of the squamoso-mastoid and t petro-squamosal sutures, traces of which are often met with in the adult bon whilst below and in front it is separated from the tympanic and petrous parts b the **Glaserian fissure**. Its *external surface*, smooth and slightly convex, enters in the formation of the floor of the temporal fossa, and affords attachment to t temporal muscle. Near its hinder part it is crossed by one or more ascendi grooves for the branches of the middle temporal artery. In front and below the springs from it the **zygomatic process** (processus zygomaticus). This arises by broad attachment, the surfaces of which are inferior and superior; curving outwar and forwards, it then becomes twisted and narrow so that its sides are turn inwards and outwards and its edges directed upwards and downwards. Anterior it ends in an oblique serrated extremity which articulates with the zygomatic pr cess of the malar bone. Posteriorly the edges of the zygomatic process separate a are termed its roots. The upper edge, which becomes the **posterior root**, sweeps ba over the external auditory meatus, and is confluent with a ridge, the **supra-mast crest**, which curves backwards and slightly upwards, and serves to define the lim of the temporal fossa posteriorly. The inferior edge turns inwards and constitut the **anterior root**; the under surface of this forms a transversely-disposed round ridge, the **articular eminence** (tuberculum articulare), behind which there is a de hollow, the **glenoid fossa** (fossa mandibularis), limited posteriorly by the tympa plate, and crossed at its deepest part by an oblique fissure, the **Glaserian fiss** (fissura petro-tympanica). This cleft, which is closed externally, transmits abo its middle the tympanic branches of the internal maxillary artery, and lodges t slender process of the malleus. At its inner end the lips of this fissure a frequently separated by a thin scale of bone, a downgrowth from the tegm tympani of the petrous part, which here separates the tympanic from the squamo elements, forming in its descent the major part of the outer wall of the osseo Eustachian canal, which lies immediately internal to it. Between this scale of bo and the posterior edge of the fissure there is a small canal (**canal of Huguier**), whi transmits the chorda tympani nerve. The part of the glenoid fossa in front of t fissure articulates with the condyle of the inferior maxilla, through the mediu of the interarticular cartilage, which is here interposed and rests as well on t tuberculum articulare. Posteriorly the part of the fossa behind the fissure is no articular and lodges a portion of the parotid gland. At the angle formed by t divergence of the two roots of the zygoma, in correspondence with the outer p of the articular eminence, there is a rounded **tubercle**; to this are attached t

ace of the external lateral ligament of the temporo-mandibular joint. In front f the inner end of the articular eminence there is a small triangular surface, mited in front by the edge of the anterior root, and internally by a thick serrated argin which articulates with the outer side of the great wing of the sphenoid; is area forms part of the roof of the zygomatic fossa. Just anterior to the xternal auditory meatus and projecting downwards from the under surface of the sterior root there is a conical process, called the **post-glenoid tubercle**, which forms prominent anterior lip to the external extremity of the Glaserian fissure; it is the presentative in man of a process which occurs in some mammals and prevents the ckward displacement of the lower jaw. By some anatomists it is referred to as he **middle root** of the zygoma.

The **zygomatic process** by its lower margin and inner surface gives origin to the asseter muscle, whilst attached to its upper edge are the layers of the temporal scia. Behind the external auditory meatus, and below the supramastoid crest, the

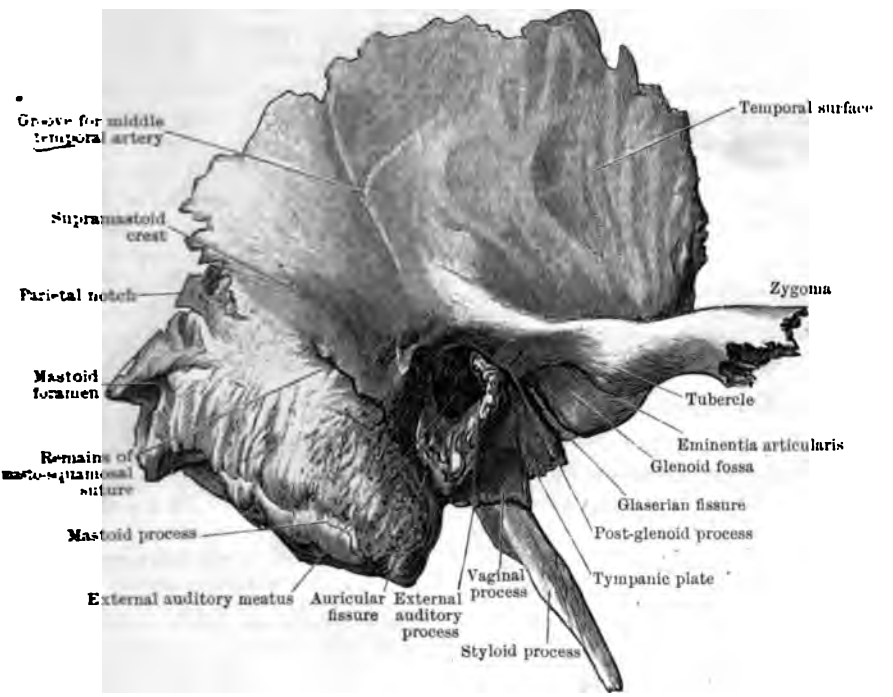

FIG. 88.—RIGHT TEMPORAL BONE AS SEEN FROM THE OUTER SIDE.

squamous element extends downwards as a pointed process, which assists in forming the roof and posterior wall of the external auditory meatus, where it unites inferiorly with the tympanic plate. In the adult this process is occasionally sharply defined posteriorly by an oblique irregular fissure, the remains of the mastoid-squamosal suture.

Professor Macewen has pointed out that this suture frequently remains open till puberty and occasionally after, and may be of importance as a channel along which infective processes may extend.

The *inner surface* of the squamous part, less extensive than the outer aspect owing to the bevelling of the superior border, is marked by the impression of the convolutions of the temporal lobe of the cerebrum, and is limited below by the petro-squamosal suture, the remains of which can frequently be seen. It is crossed in front by an ascending groove for the middle meningeal artery, branches from which course backwards over the bone in grooves more or less parallel to its upper border.

The *superior border* of the squamous part is curved, sharp, and scale-like, being bevelled at the expense of its inner table, except in front, where the margin is thick

and stout. Here it articulates with the great wing of the sphenoid, its union w
that bone extending to near the fore part of the summit of the curve, behind wh
it is united to the parietal overlapping the lower border of that bone; posteri
the free margin of the squamous part ends at an angle formed between it and
mastoid process called the **incisura parietalis.**

The **tympanic part** (pars tympanica) of the temporal bone forms the ante
lower, and part of the posterior wall of the external auditory meatus. Boun
in front and above by the Glaserian fissure, it forms the hinder wall of the
articular part of the glenoid fossa. Fused internally with the petrous part,
lower edge, sharp and well defined internally, splits to enclose the root of
projecting **styloid process**, and is hence called the **vaginal process.** Externally
unites with the fore part of the mastoid process, and higher up with the descend
process of the squamous part, from both of which it is separated by the auri
fissure (fissura tympano-mastoidea) through which the auricular branch of

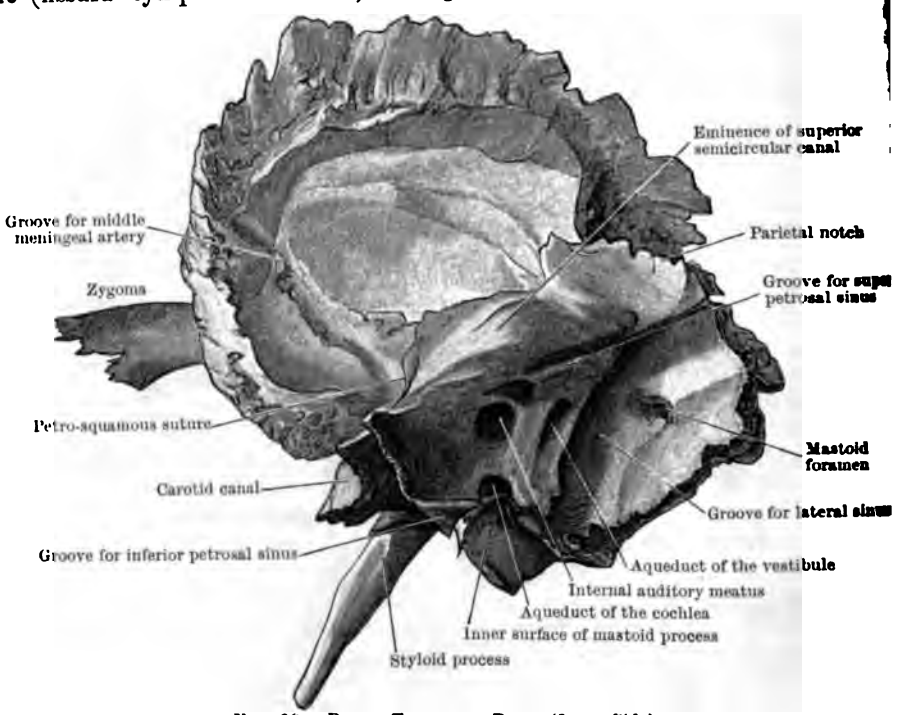

FIG. 89.—RIGHT TEMPORAL BONE (Inner Side).

vagus escapes. Its free border, which forms the anterior, lower, and part of
posterior border of the external auditory meatus, is usually somewhat thicke
and rough, and serves for the attachment of the cartilaginous part of the canal.

The **external auditory meatus** (meatus acusticus externus) is directed obliqu
inwards and a little forwards, and describes a slight curve, the convexity of wh
is directed upwards; of oval form, its long axis, close to its orifice, is nearly verti
but, as it passes inwards, inclines somewhat forwards so as to give a twist to
canal. The depth of the canal to the attachment of the membrana tymp
averages from 14 to 16 mm. The upper margin of the outer orifice overha
considerably the lower edge, but owing to the obliquity of the inner apertur
which the membrana tympani is attached, the upper wall of the osseous c
only exceeds the length of the lower wall by one or two millimetres.

The **petro-mastoid part** (pars petrosa et mastoidea) of the temporal bon
pyramidal form, is fused to the inner aspect of the tympanic and squam
portions, extending behind them, however, to form the well-marked and promi
mastoid process, which lies posterior to the external auditory meatus. This pr
(pars mastoidea) forms a nipple-like projection, the size of which differs consider
in different individuals. Usually larger in the male than in the female, its r

outer surface and lower border serve for the insertions of the sterno-mastoid, splenius capitis, and trachelo-mastoid muscles. Within and below its pointed extremity there is a deep groove (incisura mastoidea), usually well marked, which gives origin to the posterior belly of the digastric muscle; whilst lying to the inner side of this, and separated from it by a more or less well-defined rough ridge, there can oftentimes be seen a narrow, shallow furrow, which indicates the course of the occipital artery. The **inner surface** of the mastoid portion forms, in part, the lateral wall of the posterior cranial fossa, in which the cerebellar lobes are lodged. Coursing across this aspect of the bone there is a broad curved groove, the concavity of which is directed forwards and lies in the angle formed by the base of the petrous part and its fusion with the mastoid portion. The depth to which the bone is here channelled varies considerably, and is important from a surgical standpoint, as herein lies the sigmoid portion of the lateral venous sinus. Anteriorly the mastoid is fused with the descending process of the squamosal above, and below, where it is united with the tympanic, it enters into the formation of the posterior wall of the external auditory meatus and the cavity of the tympanum. Above, its free margin is rough and serrated, and articulates with the posterior inferior angle of the parietal; behind and below it articulates by a jagged suture with the occipital. Traversing this suture, or near it, is the **mastoid foramen** (foramen mastoideum), which transmits a vein from the lateral sinus to the cutaneous occipital vein, together with a small branch of the occipital artery.

The **petrous part** of the petro-mastoid is of the form of an elongated three-sided pyramid. By its base it is united obliquely to the inner sides of the squamosal and tympanic parts. Its apex is directed inwards, forwards, and a little upwards. Its three surfaces are arranged as follows:—The *superior* or *anterior* looks upwards, slightly forwards, and a little outwards, and forms part of the floor of the middle cranial fossa. The *posterior* is directed backwards and inwards, and forms part of the anterior wall of the posterior cranial fossa. The *inferior* is seen on the under surface of the base of the skull, and is directed downwards. The borders are named respectively anterior, superior, and posterior.

The *anterior border* is short, and forms an acute angle with the fore part of the squamous part; within this angle is wedged the spinous part of the great wing of the sphenoid. Here, too, the osseous **Eustachian canal** (canalis musculotubarius) may be seen leading backwards and outwards from the summit of the angle to reach the fore part of the cavity of the tympanum. On looking into it, the canal is seen to be divided into two unequal parts by an osseous partition, the **cochleariform process** (septum tubæ). The upper compartment, the smaller of the two (semicanalis m. tensoris tympani), lodges the tensor tympani muscle, whilst the lower (semicanalis tubæ auditivæ) forms the osseous part of a channel (the **Eustachian tube**), which serves to conduct air from the pharynx to the tympanum.

The *posterior border* is in part articular and in part non-articular. Posteriorly and externally it corresponds to the upper margin of an area on the inferior surface with which the extremity of the jugular process of the exoccipital articulates. In front of that it is irregularly notched, and forms the free anterior edge of the jugular foramen, internal to which it has a sharp curved border, often grooved, reaching to the apex. This groove, which is completed by articulation with the outer side of the basi-occipital, lodges the inferior petrosal venous sinus.

The *superior border* is a twisted edge which is continuous with the upper margin of the groove for the lateral sinus posteriorly, and anteriorly and internally reaches the apex of the bone. Running along it there is usually a well-marked groove for the superior petrosal venous sinus, and near its inner extremity it is slightly notched for the passage of the trigeminal nerve. Along the entire length of this border the tentorium cerebelli is attached.

On the *inferior surface* of the petrous part, which is bounded in front by the anterior border internally, and the tympanic plate externally, and behind by the posterior border, the following structures are to be noted:— Springing from and ensheathed by the vaginal process is the slender and pointed **styloid process** (processus styloideus), the length of which varies much. Projecting downwards and slightly forwards and inwards, it affords attachments for the stylo-glossus,

stylo-hyoid, and stylo-pharyngeus muscles as well as the stylo-hyoid and sty
mandibular ligaments. Just behind it, and between it and the mastoid proc
is the **stylo-mastoid foramen** (foramen stylomastoideum), which lies at the ante
end of the digastric groove, and transmits the facial nerve and the stylo-mast
artery. Immediately internal to the styloid process there is a deep, smoo
excavated hollow, the **jugular fossa** (fossa jugularis), which is converted into
foramen (jugular) by articulation with the occipital bone. Behind and external
the fossa there is a small **quadrilateral surface** of variable size, which is united
the extremity of the jugular process of the exoccipital by a synchondrosis. In
the fossa, on its outer aspect, or placed on its external border, is the opening o
small canal (canaliculus mastoideus), which passes outwards to open into the cana
facialis, and transmits the auricular branch of the vagus (Arnold's nerve), wh
ultimately escapes through the auricular fissure (see *ante*). In front of t
jugular fossa and separat
from it by a sharp crest, a
just internal to the tympa
plate, is the circular openi
of the inferior orifice of t
carotid canal (canalis caro
cus). Directed at first p
wards, this canal bends a
right angle and turns fo
wards and inwards, lyi

of the carotid canal anoth
small opening or openings (canaliculi carotici tympanici) may be noticed whi
afford passage to the tympanic branches of the internal carotid artery and caroti
sympathetic plexus. Occupying the interval between the jugular fossa an
the carotid canal on the inner side is a V-shaped depression (fossula fenestr
cochleæ), on the floor of which and close to the posterior border is the orifice
the **aqueduct** of the **cochlea** (apertura externa aquæductus cochleæ). In the fos
is lodged the petrous ganglion of the glosso-pharyngeal nerve, and the aqueduc
transmits a tubular prolongation of the dura mater, which forms a channel
communication between the perilymph of the cochlea and the subarachnoid spac
A small vein also passes through it. In front of and internal to the orifice of th
carotid canal the under surface of the apex of the bone corresponds to a roug
quadrilateral surface which forms the floor of the carotid canal, and also serves f
the attachment of the cartilaginous part of the Eustachian tube as well as th
origin of the levator palati muscle; elsewhere it has attached to it the dens
fibrous tissue which fills up the cleft (petro-basilar fissure) between it and th
basilar process of the occipital bone.

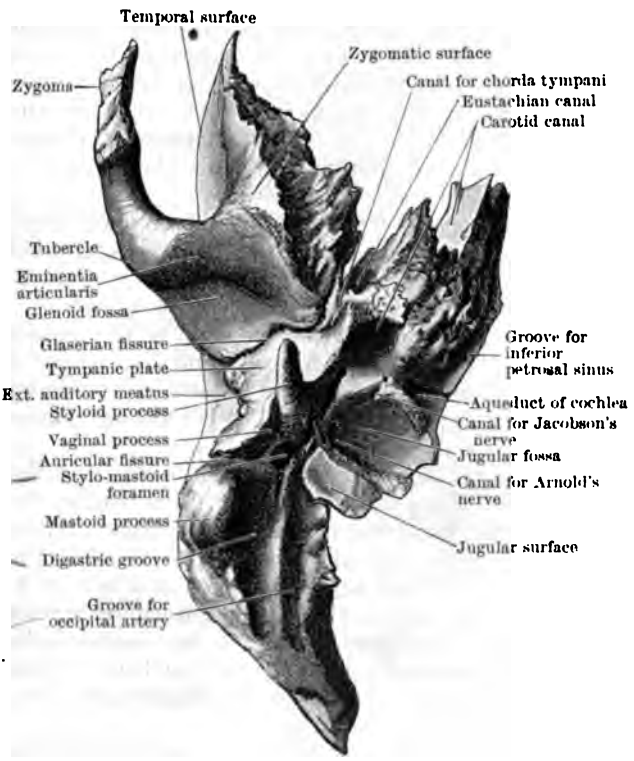

FIG. 90.—RIGHT TEMPORAL BONE AS SEEN FROM BELOW.

he *superior* or *anterior surface* bears the impress of the convolutions of the surface of the temporal lobe of the cerebrum, which rests upon it; in on, there is a distinct but shallow depression (impressio trigemini) near the corresponding to the roof of the carotid canal; in this is lodged the ian ganglion on the sensory root of the V. cranial nerve. External to the of the upper surface, and close to its posterior border, is the elevation ntia arcuata), more or less pronounced, which marks the position of the r semicircular canal here lodged within the bone. A little in front of this, and with the angle formed by the anterior border and the squamous part, is the opening of the **hiatus Fallopii** (hiatus canalis facialis), within the projecting hich two small orifices can usually be seen. These are the openings of the **tus Fallopii** (canalis facialis); if a bristle be passed through the inner of the nings it will be observed to pass into the bottom of the internal auditory if into the outer, it will pass through the aqueduct of Fallopius, and, provided nnel be clear, will appear on the under surface of the bone at the stylo- foramen. Leading forwards and inwards from the hiatus towards the border is a groove; in this lies the great superficial petrosal nerve which out of the hiatus. A small branch of the middle meningeal artery also the bone here. A little external to the hiatus is another small opening a superior canalis tympanici), often difficult to see; from this a groove runs s which channels the upper surface of the roof of the canal for the tensor i muscle. Through this foramen and along this groove passes the lesser ial petrosal nerve. Behind this, and in front of the **arcuate eminence**, the usually thin (as may be seen by holding it up to the light falling through rnal auditory meatus), roofing in the cavity of the tympanum and forming **en tympani**. Externally the line of fusion of the petrous with the squamous often indicated by a faint and irregular petro-squamous fissure.

most conspicuous object on the *posterior surface* of the petrous part of the the **internal auditory meatus** (meatus acusticus internus) about 8 mm. deep dult, which has an oblique oval aperture and leads outwards and slightly rds into the substance of the bone, giving passage to the auditory and erves, together with the pars intermedia and the auditory branch of the rtery. The canal appears to end blindly; but if it be large, or still better, if it be cut away, its fundus will be seen to be crossed by a horizontal ridge, the **crest**, which divides it into two fossæ, the floors of which (laminæ cribrosæ) ced by numerous small foramina for the branches of the auditory nerve and els passing to the membranous labyrinth, whilst in the fore and upper part nigher fossa the orifice of the **Fallopian aqueduct** (canalis facialis), through he facial nerve passes, is seen leading in the direction of the hiatus Fallopii *e*). External to the internal auditory meatus and above it, close to the border, an irregular depression, often faintly marked, with one or two small a opening into it, is to be noticed. This is the **floccular fossa** (fossa subarcuata), n in young bones, where it forms a distinct recess, which is bounded above bulging caused by the superior semicircular canal, within the concavity of t is placed; it lodges a process of the dura mater. Below and external to arated from it by a smooth, elevated curved ridge, is the opening of the **t of the vestibule** (apertura externa aquæductus vestibuli), often concealed row curved fissure overhung by a sharp scale of bone. In this is lodged the ndolymphaticus. The ridge above it corresponds to the upper half of the r semicircular canal.

exions.—The temporal bone articulates with the malar, sphenoid, parietal, and occipital d by a movable joint with the inferior maxilla. Occasionally the temporal articulates frontal, as happens normally in the anthropoid apes; although the region of the ee p. 154) is characterised by an X-like form in the lower races of man there is no that the occurrence of a fronto-squamosal suture is more frequent in the lower than the ces, its occurrence being due to the manner of fusion of the so-called epipteric ossicles surrounding bones.

itecture.—The temporal bone is remarkable for the hardness and density of its petrous rein is lodged the osseous labyrinth which contains the delicate organs associated with of **hearing** and equilibration. The **middle ear** or **tympanum** is a cavity which contains

the small auditory ossicles, and is separated from the external auditory meatus by the mem tympani. *In front* it communicates with the pharynx by the Eustachian tube; *behind*, it into the mastoid antrum and mastoid air-cells by the aditus ad antrum. *Superiorly* separated from the middle cranial foss thin plate of bone called the tegmen ty *Inferiorly*, its floor is formed in part l roof of the jugular fossa and the carotid *Internally*, it is related to the structures form the inner ear, notably the **cochl vestibule**, in front of which it is separate thin plate of bone from the carotid Curving over the cavity of the tympan the aquæductus Fallopii, the thin w which are occasionally deficient. These will be further dealt with in the secti voted to the Organs of Sense.

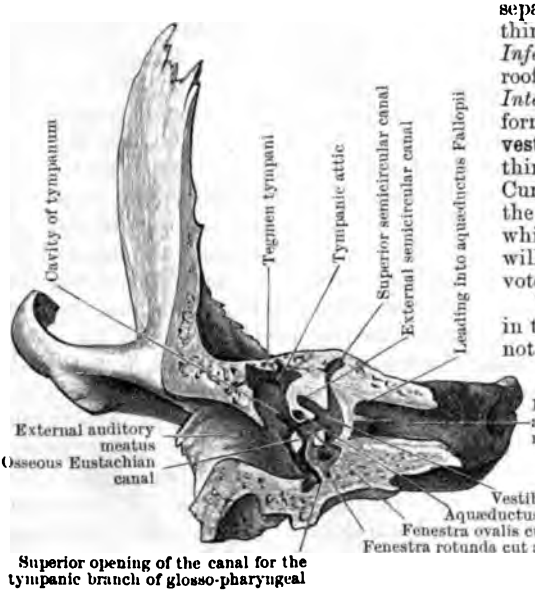

FIG. 91.—VERTICAL TRANSVERSE SECTION THROUGH LEFT TEMPORAL BONE (Anterior Half of Section).

Variations.—The occurrence of a defi in the floor of the external auditory me not uncommon in the adult. It is me commonly in the child till the age of five, and is due to plete ossification of the ty plate. The line of the squamosal suture is occas grooved for the lodgment of (petro-squamosal); sometim posterior end of this is cont with a canal which pierc superior border of the bo opens into the lateral sinus teriorly the groove may pa a canal which pierces the the zygoma and appears ext above the external extremity of the Glaserian fissure. These are the remains of channels t which the blood passed in the fœtal condition (see *ante*). Symington has described a which the squamous part was distinct and separate from the rest of the temporal bone in an adult; whilst Hyrtl has observed the division of the temporal squama into two by a transverse suture. P. P. Laidlaw (*Journ. Anat. and Physiol.* vol. xxxvii. p. 364) describes a temporal bone in which there was absence of the internal auditory meatus and of the stylo-mastoid foramen. The jugular fossa also was absent, and there was partial absence of the groove for the lateral sinus associated with the presence of a large mastoid foramen. An instance of a rudimentary condition of the carotid canal is also referred to in the same volume by G. H. K. Macalister.

G. Caribbe (*Anat. Anz.* vol. xx. p. 81) notes the occurrence in idiots and imbeciles of a more pronounced form of post-glenoid tubercle, and associates it with regressive changes in the development of the temporal bone.

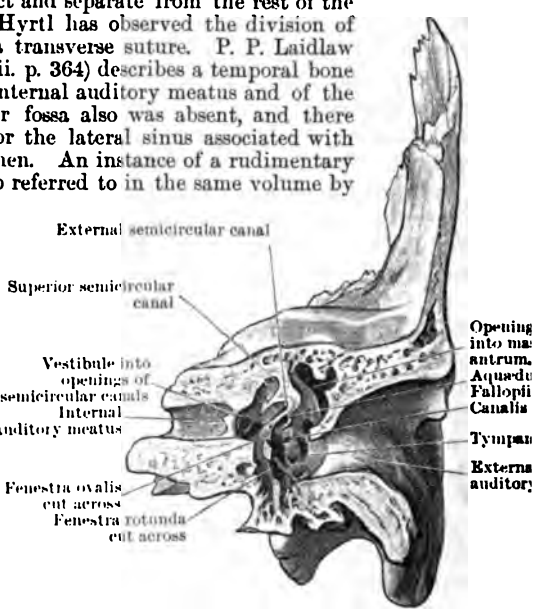

FIG. 92.- VERTICAL TRANSVERSE SECTION THROUGH LE TEMPORAL BONE (Posterior Half of Section).

Ossification.—The petro-mastoid portion of the bone is developed by the deposition of earthy matter in the cartilaginous ear capsule and the perichondrium lining the labyrinth. The squamous and tympanic parts are ossified in membrane.

Ossification commences in the ear capsule in the fifth month, and proceeds so rapidly that by the end of the sixth month the individual centres are more or less fused. Of these, one which appe the vicinity of the eminentia arcuata is the most definite in position and form this a lamina of bone of spiral form is developed, which covers in the inner l the superior semicircular canal, and forms the roof of the internal auditory m together with the commencement of the Fallopian aqueduct. Reaching forwa extends to the apex of the petrous part; whilst externally it forms part of the

single or multiple, appear in the base of the petrous part, and envelop the posterior
ternal semicircular canals. It is by extension from this part that the mastoid process
imately developed. To these centres the terms pro-otic, opisthotic, pterotic, and
, respectively, have been applied by Huxley and others. The **styloid process**, an
endent development from the upper end of the cartilage of the second visceral arch,
fied from two centres. The upper or basal appears before birth, and rapidly unites
the petro-mastoid, the tympanic plate encircling it in front. This represents the
anohyal of comparative anatomy. At birth, or subsequent to it, another centre
rs in the cartilage below the above: this is the **stylohyal**. Ankylosis usually occurs
ult life between the tympanohyal and stylohyal, the union of the two constituting
-called styloid process of human anatomy.

he centre from which the **squamo-zygomatic** develops appears in membrane about
d of the second month. Situated near the root of the zygoma, it extends forwards
utwards into that process, inwards to form the floor of the glenoid fossa, and
ds into the squamosal. From this latter there is a downward and backward exten-
which forms the post-auditory process; this ultimately blends with the posterior limb
tympanic ring, being separated from it in the adult by the auricular fissure. It forms
uter wall of the mastoid antrum, and constitutes the fore and upper part of the
id process in the adult. About the third month a centre appears in the outer
ranous wall of the tympanum: from this the **tympanic ring** is developed. Incom-
above, it displays two free extremities. Of these, the anterior is somewhat enlarged,
unites in front with the glenoid portion of the squamo-zygomatic, being separated
it by the Glaserian fissure and the downgrowth from the tegmen tympani; the
ior joins the post-auditory process of the squamo-zygomatic above mentioned.
, it blends internally with the portion of the petro-mastoid which forms the floor of
mpanum, and ensheathes the tympanohyal behind. From the outer side of the
part of this ring two tubercles arise; these grow outwards, and so form the floor
e external auditory meatus. The interval between them remains unossified till
the age of five or six, after which closure takes place. This deficiency may, how-
persist even in adult life (see *ante*, Variations).

birth the temporal bone can usually be separated into its component parts. The

outer surface of the petrous part not only forms the inner wall of the tympani hollowed out behind and above to form the inner side of the mastoid an outer wall of which is completed by the post-auditory process of the squamo- As yet the mastoid process is undeveloped. It only assumes its nipple-like form second year. Towards puberty its cancellous tissue becomes permeated with

which are in communication with and extensions from the mastoid antrum. Th auditory meatus is unossified in front and below, the outgrowth from the tym occurring subsequent to birth. The glenoid fossa is shallow and everted; th fossa is ill-marked; whilst the subarcuate fossa is represented by a deep pit, th flocculer fossa of comparative anatomy. The hiatus Fallopii is an open groove, at either end the openings of the inner and outer portions of the Fallopian aque

THE SPHENOID BONE.

The **sphenoid bone** (os sphenoidale) lies in front of the basi-occipital and the temporals on either side. It enters into the formation of the orbital, and nasal cavities, as well as the temporal, zygomatic, pteryg spheno-maxillary fossæ. It consists of a body with three pairs of expan cesses, the great wings, the lesser wings, and the pterygoid processes.

The **body** (corpus), more or less cubical in form, is hollow, and contain it the two large **sphenoidal air sinuses**. These are separated by a partitio is usually deflected to one or other side of the middle line. Each sinus outwards for a short distance into the root of the great wing, and downw outwards towards the base of the pterygoid process of the same side communicate by apertures with the upper and back part of the nasal fossæ. adult the *posterior aspect* of the body displays a sawn surface due to its se from the basi-occipital with which in the adult it is firmly ankylosed. The *surface*, from the fore angles of which the lesser wings arise, displays an ap comparable to that of an oriental saddle, over its middle there is a deep de the **sella turcica** or **pituitary fossa** (fossa hypophyseos), in which is lod pituitary body. Behind, this is overhung by a sloping ridge, the **dorsum** posterior surface of which is inclined upwards, and is in continuation v basilar groove of the occipital bone. Anteriorly and externally the angle ridge project over the pituitary fossa in the form of prominent tubercles, ca **posterior clinoid processes** (processus clinoidei posteriores). In front of the p fossa there is a transverse elevation, the **olivary eminence** (tuberculum towards the outer extremities of which, and somewhat behind, there ar

s little spurs of bone, the **middle clinoid processes** (processus clinoidei medii). ront of the olivary eminence is the **optic groove** (sulcus chiasmatis), which es outwards on either side to become continuous, between the roots of the r wings, with the optic foramina.

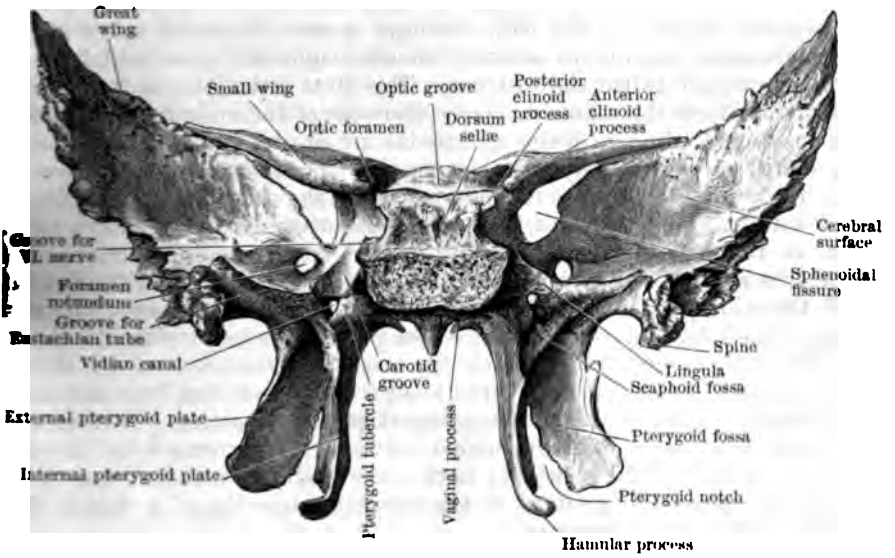

FIG. 95.—SPHENOID AS SEEN FROM BEHIND.

This groove is liable to considerable variations, and apparently does not always serve for the ment of the optic chiasma. (Lawrence, "Proc. Soc. Anat.," *Journ. Anat. and Physiol.* xxviii. p. 18.)

In front of the optic groove, from which it is often separated by a thin sharp edge, superior surface continues forwards on the same plane as the upper surfaces of

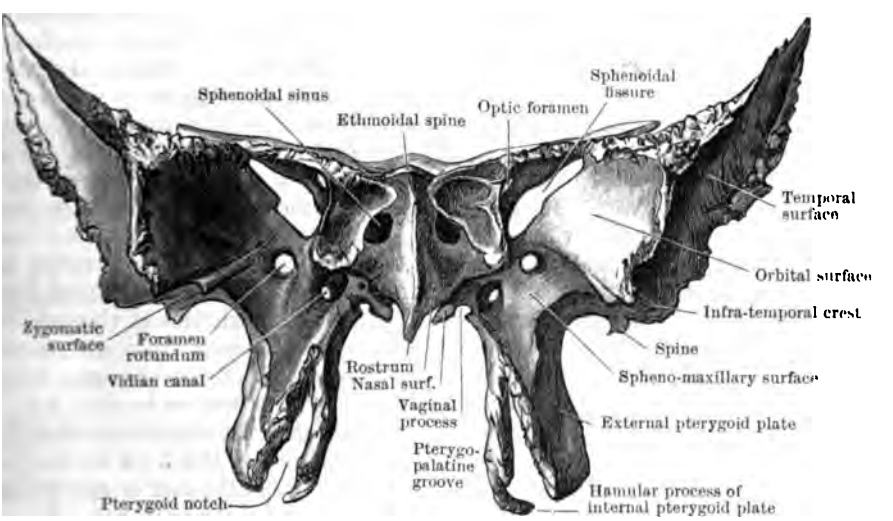

FIG. 96.—SPHENOID AS SEEN FROM THE FRONT.

he lesser wings, and terminates anteriorly in a ragged edge, which articulates with he cribriform plate of the ethmoid, and has often projecting from it, mesially, a inted process, the **ethmoidal spine**. The *lateral aspects* of the body are fused ith the great wings, and in part also with the roots of the pterygoid processes. urving along the side of the body, superior to its attachment to the great wing, an *S*-shaped groove, the **carotid groove** (sulcus caroticus), which marks the

position and course of the internal carotid artery. Posteriorly, the hinder mar of this groove, formed by the salient outer edge of the posterior surface of body, articulates with the apex of the petrous portion of the temporal bone, is hence called the **petrosal process**; just above this, on the lateral border of dorsum sellæ, there is often a groove for the sixth nerve.

The *anterior surface* of the body displays a vertical mesial **sphenoidal** (crista sphenoidalis), continuous above with the ethmoidal spine, and below w the pointed projection called the rostrum. This crest articulates in front with perpendicular plate of the ethmoid. On either side of the middle line are seen irregular openings leading into the sphenoidal air sinuses, the thin anterior w of which are in part formed by the absorption of the sphenoidal turbinated bo with which in early life they are in contact. With the exception of a broad gro leading downwards from the apertures above mentioned, which enters into formation of the roof of the nasal fossa of the corresponding side, the lat aspects of this surface of the bone are elsewhere in articulation with the lat masses of the ethmoid and the orbital processes of the palate bones. The rost is continued mesially for some distance along the *inferior surface* of the bo where it forms a prominent keel which fits into the recess formed by the ala the vomer. The edges of the latter serve to separate the rostrum from the incur vaginal processes at the roots of the internal pterygoid plates. Posteriorly under surface of the body of the sphenoid is rougher, and covered by the muc membrane of the roof of the pharynx; here, occasionally, a median depression be seen which marks the position of the inferior extremity of a fœtal chan called the **canalis cranio-pharyngeus.**

The **lesser** or **orbital wings** (alæ parvæ) are two flattened triangular plate bone which project forwards and outwards from the fore and upper part of body of the bone, with which they are united by two roots which enclose betw them the **optic foramina** (foramina optica) for the transmission of the optic ner and ophthalmic arteries. Of these roots, the posterior springs from the body wide of the olivary eminence, separating the carotid groove behind from the o foramen in front; externally this root is confluent with the recurved posterior a of the lesser wing, forming the projection known as the **anterior clinoid proc** (processus clinoideus anterior), which overhangs the fore part of the body of bone. The anterior root, broad and compressed, unites the upper surface of lesser wing with the fore and upper part of the body. Externally the ou angle terminates in a pointed process which reaches the region of the pterion there articulates with the frontal, and may come in contact with the great wi The superior aspect is smooth, and forms in part the floor of the anterior cra fossa. The inferior surface constitutes part of the posterior portion of the up wall of the orbit, and also serves to roof in the **sphenoidal fissure** which separa the lesser from the greater wings below. The anterior edge is ragged and irregul and articulates with the orbital plates of the frontal. The posterior marg sharp and sickle-shaped, separates the anterior from the middle cranial fossa, corresponds to the position of the Sylvian fissure on the surface of the cerebrum.

The **greater** or **temporal wings** (alæ magnæ), as seen from above, are of somewhat crescentic form. If the inner convex edge of the crescent be divid into fifths, the posterior fifth extends backwards and outwards beyond the body the bone, presenting a free posterior edge, which forms the anterior boundary of t foramen lacerum medium. This border ends behind in the horn of the cresce from which a pointed process projects downwards, called the **alar** or **sphenoidal spi** (spina angularis), this is wedged into the angle between the petrous and squamo parts of the temporal bone. The inner surface of the posterior border and spine furrowed for the cartilaginous **Eustachian tube** (sulcus tubæ), whilst on the inn side of the spine the course of the chorda tympani nerve is indicated by a groo (Lucas). The second fifth of the convex border of the crescent is fused to the si of the body and united below with the root of the pterygoid process. The ang formed by the union of the great wing with the side of the body posteriorly corr sponds to the hinder end of the carotid groove, the outer lip of which is formed b a projecting lamina called the **lingula.** The remaining three-fifths of the conve

r is divisible into two nearly equal parts; the inner is a free, curved, sharp n, which forms the inferior margin of the **sphenoidal fissure** (fissura orbitalis ior), the cleft which separates the great wing from the lesser wing, and which lishes a wide channel of communication between the middle cranial fossa and avity of the orbit, transmitting the third, fourth, ophthalmic division of the and the sixth cranial nerves, together with the ophthalmic veins. Wide of phenoidal fissure this edge becomes broad and serrated, articulating with the al bone internally, and at the part corresponding to the anterior horn of the ent, by a surface of variable width, it unites with the anterior inferior angle e parietal bone. The *external border* corresponds to the concave side of rescent, and is serrated for articulation with the squamous temporal, being and bevelled at the expense of its outer surface above and externally, and l and thick behind as it passes towards the alar spine. The *superior* or *al surface* is concave from behind forwards, and in its fore part from side to also; it forms a considerable part of the floor of the middle cranial fossa, and the impress of the convolutions of the extremity of the temporal lobe of the rum which rests upon it; towards its outer side it is grooved obliquely by an ior branch of the middle meningeal artery. The following foramina pierce great wing: close to and in front of the alar spine is the **foramen spinosum** he transmission of the middle meningeal artery and its companion vein, ber with a recurrent branch from the third division of the V. nerve. In of and internal to this, and close to the posterior free border, is the men ovale, of large size and elongated form. This gives passage to the r root and inferior sensory division of the V. nerve, and admits the small ngeal branch of the middle meningeal artery; a small emissary vein from the nous sinus usually passes through this foramen, and occasionally also the l superficial petrosal nerve. Near the fore part of the root of the great wing, just below the sphenoidal fissure, is the **foramen rotundum**, of smaller size and lar form. Through this the second division of the V. nerve escapes from the ium. Occasionally there is a small canal—the **foramen of Vesalius**—which es the root of the great wing to the inner side of the foramen ovale. This s below into the scaphoid fossa at the base of the internal pterygoid plate, and mits a small vein. Occasionally there is a small foramen (canaliculus minatus) to the inner side of the foramen spinosum for the transmission of mall superficial petrosal nerve.

The *outer surface* of the great wing is divided into three well-marked areas; of e the upper two are separated by an oblique jagged ridge, the **malar crest** go zygomaticus), for articulation with the orbital process of the malar bone. lower part of this ridge may occasionally articulate with the malar process of superior maxilla. Of these two areas the **orbital** (facies orbitalis) is directed ards and a little inwards; of quadrilateral shape, it forms the back and outer of the orbit; plane and smooth, it is bounded behind by the sharp inferior margin of the sphenoidal fissure, towards the inner extremity of which a ted spine for the attachment of the inferior common ligament of origin of the ar muscles can usually be seen. It is limited superiorly by the edge of a rough gular area which articulates with the frontal bone; anteriorly by the malar t; whilst inferiorly a free, well-defined horizontal margin constitutes the erior and external boundary of the spheno-maxillary fissure (fissura orbitalis rior), which separates this part of the bone from the orbital plate of the superior illa. Below this border there is a grooved surface which leads inwards toward orifice of the foramen rotundum. In the articulated skull this forms part of posterior wall of the spheno-maxillary fossa.

To the outer side of the malar crest, which bounds it in front, is the **temporal** (facies temporalis), concavo-convex from before backwards. It slopes inwards w, where it is separated from the zygomatic area by a well-marked muscular e, the **infra-temporal crest** or **pterygoid ridge** (crista infratemporalis). Behind, temporal surface is bounded by the margin of the great wing which articulates the squamous temporal, and above by the edge which unites it with the rior inferior angle of the parietal and the frontal bone. The temporal surface

enters into the formation of the floor of the fossa of the same name, and affords extensive attachment to the fibres of origin of the temporal muscle. The **zygomatic surface** (facies infratemporalis), situated below the infra-temporal crest, corresponds to the under surface of the posterior half of the great wing; it extends as far back as the alar spine and posterior border. Opening on it are seen the orifices of the foramen spinosum and ovale. It is slightly concave from side to side, and is confluent internally with the outer surface of the external pterygoid plate. In front it is bounded by a ridge which curves upwards and outwards from the front part of the external pterygoid plate to join the infratemporal crest. In the articulated skull this ridge forms the posterior boundary of the pterygo-maxillary fissure. The zygomatic surface overhangs the zygomatic fossa, and affords an origin for the upper head of the external pterygoid muscle.

The **pterygoid processes** (processus pterygoidei) spring from the inferior surface of the lateral aspect of the body as well as the under side of the root of the great wings, and pass vertically downwards. Each consists of two laminæ, the external and internal pterygoid plates, fused together anteriorly, and enclosing between them posteriorly the **pterygoid fossa** (fossa pterygoidea). The **external pterygoid plate** (lamina lateralis processus pterygoidei), thin and expanded, is directed obliquely backwards and outwards, its lower part being often somewhat everted. Its hinder edge is sharp, and often has projecting from it one or two spines, to one of which (processus pterygo-spinosus) the pterygo-spinous ligament which stretches towards the alar spine is attached. Externally it furnishes an origin for the lower head of the external pterygoid muscle, and on its inner side where it forms the lateral wall of the pterygoid fossa, it supplies an attachment to the internal pterygoid muscle.

The **internal pterygoid plate** (lamina medialis processus pterygoidei) is narrower and somewhat stouter. By its inner aspect it forms the posterior part of the lateral wall of the nasal fossæ; externally it is directed towards the pterygoid fossa. Its posterior edge ends below in the hook-like **hamular process** (hamulus pterygoidei), which, reaching a lower level than the external plate, curves backwards and outwards, furnishing a groove in which the tendon of the tensor palati muscle glides; superiorly, the sharp posterior margin of the inner plate bifurcates so as to enclose the shallow **scaphoid fossa** from which the tensor palati muscle arises, and wherein may occasionally be seen the inferior aperture of the foramen Vesalii. To the inner edge of this fossa, as well as to the posterior border of the internal pterygoid plate, the pharyngeal aponeurosis is attached. Here, too, the cartilage of the Eustachian tube is supported on a slight projection, and the palato-pharyngeus muscle receives an origin, whilst the superior constrictor of the pharynx arises from the lower third of the same border and from the hamular process. Superiorly and internally the inner plate forms an incurved lamina of bone, the **vaginal process** (processus vaginalis), which is applied to the under surface of the lateral aspect of the body reaching inwards, towards the root of the rostrum, from which, however, it is separated by a groove, in which, in the articulated skull, the ala of the vomer is lodged. The angle formed by the vaginal process and the internal edge of the scaphoid fossa forms a projection called the **pterygoid tubercle**, immediately above which is the posterior aperture of the **Vidian canal** (canalis pterygoideus), through which the Vidian nerve and artery are transmitted. On the under surface the vaginal process displays a groove (sulcus pterygo-palatinus), which in the articulated skull is converted into the **pterygo-palatine canal** by its union with the palate bone. In front, at its root, the pterygoid process displays a broad smooth surface (facies spheno-maxillaris), which is confluent above with the root of the great wing around the foramen rotundum, and forms the posterior wall of the spheno-maxillary fossa. Here, to the inner side of the foramen rotundum, is seen the anterior opening of the **Vidian canal**. Below, the pterygoid plates are separated by an angular cleft, the **pterygoid notch** (fissura pterygoidea); in this is lodged the tuberosity of the palate bone, the margins of which articulate with the serrated edges of the recess.

Connexions.—The sphenoid articulates with the occipital, temporals, parietals, frontal

sphenoidal turbinals, vomer, palate and malar bones, and occasionally with the superior

itecture.—In the adult the body of the bone is hollow and encloses the sphenoidal air
ally two in number, separated by a septum. The arrangement and extent of these air
; sometimes they are multilocular, at other times simple, while occasionally they extend
is into the basi-occipital and outwards and downwards into the roots of the great wings
goid processes. Cases are on record in which in the adult the body of the bone was not
ic.

stions.—Through imperfect ossification the foramen spinosum and foramen ovale are
s incomplete posteriorly. Le Double (*Bull. et mém. de la Soc. d'Anth. de Paris*, 5e ser.
. 550), records a case in which the foramen rotundum and the sphenoidal fissure were
as to form a single cleft.

ugh deficiency of its external wall, the optic foramen, in rare instances, communicates
sphenoidal fissure. Duplication of the optic foramen is also recorded as a rare
e, the artery passing through one canal, the nerve through the other. Persistence of
o-pharyngeal canal is also occasionally met with. On the other hand, owing to the
n of fibrous bands connecting the several bony points, anomalous foramina are
y met with. Cases of persistence of the cranio-pharyngeal canal have been

ification.—The sphenoid of man is formed by the fusion of two parts, the **pre-**
l and the **post-sphenoid**, each associated with certain processes. In most mammals
to-sphenoids or lesser wings fuse with the pre-sphenoid, whilst the alisphenoids or
wings, together with the internal pterygoid plate, ankylose with the post-sphenoid.
fication of these several parts takes place in cartilage, with the exception of the
pterygoid plate, which is developed from an independent centre in the connective
the lateral wall of the oral cavity (Hertwig).

he end of the second month a centre appears in the root of the great wing between
men ovale and foramen rotundum; from this the ossification spreads outwards and
ds and also downwards into the external pterygoid plate. Meanwhile two centres
bout the same time in the basi-sphenoid in relation to the floor of the sella turcica and
r side of the cranio-pharyngeal canal, around which they ossify, ultimately leading
bliteration of this channel. Somewhat later a centre appears on either side, from
ie lateral aspect of the body and the lingula are developed. Fusion between these
tres is usually complete by the sixth month.

he pre-sphenoid a pair of lateral nuclei make their appearance about the middle of
d month, just external to the optic
a; from each of these the orbito-
ls (lesser wings) and their roots are
ed. About the same time another
centres, placed mesial to the optic
a, constitute the body of the pre-
d. By the coalescence of these in
nd their ultimate union with the basi-
d behind, a cartilaginous interval is
l, of triangular shape, which, however,
s gradually reduced in size by the
h of its margins so as to form two
r-placed foramina, as may be fre-
observed in young bones—one open-

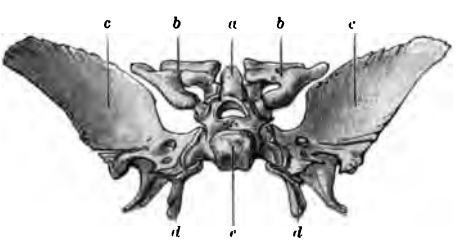

FIG. 97.—OSSIFICATION OF SPHENOID.

the surface of the olivary eminence, the other being placed anteriorly. (Lawrence, Soc. Anat.," *Journ. Anat. and Physiol.* vol. xxviii. p. 19.)

as been seen, the internal pterygoid plates are developed in membrane and are the first the sphenoid to ossify. (Fawcett, *Anat. Anz.*, vol. xxvi. 1905, p. 280.) Each is derived ingle nucleus which appears about the ninth or tenth week, and fuses with the under of the great wing, there forming a groove which is converted into the Vidian canal he alisphenoid and internal pterygoid plates fuse later with the body of the post- d. The hamular process, however, chondrifies before it ossifies during the third

Fawcett also regards the external pterygoid plate as of membranous origin.

birth the sphenoid consists of three parts: one comprising the orbito-sphenoids r with the body of the pre-sphenoid and the basi-sphenoid, the others consisting of phenoids, one on either side. Fusion of the latter with the former occurs near the the first year. The dorsum sella at birth consists of a cartilaginous plate which es the body of the post-sphenoid from the basi-occipital. This slowly ossifies, but ilage does not entirely disappear till the age of twenty-five, by which time bony anky- the basi-cranial axis is complete. For a considerable time the under surface of the

body of the pre-sphenoid displays a bullate appearance, with the sides of which sphenoidal turbinated bones articulate. It is only after the seventh or eighth year reached that the cancellous tissue within this part of the bone becomes absorbed to the sphenoidal sinuses.

The **sphenoidal turbinals** (conchæ sphenoidales), or bones of Bertin, best studied childhood, are formed by the fusion of four distinct ossicles (Cleland), the centres which appear in the later months of utero-gestation. Each bone consists of a hollow, three sided pyramid, the apex of which is in contact with the fore part of the vaginal process the internal pterygoid, whilst the base fits on to the posterior surface of the lateral mass of the ethmoid. The *inferior surface* of each forms the roof of the corresponding nasal fossa, and completes the formation of the spheno-palatine foramen, whilst the external aspect is united with the palate bone and forms the inner wall of the spheno-maxillary fossa, and occasionally constitutes a part of the orbital wall posterior to the os planum the ethmoid. The *superior surface* of the sphenoidal turbinal is applied to the fore under surface of the body of the pre-sphenoid on either side of the rostrum. It is by absorption of this wall that the sphenoidal sinuses are ultimately opened up. The of the pyramid forms the aperture through which each of these sinuses opens into nasal fossæ in the adult. Owing to their firm ankylosis with the surrounding bones, ossicles are merely represented in the adult disarticulated skull by the irregular fragments adherent to the separated borders of the ethmoid, palate, and sphenoid bones.

The Ethmoid Bone.

The **ethmoid bone** (os ethmoidale) lies in front of the sphenoid, and occupies the interval between the orbital plates of the frontal, thus entering into the formation of the anterior cranial fossa as well as the inner walls of the orbits and roof and inner and outer walls of the nasal fossæ. The bone, which is extremely light, consists of two cellular parts—the **lateral masses**, which are united superiorly to a mesial **vertical plate** by a thin horizontal lamina which, from its perforated condition, is called the **cribriform plate**.

The study of this bone will be much facilitated by cutting through the cribriform plate on one side of the vertical plate, thus removing the lateral mass of one side exposing more fully the central perpendicular lamina.

The **vertical plate** (lamina perpendicularis), of irregular pentagonal shape, forms the upper part of the nasal septum. Its superior border projects above the level of the cribriform plate so as to form a crest, which is much elevated anteriorly, where it terminates in a bullate process called the **crista galli**, the upper edge of which is sharp and pointed, and affords attachment to the falx cerebri. In front of this process there is a groove which separates the **alar processes** (processus alares) which project from the crista galli on either side. By articulation with the frontal bone this groove is converted into a canal, the **foramen cæcum**; this, however, is not always blind, but frequently transmits a vein to the roof of the nose. The *posterior margin* of the vertical plate is thin, and articulates with the crest of the sphenoid.

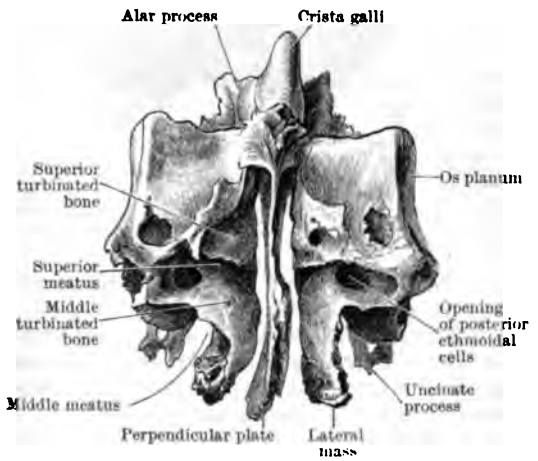

Fig. 98.—Ethmoid as seen from Behind.

The *posterior inferior border* in the adult is ankylosed with the vomer; at the *anterior inferior edge*, which is usually thicker than the others, unites with the cartilaginous nasal septum. The *anterior superior border* articulates with the nasal spine of the frontal bone and with the median crest formed by the union of the two nasal bones. The vertical plate, which is usually deflected to one or other side, has generally smooth *surfaces*, except above, where they are channelled

nd **shallow grooves** leading to the foramina which pierce the cribriform plate; re for the lodgment of the olfactory nerves.

: **lateral mass** or **labyrinth** (labyrinthus) is composed of papery bone, ng a large number of air-cells; these are arranged in three groups—an r, a middle, and rior, the walls of have been broken it, above, behind, elow, in the pro- f disarticulation. ally they are in by a thin, ob- mina, the **orbital** or **os planum** ia papyracea), forms a part of ner wall of the and articulates with the orbital of the frontal, here roofs in the dal cells. The line of this suture is pierced by two canals, the **anterior** and **or ethmoidal canals**, both of which transmit small ethmoidal vessels, whilst terior also gives passage to the nasal nerve. *In front* the os planum articu- ith the lachrymal bone; whilst *below*, by its union with the orbital surface superior maxillary bone, the air-sinuses in both situations are completed. *orly* the os planum articulates with the sphenoid, and at its posterior r angle for a variable distance with the orbital process of the palate bone, f which serve to close in the air-cells. The *mesial aspect* of the **lateral mass** s the convoluted **turbinated processes**, usually two in number, though nally there may be three—rarely more. In cases where there are two **turbinals** they are separated posteriorly by a deep groove. A channel is rmed in the back part of the lateral and upper aspect of the nasal fossæ, the **superior meatus**, which is roofed in by the superior **turbinated process** a superior), whilst its floor is formed by the upper surface of the **middle ated process** (concha media). The posterior ethmoidal cells open into this meatus. In front of the superior meatus, which only grooves the posterior half of this aspect of the bone, the surface is rounded from above downwards and before backwards, and forms the inner wall of the anterior and middle ethmoidal cells. Running obliquely from above downwards and backwards over the mesial surface of the superior concha, are a number of fine grooves continuous above with the foramina in the cribriform plate; these are fewer and more scattered in front, do not pass on to the middle concha, and are for the olfactory nerves.

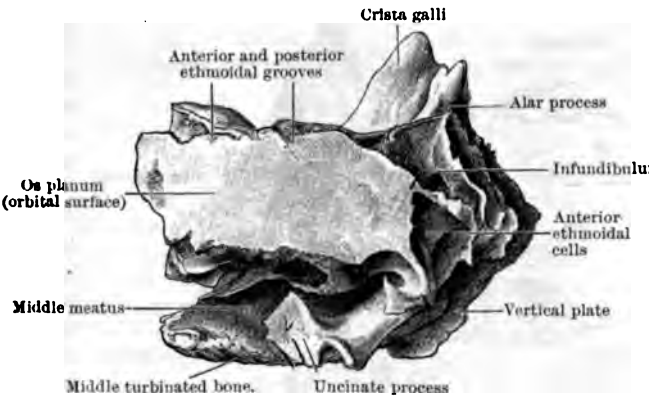

FIG. 99.—ETHMOID AS SEEN FROM THE RIGHT SIDE.

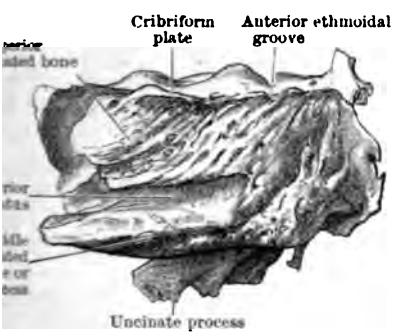

90.—SECTION SHOWING NASAL ASPECT OF LEFT LATERAL MASS OF ETHMOID.

The **middle turbinated process** (concha) is nearly twice the length of the superior. Its anterior extremity is united short distance to the superior turbinated crest on the inner side of the l process of the superior maxilla. By its thickened, free convoluted border hangs a deep groove which runs along the under surface of the lateral mass. s the **middle meatus of the nose**. It receives the openings of the middle idal cells and a passage which runs upwards and forwards from it, the ibulum. This communicates with the anterior ethmoidal cells and the l sinus. The outer side of the middle meatus is formed by the thin inner

walls of the ethmoidal cells. Curving downwards, backwards, and a litt
wards from the roof of the fore-part of this meatus is the **uncinate proce**
cessus uncinatus). This bridges across the irregular opening on the inner
the maxillary sinus, and
lates inferiorly with th
moidal process of the i
turbinated bone. The
extremity of the middle
ated bone articulates wi
ethmoidal crest on the
plate of palate bone.

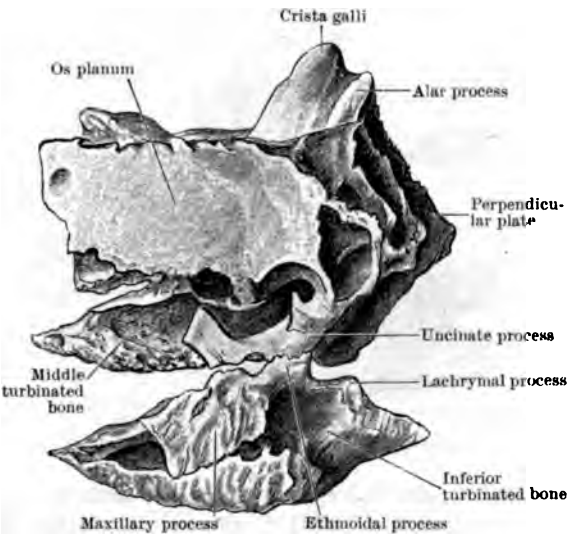

FIG. 101.—SHOWING ARTICULATION OF INFERIOR TURBINATED BONE WITH ETHMOID.

The **cribriform plate** (
cribrosa) is the hor
lamina which connect
lateral masses with the
plate, much in the same
as the cross limb of a ca
is arranged. It occupi
interval between the
plates of the frontal
roofing in the nasal fos
feriorly, and superiorly f
on either side of the crist
two shallow **olfactory groo**
which, in the recent con
the olfactory lobes of th
brum are lodged. Numerous foramina for the transmission of the olfactory
pierce this part of the bone; those to the inner and outer sides of the
are the largest and most regular in their arrangement. Along the outer edges of the cribriform plate two notches can usually be distinguished; when articulated with the frontal bone these form the inner openings of the **ethmoidal canals**. Leading forward from the anterior of these there is often a groove which crosses to the side of the crista galli, where it ends in a slit which allows of the transmission of the nasal nerve to the nose. Posteriorly the cribriform plate articulates with the ethmoidal spine of the sphenoid.

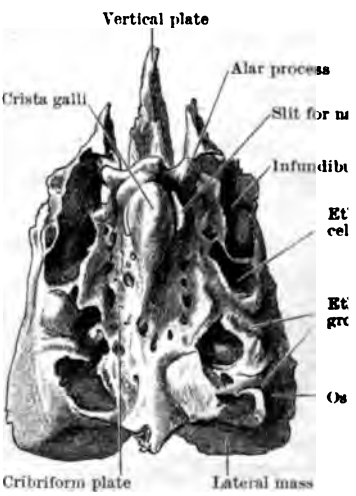

FIG. 102.—ETHMOID AS SEEN FROM

Connexions.—The ethmoid articulates with the sphenoid and sphenoidal turbinals, the frontal, the two nasals, two superior maxillæ, two lachrymals, two inferior turbinals, two palates, and the vomer.

Variations.—The size of the os planum is liable to considerable variations. In the lower races it tends to be narrower from above downwards than in the higher, in this respect resembling the condition met with in the anthropoids. The os planum may fail to articulate with the lachrymal owing to the union of the frontal with the orbital proce superior maxilla in front of it. (Orbito-maxillary frontal suture. A. Thomson, *Jour and Physiol.* vol. xxiv. p. 349.) Division of the os planum by a vertical suture into an and posterior part has been frequently recorded. The number of the turbinals may be i from two to four, or may be reduced to one. (Report of Committee of Collect. Invest. *Anat. and Physiol.*, vol. xxviii. p. 74.)

Ossification takes place in the cartilage of the nasal capsule. Each lateral n one centre, which appears about the fourth or fifth month in the neighbourhood os planum. From this the laminæ around the ethmoidal air cells are formed wl complete at birth, the air-sinuses in this instance not being formed by the abs of cancellous bone. From these centres the turbinals are also developed, and the are ossified at the ninth month.

At birth the ossified lateral masses are united to the central cartilaginous plate by a mous layer. Two centres make their appearance in the mesial cartilage on either side the root of the crista galli about the end of the first year; from these, the crista galli d the vertical plate are ossified as well as the mesial part of the cribriform plate, the teral portions of which are derived from an inward extension of the lateral mass.

Ossification is usually complete about the fifth or sixth year. About the twenty-fifth ar bony union has taken place between the cribriform plate and the sphenoid, but kylosis between the vertical plate and the vomer is not usual till the fortieth or forty-th year.

Wormian Bones.

Along the line of the cranial sutures and in the region of the fontanelles, isolated nes of irregular form and variable size are occasionally met with. These are the called Wormian bones, named after the Danish anatomist Wormius. They are also ed sutural or epactal bones. Their presence depends on the fact that they are either veloped from distinct ossific nuclei, or it may be from a division of the primary ossific posit. Their occurrence may also be associated with certain pathological conditions ich modify the development of the bone. They usually include the whole thickness the cranial wall, or it may be only involve the outer or inner tables of the cranial nes. They are most frequent in the region of the lambda and the lambdoid suture. y occur commonly about the pterion, and in this situation are called epipteric bones lower). By their fusion with one or other of the adjacent bones they here lead to the currence of a fronto-squamosal suture. Their presence has also been noted along the se of the sagittal suture, and sometimes in metopic skulls in the inter-frontal suture. ey are occasionally met with at the asterion and more rarely at the obelion. They pear less frequently in the face, but their presence has been noted around the lachrymal ne, and also at the extremity of the spheno-maxillary fissure, where they may form an dependent nodule wedged in between the great wing of the sphenoid, the malar, and e superior maxillary bones.

BONES OF THE FACE.

The bones of the face (ossa faciei), fourteen in number, comprise two superior axillæ, two palates, two malars, two lachrymals, and two nasals, together with the omer and inferior maxilla.

The Superior Maxillary Bones.

The **superior maxillæ** (maxillæ), of which there are two, unite to form the pper jaw. Each consists of a **body**, with which are connected four projections, named respectively the **zygomatic, frontal, alveolar**, and **palatal processes.**

The **body** (corpus) is of pyramidal form, and contains within it a hollow called the **antrum** or **maxillary air-sinus**. It has four surfaces—an antero-external or facial, a postero-external or zygomatic, a supero-external or orbital, and an internal or nasal. The *antero-external* or **facial surface** (facies anterior) is confluent below with the alveolar process. Above, it is separated from the orbital aspect by the **infraorbital margin** (margo infraorbitalis), whilst internally it is limited by the free margin of the **nasal notch**, which ends below in the pointed **anterior nasal spine** (spina nasalis anterior). Posteriorly it is separated from the zygomatic surface by the inferior border of the **zygomatic process**. The facial aspect of the bone is ridged by the sockets of the teeth (juga alveolaria). The ridge corresponding to the root of the canine tooth is usually the most pronounced; internal to this, and overlying the roots of the incisor teeth, is the shallow **incisive** or **myrtiform fossa**, whilst placed externally, on a higher level, is the deeper **canine fossa**, the floor of which is formed in part by the projecting zygomatic process. Above this, and near the infraorbital margin, is the **infraorbital foramen**, the external opening of the infraorbital canal, which transmits the infraorbital nerve and artery. The *postero-external* or **zygomatic surface** is separated above from the orbital aspect by a rounded free edge, which forms the anterior margin of the **spheno-maxillary fissure** in the articulated skull. Inferiorly and in front it is separated from the facial surface by the zygomatic process and its free lower border. Internally it is limited

by a sharp, irregular margin with which the palate bone articulates. This s
is more or less convex, and is directed towards the zygomatic and spheno-max
fossæ. It is pierced in a downward direction by the apertures of the **pos**
dental canals (fora
alveolaria), two
more in number, t
transmit the c
sponding nerves
vessels to the t
teeth. Its lower
slightly more p
nent where it overl

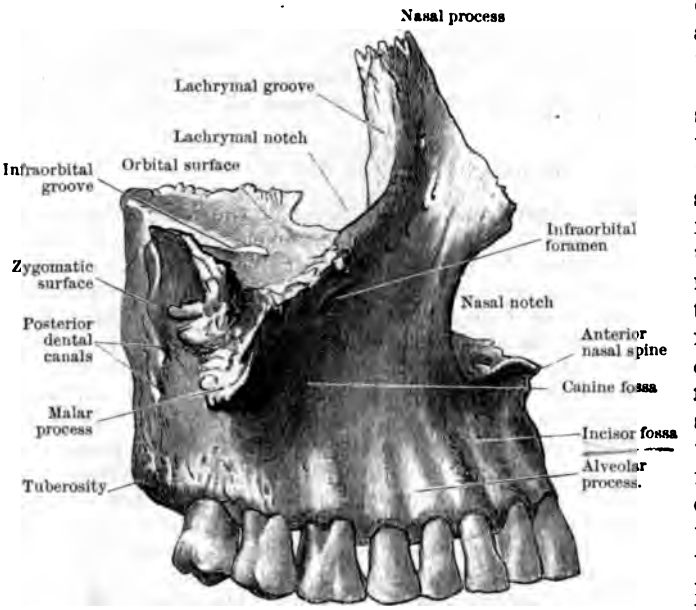

FIG. 103.—RIGHT SUPERIOR MAXILLA (Outer View).

of the spheno-maxillary fissure. Its thin inner edge, which may be regarded a
base of the triangle, is notched in front to form the **lachrymal groove** (sulcus
malis), behind which it articulates with the lachrymal bone for a short dist
then for a greater length with the os planum of the ethmoid, and terminates posteriorly in a surface for articulation with the orbital process of the palate bone. Its external angle corresponds to the outspring of the zygomatic process. Traversing its substance is the **infraorbital canal**, the anterior opening of which has been already noticed on the facial aspect of the body. Behind, however, owing to deficiency of its roof, the canal forms a groove which lips the edge of the bone which constitutes the anterior boundary of the spheno-maxillary fissure. If this canal be laid open, the orifices of the middle and anterior dental canals will be seen, which transmit the corresponding vessels and nerves to the bic
and incisor teeth. The *inner* or **nasal surface** (facies nasalis) of the bc
directed inwards towards the nasal fossæ. Below it is confluent with the

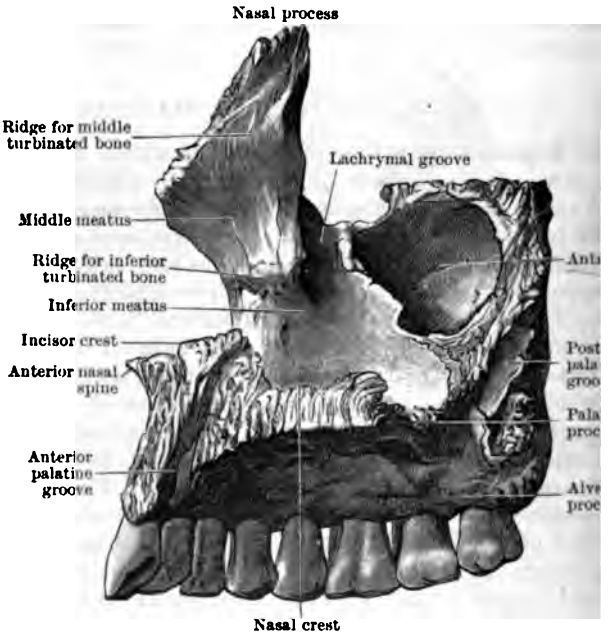

FIG. 104.—RIGHT SUPERIOR MAXILLA (Inner Aspect).

of the palatal process; in front it is limited by the sharp edge of the notch; above and in front it is continuous with the inner surface of the process; behind this it is deeply channelled by the **lachrymal groove**, which erted into a canal by articulation with the lachrymal and inferior turbinated

The channel so formed conveys the nasal duct from the orbital cavity to the inferior nasal meatus below. Behind this groove the upper edge of ea corresponds to the inner margin of the orbital surface, and articulates efore backwards with the lachrymal, os planum of the ethmoid, and the process of the palate bone. The posterior border, rough for articulation he palate bone, is traversed obliquely from above downwards and slightly ls by a groove, which, by articulation with the palate bone, is converted into sterior palatine or **palato-maxillary canal** which transmits the descending pala- rtery and great palatine nerve. Towards its upper and hinder part the nasal e of the body displays the irregular, more or less triangular, opening of the a (sinus maxillaris). This aperture, which, in the articulated skull opens ne middle meatus of the nose, is much reduced in size by articulation with achrymal, ethmoid, palate, and inferior turbinal bones. In front of the mal groove the inner surface is ridged horizontally by the **inferior turbinated** crista conchalis), to which the inferior turbinated bone is attached. Below he bone forms the outer wall of the inferior nasal meatus, receiving the ation of the lachrymal groove. Above, and for some little distance also on ner side of the frontal process, it constitutes the smooth outer wall of the of the middle meatus.

ne **zygomatic** or **malar process** (processus zygomaticus), which is placed on ter surface of the body, is confluent anteriorly with the facial surface of the posteriorly, where it is concave from side to side, with the zygomatic surface; superiorly, where it is rough and articular, it forms the apex of the triangular l plate, and supports the malar bone. Inferiorly, its anterior and posterior es meet to form an arched border, which fuses with the alveolar process ite the root of the first molar tooth, and serves to separate the facial from the atic aspects of the body.

ne **frontal** or **nasal process** (processus frontalis) rises from the upper and art of the body. It has two surfaces—one external, the other internal. The *al* is divided into two by a vertical ridge (crista lachrymalis anterior), which upward extension of the infraorbital margin. The narrow strip of bone l this ridge is hollowed out, and leads into the lachrymal groove below. riorly the edge of the frontal process here articulates with the lachrymal, and ms the fossa for the lodgment of the lachrymal sac (fossa sacci lacrimalis). ont of the vertical crest, to which the tendo oculi is attached, the external e is confluent below with the facial aspect of the body, and forms the side of ot of the nose. Its anterior edge is rough, or grooved, for articulation with asal bone. Superiorly the summit of the process is serrated for articulation he nasal notch of the frontal bone. The *inner surface* of the nasal process is ed towards the nasal fossæ. It is crossed obliquely from below upwards and ards by a ridge—the **agger nasi** or **superior turbinated crest** (crista ethmoidalis). this the bone is smooth and forms the upper part of the atrium, whilst the itself articulates posteriorly with the fore-part of the middle turbinated bone, d by the inferior turbinated process of the ethmoid bone.

ne **alveolar process** (processus alveolaris) projects from the under surface of dy of the bone below the level of the palatal process. Of curved form, it etes, with its fellow of the opposite side, the alveolar arch, in which are lded in sockets or alveoli the roots of the teeth of the upper jaw; ordinarily adult, when dentition is complete, each alveolar process supports eight teeth. ng the inner surface of the alveolar border behind the incisor teeth two vascular foramina are usually visible. When any or all the teeth are shed veoli become absorbed, and the process may under these circumstances be d to the level of the plane of the palatal process. Posteriorly the alveolar s ends below the **tuberosity** of the body; anteriorly it shares in the formation **intermaxillary suture.**

The **palatal process** (processus palatinus), of the form of a quadrant, lies in t horizontal plane; it has two surfaces—upper and under—and three borders, a stra internal, a more or less straight posterior, and a curved external, by which la it is attached to the inner side of the body and alveolar process as far back as interval between the second and third molar teeth. Its *under surface*, toge with that of its fellow, forms the anterior three-fourths of the vaulted hard pal it is rough and pitted for the glands of the mucous membrane of the roof of mouth, and is grooved on either side near the alveolar margin by a channel wh passes forward from the **posterior palatine canal** and transmits the great pala nerve and descending palatine artery. Its *superior surface*, smooth and conc from side to side, forms the floor of the corresponding nasal fossa. Its *interna mesial border*, broad and serrated, rises in a ridge superiorly, so as to form with fellow of the opposite side the **nasal crest** (crista nasalis), which is grooved superi to receive the lower border of the vomer. In front of its articulation with vomer this ridge rises somewhat higher, being named the **incisor crest**, anterior which it projects beyond the free border of the nasal notch, and together with fellow forms the pointed projection called the **anterior nasal spine** (spina nas anterior). These parts support the septal cartilage of the nose. Immediately the outer side of the incisor crest the superior surface of the palatal proces pierced by a foramen which leads downwards, forward, and a little inwards, to o into a broad groove on the mesial border of the bone immediately behind central incisor tooth. When the two maxillæ are articulated, the two groo form the oval **anterior palatine canal** or **fossa**, into which the two aforementio foramina open like the limbs of a Y; these are called the **incisor foramina, or foramina of Stensen**, and contain the remains of the organs of Jacobson. In fr and behind these, and lying within the fossa and in *the line* of the suture, are smaller **foramina of Scarpa**, which transmit the naso-palatine nerves, the right ne usually passing through the posterior foramen, the left through the anterior. *posterior border* of the palatal process, which is sharp and thin, falls in line wi the interval between the second and third molar, and articulates with the horizon plate of the palate bone.

The **maxillary sinus** or **antrum of Highmore** (sinus maxillaris) lies within body of the bone, and is of corresponding pyramidal form, its base being direc towards the nasal fossa, with the middle meatus of which it communicates, summit extending outwards into the root of the zygomatic process. It is clo in externally and above by the thin walls which form the facial, zygomatic, a orbital surfaces of the body. Inferiorly it overlies the alveolar process in wh the molar teeth are implanted, the sockets of which are separated from it by a th layer of bone.

Advantage is taken of this circumstance to pierce the floor of the antrum in such conditi as necessitate its thorough drainage, as its natural outlet into the middle meatus is of the nat of an overflow aperture, and so prevents purulent fluids, which may here accumulate, from be readily discharged.

The angles and corners of this cavity are frequently groined by narrow rid of bone, one superiorly corresponds to the relief formed by the infraorbital can A vascular and nervous groove is often exposed, curving along the floor of antrum just above the alveoli of the teeth. The interior of the cavity is lined an extension from the mucous membrane of the nose.

Connexions.—The superior maxillary bone articulates with the nasal, frontal, lachryn and ethmoid bones above, externally with the malar, and occasionally with the sphen posteriorly and internally with the palate, whilst on its inner side it unites with its fellow the opposite side, and also supports the inferior turbinated bone and the vomer.

Architecture.—The disposition of the maxillary sinus within the body of the bone has b already referred to. In union with its fellow, the vaulted arrangement of the hard palate is displayed, and the arched arrangement of the superior alveolar processes is obvious. It is these latter processes around the sockets for the reception of the teeth that the cancellous ti of the bone is seen; elsewhere its walls are formed by thin and dense bone.

Variations.—Not unfrequently there is a suture running vertically through the bar of b which separates the infraorbital foramen from the infraorbital margin. Through imperfect in ossification the infraorbital canal may form an open groove along the floor of the orbit.

sification.—The superior maxillæ are developed in the connective tissue around l aperture of the embryo. The centres from which the bone ossifies are not l by a cartilaginous stage. Their number is uncertain, as early fusion occurs them. They first make their appearance in the second month of intrauterine tly after the clavicle has begun to ossify. By the sixth month they are so united r independent character is obscured. Five centres are described—an *external* or hich forms the bone to the outer side of the infraorbital canal; an *inner* or *al*, from which is developed the inner part of the floor of the orbit, the frontal and the wall of the antrum; a *palatine*, for the posterior three-fourths of the rocess; a *nasal*, situated between the frontal process and the canine tooth; and is and nearer the middle line and below, an *incisive centre*, from which the pre- are developed, thus forming the anterior fourth of the palatal process in the n the early stages of the development of the bone the alveolar groove, in which are developed, lies close below the infraorbital groove, and it is not till later y become separated by the growth of the which first makes its appearance as a shallow he inner side of the orbito-nasal element about h month. In the adult bone the course of the tal canal and foramen indicates the line of fusion bito-nasal and malar elements, whilst the position terior palatine canal serves to determine the line of the incisive with the palatal elements. In to the foregoing centres, Rambaud and Renault another which, together with its fellow, is wedged en the incisive and the palatal elements beneath r, thus explaining the Y-shaped arrangement of mina of Stensen, which open into the anterior canal.

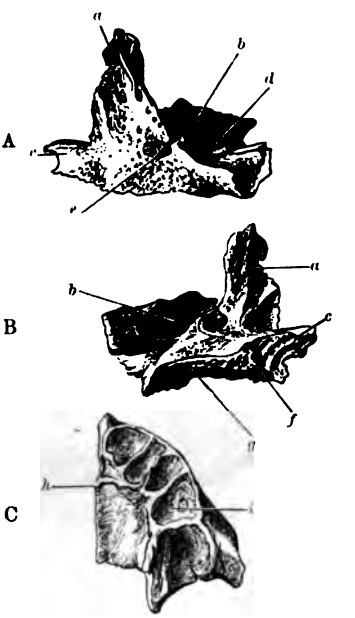

FIG. 105.—OSSIFICATION OF SUPERIOR MAXILLA.

A, Outer side; B, Inner side; C, Under side. *a*, Nasal process; *b*, Orbital plate; *c*, Anterior nasal spine; *d*, Infraorbital groove; *e*, Infraorbital foramen; *f*, Anterior palatine groove; *g*, Palatal process; *h*, Premaxillary suture; *i*, Alveolar process.

premaxillæ, which in most vertebrates are in- at bones lying in front of the superior maxillæ, e in man and apes the portions of the upper ch lie in front of the anterior palatine foramen, port the superior incisor teeth. They are de- from the incisive centres above described; the usion of these elements with the maxillæ proper lily be seen in young skulls, and occasionally the adult. It corresponds to a suture which n the palate obliquely outwards and forwards, e anterior palatine foramen to the interval the lateral incisor and the canine tooth. In alveolar cleft palate the adjacent bones fail to ng the line of the suture. In some instances, , the cleft passes outwards between the central ral incisor teeth, and this condition suggests the ion that the premaxillary element is derived centres—a lateral and a mesial. The researches echt and Warinski have confirmed this view. er anatomist further observes that the lateral cleavage may lead to a division of the erm of the lateral incisor tooth, and so explain the occurrence of the supernumer- sor which is occasionally met with. In this way the different varieties of cleft re readily explained; mesial cleft palate being due to failure of union between the maxillary bones. Lateral cleft palate may be of two types: the cleft in one case forward between the central and lateral incisor, and being due to the non-union two elements from which the premaxilla is primarily developed; the other, in he cleft passes between the lateral incisor and the canine, or between the lateral and a supernumerary incisor, owing to the imperfect fusion of the premaxilla r with the maxilla.

THE MALAR BONES.

malar bone (os zygomaticum) underlies the most prominent part of the and is hence often called the cheek-bone. Placed to the outer side of the cavity, it forms the sharp external border of that hollow, and serves to

separate that space from the temporal and zygomatic fossæ which lie behin below, it rests upon and is united to the superior maxilla; behind, it enters int the formation of the zygomatic arch which bridges across the temporal fossa.

As viewed from the outer side, the bone is convex from side to side, and ha four angles, of which three are prominent. These are the **ascending** or **fronta** (processus fronto-sphenoidalis), the **anterior** or pointed extremity of the maxillar border, and the **posterior** or **temporal** (processus temporalis).

The most elevated part of the convex *outer surface* (facies anterior) forms th **malar tuberosity**. The **processus temporalis**, sometimes called the zygomatic proces ends posteriorly in an oblique edge, which articulates with the extremity of th zygomatic process of the temporal bone. The **frontal**, the most prominent of it processes, is united superiorly to the external angular process of the frontal bon The edge between the frontal and temporal processes is thin and sharp; it afford attachment to the temporal fascia, and near its upper end there is usually pronounced angle (processus marginalis), formed by a sudden change in the direc tion of the border of the bone. It is just below this point that the tempor branch of the orbital nerve becomes cutaneous. The lower margin of the tempor process is somewhat thicker and rounded; it extends downwards and forwar towards the inferior angle, where the bone articulates with the superior maxill

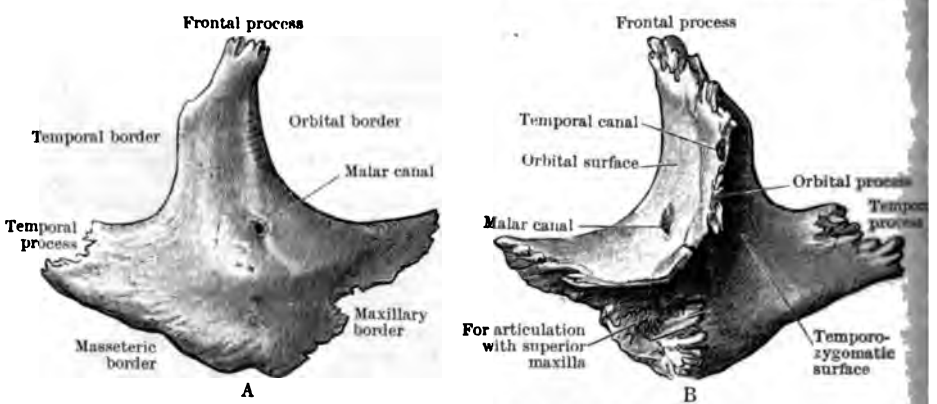

FIG. 106.—RIGHT MALAR BONE. A, Outer Side; B, Inner Side.

and is there confluent with the ridge which separates the facial from the zygomat aspect of the upper jaw. This edge of the bone is sometimes called the **masseter border**, since it affords attachment to the fibres of origin of the masseter musc Sweeping downwards in front of the frontal process is a curved edge whic terminates inferiorly in a pointed process. This border forms the outer and, i part, the inferior margin of the orbital cavity. Between the anterior extremity the masseteric edge and the pointed anterior angle there is an irregular suture b which the bone is joined to the maxilla. The opening of the **malar canal** (forame zygomatico-faciale) is seen on the outer surface of the bone; its size and positio are very variable.

The *mesial aspect* of the bone is distinguished by a curved elevated crest, calle the **orbital process**, which extends inwards and backwards, and is confluer externally with the orbital margin. This process has two surfaces—one anterio which forms a part of the outer and lower wall of the orbit, and one posterio which is directed towards the temporal fossa above and the zygomatic fossa belo The free edge of the orbital process is thin and serrated; a little below its middle is usually interrupted by a non-articular notch, which corresponds to the anteri extremity of the spheno-maxillary fissure. The part above this articulates with th great wing of the sphenoid, the portion below with the orbital plate of the superi maxilla. Behind the orbital process the inner surface of the bone is concave fro side to side, and extends backwards along the mesial aspect of the temporal proce and upwards over the posterior half of the inner side of the frontal process, thu entering into the formation of the zygomatic and temporal fossæ respectivel

ital surface of the orbital process usually displays the openings of two foramina zygomatic-orbitalia)—one which traverses the bone below the nargin and appears on the front of the bone as already described, the other asses obliquely upwards and outwards through the orbital process and in the temporal fossa, to the inner side of the frontal process (foramen ico-temporale). The former transmits the ramus subcutaneous malæ; the ie temporal branch of the orbital nerve.

w the orbital process there is a rough triangular area, bounded externally naxillary border. This articulates with the malar process of the superior and occasionally forms the outer wall of the antrum.

xions.—The malar bone articulates with the frontal, sphenoid, superior maxilla, and bones.

itecture.—In structure the bone is compact, with little cancellous tissue. Together zygomatic process of the temporal bone it forms the buttress which supports the superior and the outer orbital wall externally. Additional strength is imparted to the bone by lar mode of union of its orbital and facial parts.

itions.—Cases of division of the malar bone by a horizontal suture have been recorded, instances of its separation into two parts by a vertical suture. Owing to the supposed uent occurrence of this divided condition in Asiatics the malar has been named the os m. Barclay Smith ("Proc. Anat. Soc.," *Jour. Anat. and Physiol.*, April 1898, p. 40) a case in which the malar bone was divided into two parts, an upper and lower, by a l extension of the maxilla, which articulated with the zygomatic process of the temporal, ning a temporo-maxillary arch. Varieties of a like kind have also been described by nd others. Cases have been noted where, owing to deficiency in the development of the e continuity of the zygomatic arch has been incomplete.

ification.—The malar ossifies in membrane. Its basis appears about the tenth a thin ossifying lamina which corresponds to the orbital margin, attached to here is a backward expansion corresponding to of the bone; from this posteriorly there extends ent of the temporal process. On the inner side, re the angle formed by the orbital and temporal there appears a secondary thickening, which into a cap-shaped layer which fits into the nd ultimately forms the surface of the bone to the temporal fossa. Below the orbital on the inner side, and extending backwards the temporal process, is another secondary ng which forms a club-shaped nodule, the thick which is directed forwards, whilst posteriorly it forms, in part, the lower margin body and temporal process. The overlap of these several parts leads to the n of grooves which may persist in the adult as sutures. (Karl Toldt, junr., *der Akad. des Wiss.*, Wien. July 1902.)

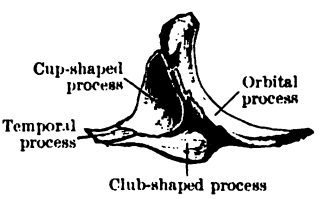

FIG. 107.—INNER SURFACE OF MALAR BONE AT BIRTH.

THE NASAL BONES.

nasal bones (ossa nasalia), two in number, lie in the interval between the processes of the superior maxillæ, there forming the root or bridge of the Each bone is of elongated quadrangular form, having two surfaces—an nd outer—and four borders. The *external surface*, somewhat constricted its middle, is convex from side to side, and slightly concavo-convex from downwards. Near its centre there is usually the opening of a nutrient canal. *internal surface* is not so extensive as the external, as the superior and r articular borders encroach somewhat upon it above. Concave from side to d also from above downwards, it is covered, in the recent condition, by the membrane of the nose. Running downwards along this surface is a groove (sulcus ethmoidalis) which transmits the internal nasal nerve. The r or *internal border*, narrow below, is thick above, and, in conjunction with ow at the opposite side, with which it articulates, forms a median crest orly, which is united to the nasal spine of the frontal, the vertical plate of moid, and the septal cartilage of the nose, in that order from above down-

The *posterior* or *external border*, usually the longest, is serrated and

bevelled to fit on to the anterior edge of the frontal process of the superior
The *superior border* forms a wide toothed surface, which articulates with t
part of the nasal notch of th
bone anteriorly; whilst, behin
in contact with the root of t
process of the same bone. Th
border is thin and sharp, an
nected below with the lateral
of the nose, and is usuall
notched near its mesial extre

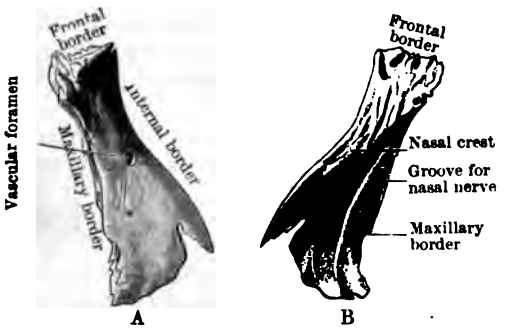

FIG. 108.—RIGHT NASAL BONE. A, Outer side; B, Inner side.

Connexions.—The nasal bone
with its fellow of the opposite
the frontal above, behind with
plate of the ethmoid and with t
process of the superior maxilla.
united to the septal and upper la
lages of the nose.

Architecture.—Formed of
compact bone; the strength of the nasal bones is increased by their mode of unic
formation of a median crest posteriorly.

Variations.—The size and configuration of the nasal bones vary greatly in diffe
being, as a rule, large and prominent in the white races, and flat and reduced in size
depressed, in the Mongolian and Negro stock. Obliteration of the internasal suture i
it is stated to occur more frequently in negroes, and is the recognised condition in adu

Duckworth has recorded a case (*Journ. Anat. and Physiol.*, vol. xxxvi. p. 257) of undu
downwards of the nasal bone, which may be perhaps accounted for on the supposition
lower part is a persistent portion of the premaxilla.

Ossification.—The nasal bones are each developed from a single centre, wh
its appearance about the end of the second month in the membrane coverin
part of the cartilaginous nasal capsule. Subsequent to birth the underlying ca
stratum disappears, persisting, however, below in the form of the lateral nasal
and behind as the septal cartilage of the nose.

THE LACHRYMAL BONES.

The **lachrymal bone** (os lachrymale), or os unguis, a thin scale of bone
size of a finger-nail, forms part of the inner orbital wall behind the fr
cess of the superior maxilla. Irregularly quadrangular, it has two sur
inner and outer—and four borders.

Its *external* or *orbital surface* has a vertical ridge, the **lachrymal cr**
lachrymalis posterior), running downwards upon it. In front of this is the
groove (sulcus lachrymalis) for the lodgment of the lachry-
mal sac. The floor of this groove descends below the level
of the bulk of the bone, and forms the **descending process**,
which helps to complete the osseous canal for the nasal
duct, and articulates inferiorly with the inferior turbinal.
The lower end of the lachrymal crest terminates in a
hook-like projection, the **hamular process** (hamulus lachry-
malis), which curves round the posterior and outer edge
of the lachrymal notch of the superior maxilla, and thus
defines the upper aperture of the canal for the nasal duct.
To the free edge of the crest behind the lachrymal groove
are attached the reflected portion of the tendo oculi, and
the tensor tarsi muscle. The part of the bone behind the
lachrymal crest is smooth and continuous with the surface of the os p
the ethmoid. The *inner surface* is irregular and cellular above; it close
of the anterior ethmoidal cells. Where it is smoother it forms a pa
lateral wall of the middle meatus of the nose immediately behind th
process of the superior maxilla, and above the inferior turbinated bo
superior border articulates with the orbital plate of the frontal; the *ant*
with the posterior border of the frontal process of the superior maxi

FIG. 109.—RIGHT BONE (Orbital

it completes the lachrymal groove for the lodgment of the lachrymal sac. *erior margin* articulates with the orbital surface of the superior maxilla, front by its **descending process** with the inferior turbinal. *Posteriorly* the iculates with the anterior border of the os planum of the ethmoid.

ıxions.—The lachrymal bone articulates with four bones—the frontal, ethmoid, inferior and the superior maxilla.

tecture.—The bone consists of a thin papery translucent lamina, somewhat strengthhe addition of the vertical crest.

tions.—The lachrymal is occasionally absent. In some cases it is divided into two others replaced by a number of smaller ossicles. In rare instances the hamular process ıd forwards to reach the orbital margin, and so bear a share in the formation of the face, ırs (Gegenbauer). In other instances the hamulus is much reduced in size. Occasionachrymal is separated from the os planum of the ethmoid by a down-growth from the hich articulates with the orbital process of the superior maxilla, as is the normal n in the gorilla and chimpanzee. (Turner, *Challenger Reports*, "Zoology," vol. x. Plate I.; and A. Thomson, *Journ. Anat. and Physiol.*, London, vol. xxiv. p. 349.)

fication.—The lachrymal is developed from a single centre, which makes its ce about the end of the second or the beginning of the third month of intrafe in the membrane around the cartilaginous nasal capsule.

The Inferior Turbinated Bones.

inferior turbinated or spongy bone (concha inferior) is a shell-like lamina lying along the lower part of the outer wall of the nasal fossa. Of d form, the bone displays two curved borders enclosing an internal and surface.

superior or *attached* border is thin and sharp in front and behind, where

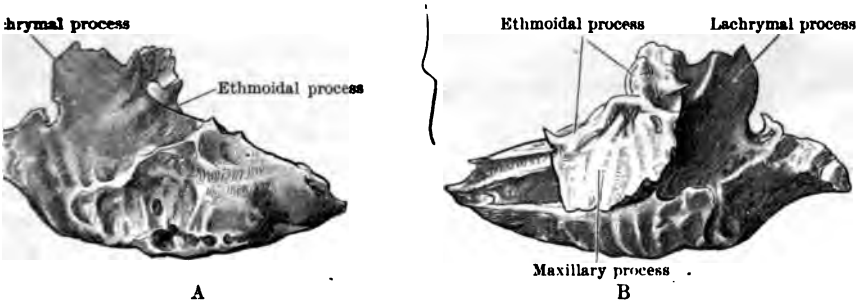

Fig. 110.—Right Inferior Turbinated Bone. A, Inner Surface; B, Outer Surface.

culates with the inferior turbinal crests on the inner surface of the body superior maxilla and the vertical plate of the palate bone respectively. en these two borders the central part of the upper edge rises in the form of p crest, the fore-part of which forms the upstanding **lachrymal process** (pro- lachrymalis), which articulates above with the descending process of the mal bone, as well as with the edges of the nasal groove of the superior la, thus completing the osseous canal of the nasal duct. The posterior end is crest is elevated in the form of an irregular projection called the **ethmoidal s** (processus ethmoidalis). This unites with the uncinate process of the oid bone (see Fig. 101). Spreading downwards from the middle of the ior border, on its outer side, is a thin, irregular plate of bone, the **maxillary s** (processus maxillaris), which partially conceals the outer concave surface e bone, and, by its union with the inner wall of the maxillary sinus, assists in ompletion of the partition which separates that cavity from the inferior nasal ıs. The *inferior* or *free border*, gently curved from before backwards and ly out-turned, is rounded and full, and formed of bone which is deeply pitted f a somewhat cellular character. The anterior and posterior extremities of ne, formed by the convergence of the upper and lower borders, are thin and ; as a rule the hinder end is the more pointed of the two. The *internal* e projects into the nasal fossa; convex from above downwards, and slightly

curved from before backwards, it forms the floor of the middle meatus. It rough and pitted, and displays some scattered and longitudinally directed vasc grooves. The *outer surface* overhangs the inferior nasal meatus. Concave f above downwards, and to some extent from before backwards, it is directed tow the outer wall of the nasal fossa. It is smooth in front, where it correspond the opening of the canal for the nasal duct; behind and towards its lower bo it is irregular and pitted. In the disarticulated bone this surface is in part c cealed by the downward projecting maxillary process.

Connexions.—The inferior turbinal articulates with the superior maxilla, lachry ethmoid, and palate bones.

Variation.—A case in which the inferior turbinals were absent has been recorded Hyrtl.

Ossification.—The inferior turbinate bone, the maxillo-turbinal of compara anatomy, is derived from the cartilage forming the outer wall of the nasal capsule, upper portion of which forms the ethmo-turbinals. It ossifies, however, from a sepa centre, which appears about the fifth month of fœtal life, and later contracts a u by a horizontal lamella on its outer side with the superior maxillary bone.

The Vomer.

The **vomer**, a bone of irregular quadrilateral shape, is placed mesially in hinder part of the nasal septum. It has four borders and two surfaces. *superior border*, which can readily be distinguished by the presence on either of an everted lip or ala, slopes from be upwards and forwards, and articul with the under surface of the body of sphenoid, the pointed rostrum of w is received into the groove formed by projecting alæ. Laterally these ala wedged in between the sphenoidal cesses of the palate bone in front, the vaginal processes at the root o internal pterygoid plates behind.

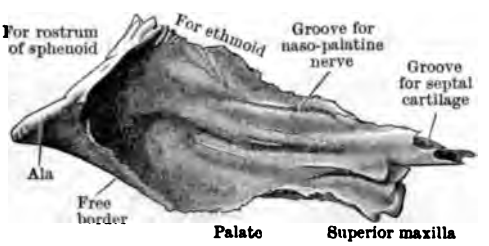

Fig. 111.—Vomer as seen from the Right Side.

posterior border, which slopes from be downwards and forwards, is free, and forms a sharp, slightly curved edge; constitutes the posterior margin of the nasal septum, and serves to separate openings of the posterior nares. The *inferior border*, more or less horizontal direction, articulates with the nasal crest formed by the superior maxillary palate bones. The *anterior edge* is the longest; it slopes obliquely from ab downwards and forwards. In its upper half it is ankylosed to the perpendic plate of the ethmoid; in its lower half this margin is grooved for the recep of the septal cartilage of the nose. The *anterior extremity* of the bone form truncated angle, which articulates with the hinder border of the incisor cre the superior maxillæ, and sends downwards a pointed process which passes betw the incisor foramina. The *right* and *left surfaces* of the bone are smooth, covered by mucous membrane. It is not uncommon to find them deflected one or other side. A few vascular grooves may be noticed scattered over th surfaces, and one, usually more distinct than the others, running obliquely do wards and forwards, indicates the course of the naso-palatine nerve.

Connexions.—The vomer articulates with the sphenoid, the ethmoid, the palates, and superior maxillæ. In front it supports the septal cartilage.

Architecture.—The bone is composed of two compact layers fused below, but separated ab by the groove for the lodgment of the rostrum of the sphenoid behind, and the septal cartil front. The lamellæ are also separated from each other by a canal which runs horizontally behind forwards in the substance of the bone, and which transmits the nutrient ves the bone.

Variations.—Owing to imperfect ossification there may be a deficiency in the bone, filled during life by cartilage. The separation of the two lamellæ along the anterior border va considerably, and instances are recorded where they were separated by a considerable cav within the substance of the bone. The spheno-vomerine canal is a minute opening beh

e rostrum of the sphenoid, and between it and the alæ of the vomer, by which the nutrient tery enters the bone.

Ossification.—The vomer, primitively double, begins to ossify about the end of the cond month of fœtal life. A nucleus appears on either side in the membrane overlying e back and lower part of the vomerine cartilage; these form the primitive lamellæ veloped on either side of, and not from, the cartilage. About the third month these minæ become fused behind and below, thus forming a deep groove in which the cartilage lodged. As growth goes on the groove becomes reduced by the further fusion of the teral plates and the absorption of the cartilage, until the age of puberty, by which ne the lateral laminæ have united to form a mesial plate, the primitively divided con- tion of which is now only represented by the eversion of the alæ and the grooving ng the anterior border.

The Palate Bones.

The **palate bone** (os palatinum), of irregular shape, assists in the formation of e outer wall of the back part of the nasal fossæ, the posterior portion of the hard alate, the orbit, the spheno-maxillary, zygomatic, and the pterygoid fossæ. It

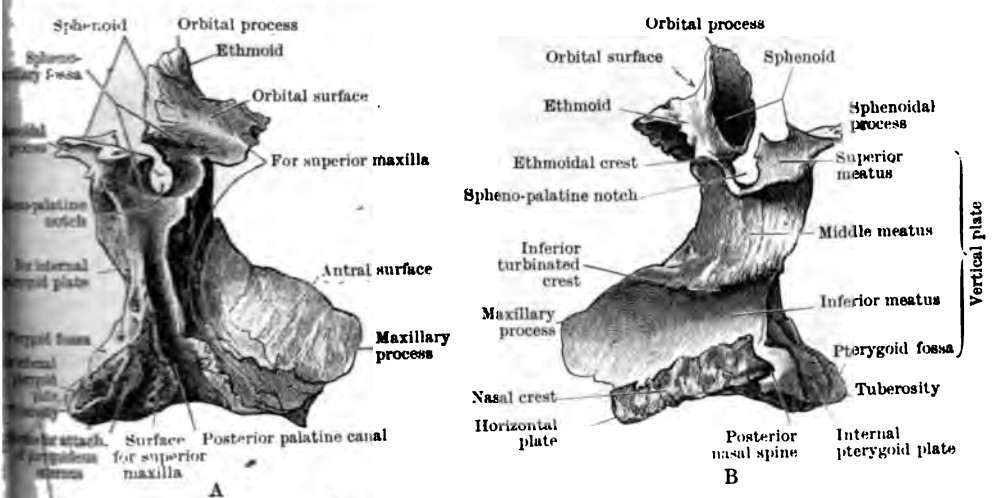

Fig. 112.—Right Palate Bone.

A, As seen from the Outer Side; B, As viewed from the Inner Side.

consists of a **horizontal** and a **vertical plate**, united to each other like the limbs of the letter L. At their point of union there is an irregular outstanding process, called the **tuberosity**, whilst capping the summit of the vertical plate and separated by a deep cleft are two irregular pieces of bone, called the **sphenoidal** and **orbital** processes.

The **horizontal plate** (pars horizontalis) has two surfaces and four borders. As its name implies, it is horizontal in position, and forms the posterior third of the hard palate. Its *upper surface*, which is smooth, is slightly concave from side to side, and forms the floor of the hinder part of the nasal fossæ. Its *inferior surface*, rougher, is directed towards the mouth, and near its posterior edge often displays a transverse ridge for the attachment of a part of the aponeurosis of the tensor palati muscle. The *anterior border* articulates by means of an irregular suture with the hinder edge of the palatal process of the superior maxilla. The *posterior margin* is free and concave from side to side; by its sharp edge it furnishes attachment to the aponeurosis of the soft palate. The *internal border* is upturned, and when it articulates with its fellow of the opposite side it forms superiorly a central crest continuous in front with the nasal crest of the superior maxilla; it supports the hinder part of the lower border of the vomer, and projecting beyond the line of the posterior border forms the **posterior nasal** or **palatine spine** (spina nasalis posterior). The *external border* fuses with the vertical plate, forming with

it a right angle. The hinder extremity of this edge is grooved by the l
the **posterior palatine canal.**

The **vertical plate** (pars perpendicularis) is very much broader
above. Composed of thin bone, it is liable to be broken in the process
lation, particularly at its upper part, so that it is somewhat uncomm
with a perfect specimen. It may be described as possessing two s
four borders. Its *inner surface*, which is directed towards the cavity
is crossed horizontally about its middle by the **inferior turbinated**
turbinalis) with which the hinder end of the superior border of
turbinated bone articulates; above and below this it enters into the
the outer wall of the middle and inferior meatuses of the nose respecti
the upper extremity of the vertical plate, and below the processes w
from it, there is another ridge more or less parallel to that alread
This is the **superior turbinated** or **ethmoidal crest** (crista ethmoidalis), an

maxillary fossa; whilst the *inferior*, which is confluent with the inner
the vertical plate, is of variable extent, and overhangs the superior
he nose.
ıenoidal process (processus sphenoidalis), much smaller than the orbital,
ards, inwards, and backwards from the hinder part of the summit of the
te. Its superior surface, which is grooved, articulates with the fore-part
er surface of the body of the sphenoid and the root of the internal
late, thereby converting the groove into the **pterygo-palatine canal**, which
n artery of the same name together with a pharyngeal branch from the
ıtine ganglion. Its outer side enters into the formation of part of the
of the spheno-maxillary fossa. Its internal curved aspect is directed
e nasal fossa, whilst its inner edge is in contact with the ala of the

ns.—The palate bone articulates with its fellow of the opposite side, with the
ıer, sphenoid, superior maxilla, and inferior turbinated bones.

ıtion.—The palate bones are developed from the ossification of the membrane
sides of the oral cavity. According to Rambaud and Renault, two primitive
ar about the sixth week of fœtal life. From one of these the tuberosity and
:he vertical plate behind the posterior palatine groove is developed; from the
mainder of the bone is formed, with the exception of the orbital and sphenoidal
hich are derived from secondary centres that make their appearance some-
Other authorities describe the bone as ossifying from a single centre which
ut the end of the second month in the angle between the vertical and hori-
s.
ı the bone is much longer in its antero-posterior diameter than in its vertical
converse of its typical adult form.

The Inferior Maxillary Bone.

ıferior maxilla (mandibula) or **mandible**, of horse-shoe shape, with the
s upturned, is the only movable bone of the face. Stout and strong, it
the teeth of the lower dental arch, and articulates with the base of the
by the joints, on either side, between its condyles and the glenoid fossæ
aporal bones. The anterior or horizontal part, which contains the teeth,
:he **body** (corpus); the posterior or vertical portions constitute the **rami**
ndibulæ).
body (corpus mandibulæ) displays in the middle line in front a faint
ridge, the **symphysis**, which indicates the line of fusion of the two
ical halves from which the bone is primarily developed. Inferiorly this
ides so as to enclose, in well-marked specimens, a triangular area—the
rotuberance (protuberantia mentalis), the centre of which is somewhat
l, thus emphasising the inferior angles, which are known as the **mental**
(tubera mentalia). The *outer surface* is crossed by a faint, elevated ridge,
nal oblique line (linea obliqua), which runs upwards and backwards from
tal tubercle to the fore-part of the anterior border of the ramus, with
is confluent. A little above this, midway between the upper and lower
f the jaw, and in line with the root of the second bicuspid tooth, the bone
d by the **mental foramen** (foramen mentale); this is the anterior opening
ferior dental canal, which traverses the body of the bone. Through this
the mental vessels and nerves reach the surface. The *upper border*

supports the sixteen teeth of the lower jaw. It is thick behind and thin front, in correspondence with the size of the roots of the teeth. Anterior sockets of the incisor and canine teeth produce a series of vertical elevations alveolaria), of which that corresponding to the canine tooth is the most prom When this is outstanding it gives rise to a hollowing of the surface between the symphysis, often referred to as the **incisor fossa**; frequently, however is only faintly marked. Below the external oblique line the bone is fu rounded, and ends below in the *inferior border* or **base**. This slopes outwa the sides, and forwards in front, where it is thick and hollowed out on either of the symphysis to form the **digastric fossæ** (fossæ digastricæ), to whic anterior bellies of the digastric muscles are attached; narrowing somewhat b this, the inferior border again expands opposite the molar teeth, and becoming reduced in width, terminates posteriorly at the **angle** formed betw and the posterior border of the ramus. The *deep* or *inner surface* of the body is crossed by the **internal oblique line** or **mylo-hyoid ridge** (linea mylo-hyoidea). This slants from above downwards and forwards towards the lower part of the symphysis. It serves for the origin of the mylo-hyoid muscle, and also furnishes an attachment to the superior constrictor of the pharynx just behind the last molar tooth. Below the hinder part of this ridge the surface is hollowed to form a **fossa** for the lodgment of the submaxillary gland. Above the fore-part of the internal oblique line the bone is smooth and usually convex. Here the sublingual gland lies in relation to it. In the angle formed by the convergence of the two internal oblique lines, and in correspondence with the back of the lower part of the symphysis, there is a raised tubercle surmounted by two laterally spines, the **mental** or **genial spines** (spinæ mentales). Occasionally the again subdivided into an upper and lower pair, or it may be that the pair may fuse to form a rough median ridge. To the upper pair of the genio-hyoglossi muscles are attached, whilst the lower pair serve f origin of the genio-hyoid muscles. Immediately above the tubercle t a median foramen for the transmission of a nutrient vessel, and close alveolar border opposite the intervals between the central and lateral incisor are two little vascular canals.

lum mandibulæ), below which it is somewhat constricted to form
llum mandibulæ), which is compressed from before backwards, and
sigmoid hollow posteriorly. To the inner side of the neck, im-
elow the condyle, there is a little depression (fovea pterygoidea)
ertion of the external pterygoid muscle. The convex surface of
is transversely elongated, and so disposed that its long axis is
arly horizontally from within outwards and a little forwards. The
f the condyle is more marked in its antero-posterior than in its
iameter.

ure.—The mandible is remarkable for the density and thickness of its inner and
Where these coalesce below at the base of the body, the bone is particularly stout.
here they form the walls of the alveoli, they gradually thin, being thicker,
the inner than the outer side, except in the region of the last molar tooth,
ner wall is the thinner. The cancellous substance is open-meshed below, finer
densed where it surrounds the alveoli. The inferior dental canal is large and
definite wall; it is prolonged beyond the mental foramen to reach the incisor
it numerous channels pass upwards to the sockets of the teeth, and it com-
ely with the surrounding cancellous tissue. Above the canal the substance of the
n up by the alveoli for the reception of the *roots of the* teeth. In the substance

of the condyle the cancellous tissue is more compact, with a general striation vertical t articular surface.

The mental prominence is an essentially human characteristic; by some it is associated wi development of speech in man, others regard it as due to the reduction in the size of the te

Variations.—Considerable differences are met with in the height of the coronoid pr usually its summit reaches the same level as the condyle, or slightly above it; occasionally, ever, it rises to a much higher level; in other cases it is much reduced. These diffe naturally react on the form of the sigmoid notch. The projection of the mental protube is also liable to vary. Occasionally the mental foramen is double, and sometimes the mylo groove is for a short distance converted into a canal.

Ossification.—The development of the lower jaw is intimately associated Meckel's cartilage, the cartilaginous bar of the first visceral or mandibular arch. Me cartilages, of which there are two, are connected proximally with the periotic capsule cranial base. Their distal ends are united in the region of the symphysis. It is i connective tissue overlying the outer surface of this cartilaginous arch that the bo the lower jaw is developed. The cartilage itself is not converted into bone, but under resorption, excep anterior extre which is stat undergo ossifi to form the p the jaw lyin tween the m foramen and symphysis. Ina or fourth m fœtus the car can be traced the under surf the fore-part o tympanic ring d wards and for to reach the ja which it is att at the opening o inferior dental c from this it ma traced forwards narrow strip ap to the inner surf the mandible, w it sensibly gro

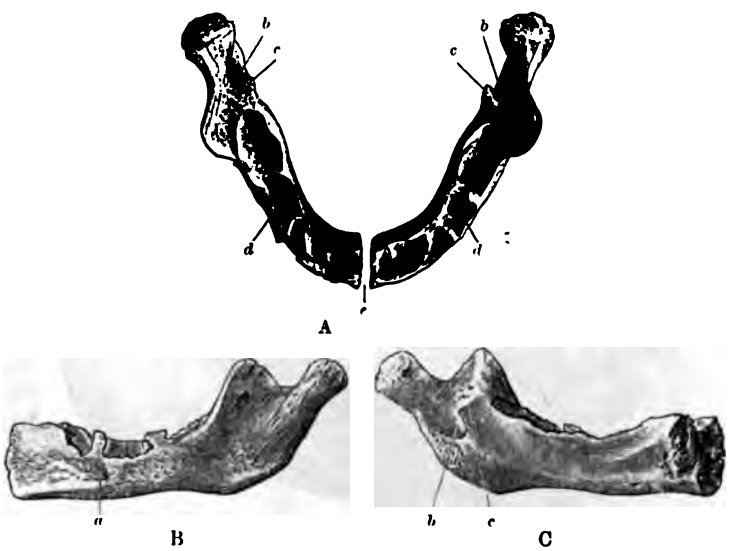

FIG. 116.—LOWER JAW AT BIRTH. A, As seen from above; B, Outer side; C, Inner side.

a, Mental foramen; *b*, Inferior dental canal; *c*, Lingula; *d*, Sockets for the dental sacs

The proximal end of this furrow remains permanently as the mylo-hyoid groove. part of the cartilage between the tympanic ring and the jaw becomes converted fibrous tissue, and persists in the adult as the so-called internal lateral ligament o temporo-maxillary articulation, its proximal end through the Glaserian fissure being tinuous with the slender process of the malleus. J. Chaine (*Comptes Rendus.* Bio 1903) takes exception to this view and regards the internal lateral ligament as the re of a muscular slip. The part which is applied to the inner surface of the lowe disappears. In the tissue overlying the cartilage ossification begins by several centr early as the sixth or seventh week of fœtal life, in this respect resembling the clavic which it is alone preceded. The dentary or basal centre forms the outer wall and l border. With this is united the splenial portion, which appears somewhat later, for the inner table from near the symphysis backwards towards the opening of the in dental canal where it terminates in the lingula. By the union of these two parts a gr is formed, which ultimately becomes covered in, and in which the inferior dental n and vessels are lodged. As has been already stated, the part of the body between symphysis and the mental foramen is regarded as directly developed by the ossificati the fore-part of the Meckelian cartilage. As will have been gathered from the a description, the upper part of the ramus and its processes have no connexion with Mec cartilage. The condyle and the coronoid process are each developed from a sepa centre, preceded by a cartilaginous matrix. These several centres are all united about fourth month.

At birth the lower jaw consists of two lateral halves united at the symphysis by fi

wards the end of the first, or during the second year, osseous union between the s is complete. In infancy the jaw is shallow and the rami proportionately small; wing to the obliquity of the ramus the angle is large, averaging about 150°. al foramen lies near the lower border of the bone. Coincident with the eruption th and the use of the jaw in mastication, the rami rapidly increase in size, and becomes more acute. After the completion of the permanent dentition it s more nearly a right angle varying from 110° to 120°. The body of the bone id deep, and the mental foramen usually lies midway between the upper and ders. As age advances, owing to the loss of the teeth and the consequent and absorption of the alveolar border of the bone, the body becomes narrow and d, and the mental foramen now lies close to the upper border. At the same time opens out again (130° to 140°), in this respect resembling the infantile condition. e the coronoid process and the condyle form a more open angle with each other ne adult.

THE HYOID BONE.

hyoid bone (os hyoideum), or **os linguæ**, though placed in the neck, is ientally connected with the skull. It lies between the mandible above larynx below, and is connected with the root of the tongue. Of U-shaped its name implies (Greek *υ* and *εἶδος*, like), it consists in the adult of a part, or **body**, with which on either side are united two long processes ig backwards—the **great cornua**. At the point where these are ossified body, the **lesser cornua**, which project upwards and backwards, are placed.

body (basis) is arched from side to side and compressed from before back- that its surfaces slope downwards and forwards. Its *anterior surface* a slight median ridge, on either side of he bone is marked by the attachment nylo-hyoid muscles. Its *posterior surface*, ollowed, is concave from side to side and ove downwards. Herein lie a quantity and a bursa which separates this aspect he thyro-hyoid membrane. The upper is broad; it is separated from the anterior by a transverse ridge, behind which are pressions for the attachment of the genio- nuscles. Its hinder edge is thin and sharp; above, are attached the genio-glossi, whilst and below the thyro-hyoid membrane is ted with it. The inferior border is well defined and narrow; it serves for the nent of the omo-hyoid, sterno-hyoid, thyro-hyoid, and stylo-hyoid muscles.

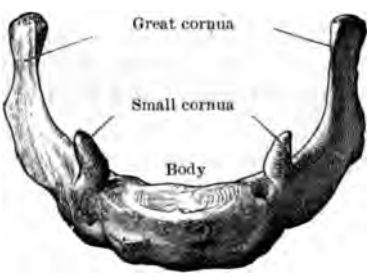

FIG. 117.—THE HYOID BONE AS SEEN FROM THE FRONT.

great cornua are connected on either side with the lateral parts of the At first, union is effected by synchondroses, which, however, ultimately These cornua curve backwards as well as upwards, and terminate in more or unded and expanded extremities. Compressed laterally, they serve for the ments externally of the thyro-hyoid and hyo-glossi muscles, and the middle ctor of the pharynx from below upwards, whilst internally they are con- with the lateral expansions of the thyro-hyoid membrane, the free edges of are somewhat thickened, and connect the extremities of the great cornua he ends of the superior cornua of the thyroid cartilage below.

e **lesser cornua**, frequently cartilaginous in part, are about the size of grains at. They rest upon the upper surface of the bone at the junctions of the cornua with the body. In youth they are separated from, but in advanced come ossified with, the rest of the bone, from which they are directed upwards, ards, and a little outwards. Their summits are connected with the stylo- ligaments; they also serve for the attachment of muscles.

nexions.—The hyoid is slung from the styloid processes of the temporal bones by the oid ligaments. Inferiorly it is connected with the thyroid cartilage of the larynx by ro-hyoid ligaments and membrane. Posteriorly it is intimately associated with the ia.

Ossification.—In considering the development of the hyoid bone it is neces refer to the arrangement and disposition of the cartilaginous bars of the second and visceral arches. That of the second visceral arch, the hyoid bar—or Reichert's car as it is sometimes called—is united above to the petrous temporal, whilst ventrall joined to its fellow of the opposite side by an independent mesial cartilage. Chond tion of the third visceral arch only occurs towards its ventral extremity, forming w known as the thyro-hyoid bar. This also unites with the mesial cartilage above ment In these cartilaginous processes ossific centres appear in certain definite situ Towards the end of fœtal life a single centre (by some authorities regarded as pri double) appears in the mesial cartilage, and forms the body of the bone (**basi** About the same time ossification begins in the lower ends of the thyro-hyoid bar from these the great cornua are developed (thyro-hyals). During the first year the ends of the hyoid bars begin to ossify and form the lesser cornua (cerato-hyals). cephalic ends of the same cartilages meanwhile ossify to form the styloid processes (hyals) (see p. 121), whilst the intervening portions of cartilage undergo resorptio become converted into the fibrous tissue of the stylo-hyoid ligaments, which in the connect the lesser cornua with the styloid processes of the temporal bone. The cornua fuse with the body in middle life; the lesser cornua only at a more adv period. Variations in the course of development lead to interesting anomalies hyoid apparatus. The lesser cornua may be unduly long or the stylo-hyoid ligamen be bony; in this case the cartilage has not undergone resorption, but has passed on further stage of ossification, thus forming an epihyal element comparable to that dog. The ossified stylo-hyoid ligament, as felt through the pharyngeal wall, m mistaken for a foreign body. (Farmer, G. W. S., *Brit. Med. Journ.* 1900, vol. i. p.

THE SKULL AS A WHOLE.

The skull as a whole may be studied as seen from the front (norma fron from the side (norma lateralis), from the back (norma occipitalis), from (norma verticalis), and from below (norma basalis).

Norma Frontalis.

In front, the smooth convexity of the frontal bone limits this region a whilst inferiorly, when the lower jaw is disarticulated, the teeth of the uppe form its lower boundary. The large openings of the **orbits** are seen on either whilst placed mesially and at a somewhat lower level is the **anterior nasal ap** (apertura pyriformis) leading into the **nasal fossæ**.

The **frontal region**, convex from above downwards and from side to si limited externally by two ridges, which are the anterior extremities of the tem lines. Superiorly the fulness of the bone blends with the convexity of the v Inferiorly the frontal bone forms on either side the arched superior border o orbit (margo supraorbitalis). The space between these borders corresponds t root of the nose, and here are seen the sutures which unite the frontal with nasal bones in the middle line, and with the nasal process of the superior m on either side, called the **naso-frontal** and **fronto-maxillary sutures** respectively. orbital arch is thin and sharp externally, but becomes thick and more rou towards its inner side, where it forms the **internal angular process** and unites the frontal process of the superior maxilla and the lachrymal bone on the wall of the orbit. This arched border is interrupted towards the inner sid a notch (incisura supraorbitalis), sometimes converted into a foramen, fo transmission of the supraorbital nerve and artery. In the middle line, just the naso-frontal suture, there is often the remains of a median suture (s frontalis), which marks the fusion of the two halves from which the bo primarily ossified. Here also a prominence, of variable extent—the **glabella**—i with; from this there passes out on either side above and over the orbital m a projection called the **superciliary ridge** (arcus superciliaris).

The **orbital fossæ**, of more or less conical form, display a tendency to a the shape of four-sided pyramids by the flattening of the superior, inferior lateral walls. The *base*, which is directed forwards and a little outw

›nds to the orbital aperture. The shape of this is liable to individual and ariations, being nearly circular in the Mongoloid type, whilst it displays a r less quadrangular form in Australoid skulls. The upper margin, as has ready stated, is formed by the frontal bone between the internal and external : processes. The outer, and about half the lower, margin are formed by the urved edge between the facial and orbital surfaces of the malar bone. The l border and the remainder of the lower margin are determined by the urface of the frontal process of the superior maxilla, and the sharp edge ing the facial from the orbital surface of the same bone. Three sutures pt the continuity of the orbital margin—the **fronto-malar** (sutura zygomatico-s) externally, the **fronto-maxillary** (sutura fronto-maxillaris) internally, both bout the same level, and the **malo-maxillary** (sutura zygomatico-maxillaris) ly. The *apex* of the space is directed backwards and inwards, so that the alls of the two orbits lie nearly parallel to each other, whilst the outer e so disposed as to form nearly a right angle with each other. The depth of it measures, on an average, about two inches (5 cm.). At the apex there are nings; the larger, known as the **sphenoidal fissure** (fissura orbitalis superior), rom the apex of the space outwards and a little upwards for the distance -quarters of an inch or so, between the roof and outer wall of the orbit. The hird of this fissure is broad and of circular form. Externally it is consider-duced in width. Through this the third, fourth, ophthalmic division of the nd the sixth nerves enter the orbit, whilst the ophthalmic veins pass rds through it. Above and internal to the inner end of the sphenoidal there is a smaller circular opening, the **optic foramen** (foramen opticum), for nsmission of the optic nerve and ophthalmic artery.

roof of the orbit, which is very thin and brittle towards its centre, is formed t by the **orbital plate** of the **frontal bone** (pars orbitalis) and behind by a triangular piece of the **lesser wing** of the **sphenoid**, which surrounds the foramen and forms the upper border of the sphenoidal fissure. Externally rface is separated from the outer wall by the sphenoidal fissure posteriorly, rly by an irregular suture between the orbital part of the frontal and per margin of the orbital surface of the great wing of the sphenoid, ex- to which the external angular process of the frontal articulates with the

Internally the roof is marked off from the inner wall by a suture, more s horizontal in direction, between the orbital plate of the frontal and the ing bones in order from before backwards, viz. the frontal process of the ior maxilla, the lachrymal bone, and the os planum of ethmoid. In the e between the last-mentioned bone and the frontal there are two foramina, nterior and **posterior internal orbital** or **ethmoidal canals** (foramen ethmoidale ius et posterius); both transmit ethmoidal vessels—the anterior affording ge to the nasal nerve as well. The roof is concave from side to side, and me extent also from before backwards. About midway between the o-maxillary suture and the supraorbital notch or foramen, but within margin of the orbit, there is a small **depression**, occasionally replaced by a e (fovea vel. spina trochlearis), for the attachment of the cartilaginous pulley he superior oblique muscle of the eyeball. Under cover of the external lar process the roof is more deeply excavated, forming a shallow **fossa** for the ment of the lachrymal gland (fossa glandulæ lachrymalis). In front, the roof rates the orbit from the **frontal sinus**, and along its inner border it is in relation the **ethmoidal air-cells**. The relation to these air spaces is variable, depending he development and size of the sinuses. The rest of the roof, which is very thin, s by its upper surface the floor of the anterior cranial fossa, in which are lodged rontal lobes of the cerebrum.

he *floor of the orbit* is formed by the **orbital plate** of the **superior maxilla**, ther with part of the **orbital surface** of the **malar bone**, and a small triangular of bone, the **orbital process** of the **palate**, which is wedged in posteriorly. rnally, for three-quarters of its length posteriorly, it is separated from the outer which is here formed by the great wing of the sphenoid, by a cleft called the o-maxillary fissure (fissura orbitalis inferior). Through this there pass the

superior maxillary division of the fifth nerve on its way to the infraorbital c
orbital or temporo-malar branch of the same nerve, the infraorbital vessels, a

twigs from Meckel's (spheno-palatine) ganglion. By means of this fissure
communicates with the spheno-maxillary fossa behind and the zygomatic
the outer side. Internally the floor is limited from behind forwards by th

. the following bones, viz. the orbital process of the palate below with the the sphenoid above and behind, and the os planum of the ethmoid above and —anterior to which the orbital plate of the superior maxilla below articulates e os planum of the ethmoid and the lachrymal above and in front. At the · extremity of this line of sutures the inner edge of the orbital plate of the · maxilla is notched and free between the point where it articulates with the al posteriorly and the part from which its frontal process rises. Here it he outer edge of a canal, down which the membranous nasal duct passes to e. The floor of the orbit is thin behind and at the sides, but thicker in here it blends with the orbital margin. Passing in a sagittal direction its substance is the infraorbital canal, the roof of which is usually deficient where it becomes continuous with a broad, shallow groove, which leads ls from the anterior margin of the spheno-maxillary fissure. This canal infraorbitalis) opens on the facial surface of the superior maxillary imme- below the orbital margin (foramen infraorbitale) and transmits the superior ry division of the fifth nerve, together with the infraorbital vessels. The ms a thin partition which separates the orbit from the antrum or sinus of erior maxilla, which lies below. Internally it completes the lower ethmoidal s, and separates the orbit from the middle meatus of the nasal fossæ.

outer wall of the orbit, which is the strongest, is formed by the orbital of the great wing of the sphenoid and the upper part of the orbital surface malar bone. Above it, behind, is the sphenoidal fissure, whilst below, tending much farther forward, is the spheno-maxillary fissure. The anterior of the outer wall is stout and formed by the malar bone, behind which, in part by the orbital process of the malar bone and the malar edge (margo- ticus) of the great wing of the sphenoid, it forms a fairly thick partition the orbit in front and the temporal fossa behind. Crossing this surface ove downwards, close to the anterior extremity of the spheno-maxillary is the suture between the malar bone and the great wing of the sphenoid spheno-zygomatica). This wall is pierced in front by one or two anals (foramen zygomatico-orbitale), which traverse the malar bone and the transmission of the temporal and malar branches of the orbital portion uperior maxillary division of the fifth nerve.

inner wall of the orbit is formed from before backwards by a small part of tal process of the superior maxilla, by the lachrymal, and by the os planum or late of the ethmoid (lamina papyracea ossis ethmoidalis), posterior to which all part of the lateral aspect of the body of the sphenoid in front of the amen. Above, the orbital plate of the frontal bone forms a continuous rom before backwards with the bones just enumerated; whilst below, the al and the os planum of the ethmoid articulate with the orbital plate of erior maxilla; posteriorly the hinder extremity of the os planum and the t of the body of the sphenoid articulate with the orbital process of the The orbital surface of the lachrymal bone is divided into two by a vertical he lachrymal crest (crista lachrymalis posterior)—which forms in front the r half of a hollow, the lachrymal groove (sulcus lachrymalis), the anterior which is completed by the channelled posterior border of the frontal process uperior maxilla. In the lachrymal groove or fossa (fossa sacci lachrymalis) d the lachrymal sac, whilst passing from it and occupying the canal, of he upper opening is at present seen, is the membranous nasal duct. The ly thin wall of the lower part of the lachrymal fossa separates the orbit e fore-part of the middle meatus of the nasal fossa. To the inner side of r and fore part of the lachrymal bone, and separated from the orbit merely hickness of that bone, is the passage leading from the nose to the frontal infundibulum ethmoidale), whilst the part of the bone behind the lachrymal rms the thin partition between the orbit and the anterior ethmoidal cells. where the body of the sphenoid forms part of the inner wall of the orbit, enoidal air sinus is in relation to the apex of that space, though here the n wall between the two cavities is much thicker.

skeleton of the face on its *anterior surface* is formed by the two superior

maxillæ, the frontal processes of which have been already seen to pass up to arti
late with the internal angular processes of the frontal bone, thus forming the l
halves of the inner margins of the orbit. Joined to the upper jaws externally
the **malar** or **cheek bones** (ossa zygomatica), which are supported by their u
with the temporal bones posteriorly through the medium of the zygomatic ar
The suture which separates the malar from the superior maxilla (sutura zygomat
maxillaris) commences above about the centre of the lower orbital margin
passes obliquely downward and outward, its lower end lying in vertical line w
the outer orbital margin. The two superior maxillæ are separated by the na
fossæ, which here open anteriorly. Above, the two nasal bones are wedged
between the frontal processes of the maxillæ; whilst below the **nasal aperture**, t
maxillæ themselves are united in the middle line by the intermaxillary sut
(sutura intermaxillaris).

The **nasal aperture** (apertura pyriformis), which lies below and in part betwe
the orbits, is of variable shape and size—usually pyriform, it tends to be long
narrow in Europeans, as contrasted with the shorter and wider form met with
the negroid races. Its edges are formed below and on either side by the f
curved margin of the body and the frontal process of the superior maxilla; a
above, and partly at the sides, by the free border of the nasal bones. In t
middle line, inferiorly, corresponding to the upper end of the intermaxill
suture there is an outstanding process—the **anterior nasal spine** (spina na
anterior) formed by the coalescence of spicules from both maxillæ; arising f
this, and passing backwards and upwards, is a thin bony partition—the os
septum of the nose. Often deflected to one or other side, it divides the cavi
the nose (cavum nasi) into a right and left half. Projecting into these cham
from their outer walls can be seen the inner surfaces and free borders of the mid
(concha media) and **inferior** (concha inferior) **turbinated bones**, the spaces bel
and between which form the **inferior** and **middle meatuses** of the nose respectively

Below the orbit, and to the outer side of the nasal aperture, the anterior
facial surface of the body of the superior maxilla (corpus maxillæ) is seen; this
continuous inferiorly with the outer surface of the alveolar process (process alv
laris), in which are embedded the roots of the upper teeth.

A horizontal line drawn round the jaw on the level of a point midway betwe
the lower border of the nasal aperture and the alveolar edge corresponds to t
plane of the **hard palate**. Below that the alveolar process separates the cavity
the mouth from the front of the face; whilst above, the large air space, the max
lary sinus (sinus maxillaris), or **antrum of Highmore**, lies within the body of t
superior maxilla.

The **malar** or **cheek bone** (os zygomaticum) forms the lower half of the out
and outer half of the lower border of the orbit. Its external aspect corresponds
the point of greatest width of the face, the modelling of which depends on t
flatness or projection of this bone.

When the **lower jaw** (mandibula) is in position, and the teeth in both jaws
complete, the lower dental arch will be seen to be smaller in all its diameters th
the upper, so that when the jaws are closed the upper teeth slightly overlap t
lower both in front and at the sides. Exceptionally a departure from this arrang
ment is met with.

Norma Lateralis.

Viewing this aspect of the skull, in the first instance, without the lower jaw,
is seen to be formed in part by the bones of the cranium, and in part by the bon
of the face. A line drawn from the fronto-nasal suture to the tip of the mast
process serves to define roughly the boundary between these portions of the sku
Of ovoid shape, the cranium is formed above by the **frontal, parietal,** and **occipit**
bones from before backwards; whilst below, included within these are the **sphen**
and **temporal bones**. The sutures between these several bones are arranged
follows: Commencing at the external angular process of the frontal, the sut
between that bone and the malar is first seen; tracing this backwards and a lit

the lower edge of the frontal next articulates with the upper margin of the
g of the sphenoid for a distance varying from three-quarters of an inch to
Here the posterior border of the frontal turns upwards and slightly back-
rming with the parietal the **coronal suture** (sutura coronalis). The lower
the parietal bone, which is placed immediately behind the frontal, articulates

ly with the hinder part of the upper edge of the great wing of the sphenoid.
ent of this suture (sutura spheno-parietalis) is liable to very great indi-
variation—at times being broad, in other instances being pointed and
whilst occasionally the parietal does not articulate with the sphenoid at all.
the spheno-parietal suture the parietal articulates with the squamous part
emporal (sutura squamosa). This repeats to a certain extent the curve
by the outline of the calvaria, and ends posteriorly about one inch behind
rnal auditory meatus. Here the suture alters its character and direction,
lace of being scaly, becomes toothed and irregular, uniting for the space of

an inch or so the posterior inferior angle of the parietal with the mastoid pro of the temporal bone. This suture (sutura parieto-mastoid) is more or less h zontal in direction, and lies in line and on a level with the upper border o zygomatic arch. At a point about two inches behind the external auditory me the posterior border of the parietal bone turns obliquely upwards and backw and forms with the tabular part of the occipital bone the strongly-dentical **lambdoid suture** (sutura lambdoidea). Inferiorly this suture is continued obliq downwards between the occipital bone and the hinder border of the mastoid por of the temporal, where it forms the **occipito-mastoid suture** (sutura occi mastoidea), much simpler and less serrated than the two previously menti These three sutures just described meet in tri-radiate fashion at a point c the **asterion**.

Anteriorly the curve of the squamous suture is continued downward betw the anterior edge of the squamous part of the temporal and the posterior borde the great wing of the sphenoid; inferiorly it lies in plane with the middle of zygomatic arch.

The sutures around the summit of the great wing of the sphenoid are arra like the letter H placed obliquely, the cross-piece of the H corresponding to spheno-parietal suture. When this is short, and becomes a mere point of con the arrangement then resembles the letter X. This region is named the **pteri**

Curving over the lateral region of the calvaria in a longitudinal directi the **temporal crest** (linea temporalis). This is often double. The lower line m the limit of the attachment of the temporal muscle, whilst the upper ridge de the attachment of the temporal fascia. Commencing in front at the exte angular process of the frontal, the crest sweeps upwards and backwards across lower part of that bone, and then crossing the coronal suture—a point called **stephanion**—it passes on to the parietal, over which it curves in the direction of posterior inferior angle. Here it is continued on to the temporal bone, whe sweeps forward to form the **supramastoid crest**, which serves to separate the squa from the mastoid portion of the temporal bone externally. Carried forward, ridge is seen to become continuous with the upper border of the zygom arch over the external auditory meatus. In front, the temporal ridge separ the temporal fossa from the region of the forehead; above and behind, it bou the **temporal fossa** which lies within its concavity, and serves to separate that hol from the surface of the calvaria which is overlain by the scalp. Above the l of the temporal lines the surfaces of the frontal and parietal bones are smo the latter exhibiting an elevation of varying prominence and position, but usu situated about the centre of the bone, called the **parietal eminence** (tuber parieta A slight hollowing of the surface of the parietal behind and parallel to the coro suture is not uncommon, and is referred to as the post-coronal depression. seen in profile, the part of the calvaria behind and below the lambdoid suture formed by the tabular part of the occipital bone. In line with the zygomatic a this outline is interrupted by the **external occipital protuberance** or **inion** (protub antia occipitalis externa). The projection of this point is variable; but position can usually be easily determined in the living. Passing forwards fr it, and blending anteriorly with the posterior border of the mastoid process of t temporal bone, is a rough crest, the **superior curved line** (linea nuchæ superior), little above which there is often a much fainter line, the **highest curved line** (lin nuchæ suprema); this affords attachment to the epicranial aponeurosis. These tw lines serve to separate the part of the cranium above, which is covered by scal from that below, which serves for the attachment of the fleshy muscles of the ba of the neck, the latter surface (planum nuchale) being rough and irregular contrasted with the smooth superior part (planum occipitale). The fulness these two parts of the occipital bone varies much. There is frequently a pronounc bulging of the planum occipitale, and the position of the lambda can often easily determined in the living; similarly the planum nuchale may be either com paratively flat or else full and rounded. These differences are of course associate with corresponding differences in the development of the cerebral and cerebell lobes which are lodged in relation to the internal aspect of these parts of the bon

further description of the planum nuchale is best deferred till the base of skull (norma basalis) is studied.

Temporal Fossa.—Within the limits of the temporal lines the side of the cranium es forwards, inwards, and downwards, thus leaving a considerable interval between ower part and the **zygomatic arch**. This space or hollow is called the temporal a (fossa temporalis); bounded above and behind by the temporal lines, its inferior t is defined by the level of the zygomatic arch. Deepest opposite the angle formed he frontal and temporal processes of the malar bone, the fossa becomes shallow ards its circumference. Its floor, which is slightly concavo-convex from before kwards about mid-level, is formed above by the temporal surface (facies temporalis) he frontal, behind by the anterior inferior angle (angulis sphenoidalis) of the ietal, as well as the lower portion of that bone, below the temporal crest; below . in front by the temporal surface of the great wing of the sphenoid, and behind . below by the squamous portion of the temporal bone. Inferiorly the floor is ited in front by the free inferior border of the great wing of the sphenoid, which ns the upper boundary of the **spheno-maxillary fissure**; behind that, by a rough ge, the **infratemporal crest** or **pterygoid ridge** (crista infratemporalis), which sses the external surface of the great wing of the sphenoid, to become con- uous posteriorly with a ridge on the lower surface of the squamous temporal, m which the anterior root of the zygomatic process springs. In front the nporal fossa is separated from the orbit by the external angular process of the ntal above, and by the orbital process of the malar and its junction with the ternal border of the great wing of the sphenoid between the orbital and temporal rfaces of that process. Externally and in front, the fossa is overhung by the ckward projection of the frontal process of the malar bone, and it is under cover this, and within the angle formed by the frontal and orbital processes of the malar, at we see the opening of the **temporal canal**, which pierces the orbital plate of the alar and transmits the temporal branch of the orbital nerve—a filament of the perior maxillary division of the V nerve. The fore-part of the **spheno-maxillary sure** (fissura orbita inferior) opens into the lower part of the temporal fossa, and us establishes a communication between it and the orbit. If the floor of the sa be carefully examined, some more or less distinct **vascular grooves** may seen. One passing upwards over the posterior part of the squamous mporal, immediately in front of and above the external auditory meatus, is for e middle temporal artery; two others, usually less distinct, pass up, one over the mporal surface of the great wing of the sphenoid, the other over the fore-part of he squamous temporal; these are for the anterior and posterior deep temporal anches of the internal maxillary artery. The fossa contains the temporal muscle ith its vessels and nerves, together with the temporal branch of the orbital nerve nd some fat; all of which are enclosed by the fascia which stretches over the space om the upper temporal line above to the superior border of the zygomatic arch elow. The extent of the fossa depends on the size of the temporal muscle, he development of which is correlated with the size and weight of the lower jaw.

Springing from the front and lower part of the squamous temporal is the **ygomatic process** of that bone; it has two roots, an anterior and a posterior, between nd below which are placed the **glenoid fossa** (fossa mandibularis) in front, and the pening of the **external auditory meatus** behind. Of compressed triangular form, the rocess at first has its surfaces directed upwards and downwards, but curving out- ards and forwards, it twists on itself, so that its narrowed surfaces are now turned outwards and inwards, and its edges upwards and downwards; passing forwards, it xpands somewhat, and ends in an oblique serrated surface, which unites with the emporal process of the malar bone and completes the **zygomatic arch**. It is the upper edge of this bridge of bone which forms the posterior root. The lower border, turning inwards, forms the anterior root, and serves to separate the temporal from the zygomatic surface of the squamous temporal, blending in front with the **infra- temporal crest** on the outer surface of the great wing of the sphenoid. The under surface of this root is convex from before backwards, and is thrown into relief by the **glenoid hollow**, which passes up behind it. In this way a downward projection, which is called the **eminentia articularis**, is formed.

The **alar spine** of the **sphenoid** (spina angularis) lies immediately to
inner side of the articular part of the glenoid fossa. Its size and projection
It is well to remember its relation to the condyle of the lower jaw when that
is in position; lying, as it does, to the inner side and a little in front of that
cess, it affords attachment to the so-called long internal lateral ligament (sph
mandibular) of the temporo-maxillary articulation. As will be seen hereafter,
anterior extremity of the osseous Eustachian canal lies immediately to its i
side (p. 164). A noteworthy feature about the articular part of the glenoid
is the thinness of the bony plate which serves to separate it from the mi
cranial fossa above. The **vaginal process** is a crest of bone which runs oblig
forwards from the front and inner side of the mastoid process, just below
external auditory meatus, to the alar spine of the sphenoid. Passing downw
and slightly forwards from the centre of this, and ensheathed by it in front
at the sides, is the pointed **styloid process**, the length of which is extremely vari

In the recess between the posterior root of the zygoma and the upper cu
edge of the meatus there is usually a depression, though in some instances
may be replaced by a slight bulging of the bone. If from the posterior roo
the zygoma a vertical line be let fall, tangential to the posterior edge of the me
a small triangular area is mapped off which has been named by Macewen the m
meatal triangle. Surgically this is of importance, as it is the spot selected in w
to trephine the bone to reach the **mastoid antrum** (see p. 120).

In the suture between the posterior border of the mastoid-temporal and
tabular plate of the occipital, there is usually a **foramen** (**mastoid**) for the tr
mission of an emissary vein from the lateral sinus within the cranium to
cutaneous occipital vein of the scalp; this opening, which may be double, va
greatly in size, and is usually placed on a level with the external audit
meatus.

Zygomatic Fossa.—The side of the cranium in front of the anterior root of
zygomatic process of the temporal bone is deeply hollowed, forming the **zygom**
or **infratemporal fossa** (fossa infratemporalis); this in topographical anat
corresponds to the pterygo-maxillary region. The student must bear in m
that, in examining this space, the ramus and coronoid process of the lo
jaw form its outer wall; but this bone for the present being withdrawn, enable
to get a better view of the boundaries of the space. In front its *anterior*
is formed by the convex posterior or **zygomatic surface** (facies infratempora
of the **superior maxilla**, which rises behind the socket for the last molar tooth
form the **tuberosity** (tuber-maxillare). Anteriorly the zygomatic surface of the up
jaw is separated from its facial aspect by the rounded inferior margin of the ma
or zygomatic process which supports the malar bone. This latter curves outwa
and backwards, forming part of the upper and anterior wall of the fossa. On the in
surface of this wall will be seen the suture uniting the malar and superior maxill
bones (sutura zygomatico-maxillaris), which runs obliquely upwards and inwa
to reach the external extremity of the spheno-maxillary fissure, the lower border
which forms the superior boundary of the zygomatic surface of the upper jaw. O
this aspect of the bone are to be seen the openings of the **posterior dental can**
(foramina alveolaria) two or more in number, which transmit the nerves a
vessels to the upper molar teeth. The *inner wall* of the zygomatic fossa is form
by the outer surface of the **external pterygoid plate** (lamina lateralis proces
pterygoidei), the width and shape of which varies greatly; its posterior border
thin and sharp, and often furnished with spiny points, to one of which the pteryg
spinous ligament, which stretches from this border to the alar spine of the sphenoi
is attached. It occasionally happens that this ligament becomes ossifie
Anteriorly the external pterygoid plate is separated from the superior maxil
above by an interval called the **pterygo-maxillary fissure**. Below this the bones a
apparently fused, but a careful inspection of the skull, together with an examin
tion of the disarticulated bones, will enable the student to realise that, wedged
between the two bones at this point, is a part of one of the smaller bones of t
face, the **tuberosity** of the **palate bone** (processus pyramidalis ossis palatini).

The lower border of the external pterygoid plate is usually curved and slight

Superiorly, where the external pterygoid plate is generally narrower, it
ıpwards to become continuous with the broad under surface of the great
the sphenoid; this, which overhangs in part the zygomatic fossa superiorly,
d above by the **infratemporal crest** which separates its zygomatic from its
l surface. The zygomatic surface of the great wing of the sphenoid is
in front and below by the edge which forms the upper boundary of the
naxillary fissure, whilst behind it reaches as far back as the inner
y of the Glaserian fissure, where it terminates in the alar spine. It is
is point that the suture (sutura spheno-squamosa) curves forward and
to reach the region of the pterion. The infratemporal or zygomatic
of the great wing of the sphenoid, and the outer surface of the external
d plate, alike afford extensive attachments for the external pterygoid
whilst the former is pierced by minute canals for the transmission of
veins. Occasionally a larger vascular foramen is present (foramen Vesalii),
which a vein runs from the cavernous sinus within the cranium to the
id venous plexus situated in the pterygo-maxillary region. Immediately
he root of the external pterygoid plate there is a large oval hole, the **foramen**
nd behind that, and in line with the alar spine, is the smaller **foramen**
a. These two foramina cannot usually be seen in a side view of the skull,
better studied when the base is examined; they are mentioned, however,
they transmit structures which here pass from and enter the cranium, viz.
rior maxillary division of the fifth nerve, together with its motor root, and
ll meningeal artery through the foramen ovale, and the middle meningeal
and its companion veins through the foramen spinosum. A part of the
us temporal also forms a small portion of the roof of this fossa; it consists
angular area immediately in front of the eminentia articularis, and between
the anterior root of the zygomatic process of the temporal, which is here
inwards and forwards, to become continuous with the infratemporal crest.
lly this surface is continuous with the zygomatic surface of the great wing
sphenoid, separated from it, however, by the hinder part of the spheno-
sal suture.

en the lower jaw is in position, the zygomatic fossa is concealed by the
f the mandible, the inner surface of which, in its upper half, forms the outer
that space. Viewed from the outer side, the ramus of the inferior maxilla
s considerable differences in different skulls. These are mainly due to varia-
ı its width and in the nature of the angle which it forms at its fusion with
y of the bone. A considerable interval separates the posterior border of the
from the front of the mastoid process. Within this space may be seen the
erior edge of the **tympanic plate** (vaginal process), from which, just below
ernal auditory meatus, the **styloid process** of the temporal bone is observed
downwards and slightly forwards. The width and height of the **coronoid**
vary much, oftentimes reaching the level of the top of the condyle. Its
ity, when the lower jaw is closed, lies just within the fore-part of the zygo-
ırch; at other times it rises to a much higher level, so that its point may be
ove the level of the upper border of the zygomatic arch. The posterior
f the coronoid process forms the anterior border of the sigmoid notch, and
in front the interval left between the lower border of the posterior half of
gomatic arch and the upper hollowed edge of the ramus. On looking into
terval, the floor of the zygomatic fossa may be seen, formed anteriorly by the
ıl pterygoid plate; whilst posteriorly it is possible to pass a probe right
the base of the skull from one sigmoid notch to the other, the shaft of the
ying immediately behind the pterygoid processes of the sphenoid, and cross-
foramina ovalia, through which the inferior maxillary divisions of the fifth
pass.

e **ramus** and **coronoid process** are so placed as to occupy a position inter-
e between the zygomatic arch externally and the external pterygoid plate
lly; their inner surface, therefore, forms the outer wall of the zygomatic fossa.
level with the surface of the crowns of the teeth of the lower jaw, and
d about the middle of this aspect of the ramus, is the **inferior dental foramen**

(foramen mandibulare), the superior opening of the **inferior dental canal** (cana mandibulæ), which traverses the body of the bone. Through this foramen the pass the inferior dental branch of the inferior maxillary division of the fifth ner together with the inferior dental artery and its companion veins. As will now seen, when the lower jaw is in position, the zygomatic fossa is closed in externa by the ramus of the mandible. In front there is an interval between the anter border of the ramus and the zygomatic surface of the superior maxilla, throu which pass the buccal branch of the fifth nerve and the communicating ve between the pterygoid plexus and the facial vein. Above, in the interval betwe the sigmoid edge and the lower border of the zygomatic arch, there pass from t fossa the vessels and nerves which supply the masseter muscle. Between t posterior border of the ramus and the styloid process there enter and leave t large vessels which are found within the space. Superiorly, under cover of t zygomatic arch, the zygomatic fossa communicates with the temporal fossa, whil inferiorly it is continuous with the inframaxillary region. Internally, on t floor of the fossa there is an Γ-shaped fissure, the horizontal limb of whi corresponds to the **spheno-maxillary fissure**, forming a channel of communicati between the fossa and the orbit, through which passes the orbital branch of t superior maxillary division of the fifth nerve; whilst the vertical cleft is the **pteryg maxillary fissure**, which leads into a small fossa placed between the front of the r of the pterygoid process of the sphenoid and the back of the superior maxilla, call the **spheno-maxillary fossa** (fossa pterygo-palatina).

The following foramina open into the zygomatic fossa—the foramen ova

foramen spinosum, posterior dental foramina, inferior dental foramen, mino foramina for the transmission of emissary veins; of these one of large size occasionally present, the foramen of Vesalius.

Spheno-Maxillary Fossa.—This space, which corresponds to the angular inter

ween the pterygo-maxillary and spheno-maxillary fissures, and which lies **ween the maxilla** in front and the root of the pterygoid process behind, is **nded internally** by the vertical plate of the palate bone, which separates it **m the nasal cavity**, with which, however, it communicates by means of the **sno-palatine** foramen, which lies between the orbital and sphenoidal processes of **palate bone** and the under surface of the body of the sphenoid. Opening **this fossa**, above and behind, are the foramen rotundum, the Vidian canal and **pterygo-palatine** canal from without inwards, whilst below is the superior **ce of the posterior** palatine canal, together with openings of the accessory **erior palatine canals**. Its roof is formed by the under surface of the body of **sphenoid and the orbital** plate of the palate bone. Anteriorly it lies in relation **the apex of the** orbit, with which it communicates by means of the spheno-**xillary fissure**; whilst externally, as already stated, it communicates with the **omatic fossa** through the pterygo-maxillary fissure.

Norma Occipitalis.

This view of the cranium includes the posterior halves of the two parietal **nes above**, the tabular part of the occipital bone below, and the mastoid portions **the temporal** bones on either side inferiorly. The shape of this aspect of the **ull varies much**, but ordinarily the greatest width corresponds to the level of the **rietal eminences**. The sutures on this view of the calvaria display a tri-radiate **angement**, one limb of which is vertical, and corresponds to the posterior part of **e interparietal** or **sagittal suture** (sutura sagittalis). The other two limbs pass **twards and downwards** in the direction of the mastoid processes, uniting the two **rietal bones in front** with the occipital bone behind; these constitute the Λ-shaped **mbdoid suture** (sutura lambdoidea). The point of confluence of the sagittal and **mbdoid sutures** is called the **lambda**. This can generally be felt in the living, **ring to the** tendency of the tabular part of the occipital to project slightly **mediately below** this spot. About one inch and a quarter above the lambda the **o small parietal foramina** (foramina parietalia) are seen, through which pass the **all emissary** veins of Santorini, which connect the intracranial venous system **ith** the superficial veins of scalp. These small holes lie about $\frac{5}{16}$ of an inch apart **n** either side of the sagittal suture, which here, for the space of about an inch, **isplays** a simplicity of outline in striking contrast with its serrated arrangement **lsewhere**. The term **obelion** is applied to a point on the sagittal suture in line **ith** the two parietal foramina. The **lambdoid suture** is characterised by great **regularity** of outline, and not unfrequently chains of separated ossicles are met **ith** in it, the so-called **Wormian bones**. The tabular part of the occipital bone is **ivided** into two parts by the **superior curved line** (linea nuchæ superior), the **entral** part of which forms the **external occipital protuberance** (protuberantia **ccipitalis exterior**). The part above, called the occipital surface (planum occipitale), **omes** within our present consideration; the part below, the nuchal surface (planum **uchale**, though seen in perspective, had best be considered when the base is **examined**. A little above the level of the superior curved line the occipital surface **is** crossed on either side by a faint lunated line, the **highest curved line** (linea **uchæ** suprema) to which are attached the occipitales muscles and the epicranial **aponeurosis**. The projection of the occipital surface varies much in individual **skulls**; most frequently it overhangs the external occipital protuberance, forming a **distinct** boss; exceptionally, however, the latter may be the most projecting part of **the** bone. The extremity of the superior curved line on either side corresponds to **the** position of the **asterion** (p. 154). External to these points the outline of the **skull** is determined by the downward projection of the mastoid processes, the inner **surfaces** of which are deeply grooved for the attachment of the posterior bellies of **the** digastric muscles, thus causing these processes to appear more pointed when **viewed** from this aspect.

Norma Verticalis.

This is the view of the calvaria as seen from above. It is liable to great

diversities of form. Thus its shape may vary from an elongated oval to an out more nearly circular. These differences have been classified, and form impor distinctions from a craniometrical standpoint (p. 178), the rounder varieties h termed the **brachycephalic**, whilst the elongated belong to the **dolichocephalic** gr Another noteworthy point in this view is the fact that in some instances zygomatic arches are seen, whilst in others they are concealed by the overh and bulge of the sides of the fore-part of the cranium. The former conditio described as **phœnozygous**, the latter as **cryptozygous**, and each is more or less clo associated with the long or round varieties of head-form respectively.

The sutures displayed have a T-shaped arrangement. Placed mesially betw the two parietal bones is the **sagittal suture**. This is finely denticulated, excep the region of the obelion, though, of course, this will not be apparent if obliter of the suture has taken place through fusion of the two parietal bones. Poster the sagittal suture unites with the lambdoid suture at the **lambda**, which m in the adult the position of the posterior fontanelle of the fœtus. Anterior terminates by joining the transverse suture which separates the **frontal** anteriorly from the parietals behind; this latter is called the **coronal suture**, and point of junction between the sagittal and coronal sutures is known as the **bre** which corresponds in position to the anterior fontanelle of the fœtus. The sum of the vault of the calvaria corresponds to a variable point in the line of the sagi suture, and is named the **vertex**. The **coronal suture** is less denticulated centrally t laterally. Occasionally there is a persistence of the suture which unites the halves of the frontal bone; under these conditions the line of the **sagittal sutur** carried forward to the fronto-nasal suture, and a skull displaying this peculiarit described as **metopic**. Behind the coronal suture may occasionally be seen **post-coronal depression** (p. 154), and in some instances the vault of the **calvaria** fo a broad, slightly elevated crest along the line of the sagittal suture. On ei side, the temporal ridges can be seen curving over the lateral and superior asp of the parietal bones. As the lower of these crosses the coronal suture in fro marks a spot known as the **stephanion**, useful as affording a fixed point from wh to estimate the bi-stephanic diameter. The interval between the temporal ri on either side will vary according to the form of the skull and the developmen the temporal muscle. In this view of the calvaria a small part of the lambd suture on either side of the lambda is visible posteriorly.

Norma Basalis.

The base of the cranium—*i.e.* the skull without the mandible—includes a descri tion of the under surfaces of the **skeleton of the face** (cranium viscerale) and t **cranium** (cranium cerebrale). The former includes the **hard palate** formed by t superior maxillæ and palate bones, the **superior dental arch**, and the **bodies of t superior maxillæ** as seen from below; whilst externally, and united with the bodies the superior maxilla, the **malar** bones are displayed, curving backwards to form t anterior halves of the **zygomatic arches**. In the middle line, passing from the up surface of the hard palate, is the osseous septum of the nose, here formed the vomer, which is united above to the under surface of the body of t sphenoid.

The under surface of the cranium is pierced by the **foramen magnum** for t transmission of the spinal cord and its membranes. In front of this a stout bar bone extends forwards in the middle line, formed by the union of the body of t sphenoid in front with the basilar process of the occipital bone behind. In ad skulls all trace of the fusion of these two bones has disappeared; when union is i complete, it indicates that the skull is that of a person below the age of twenty-fi The sphenoid comprises that part of the calvaria which forms the roof and sides the apertures which lie on either side of the nasal septum above the hard pal —the **choanæ** or **posterior nares**. Laterally the under surfaces of the gr sphenoidal wings extend as far forward as the posterior border of the sphe **maxillary fissure**; whilst posteriorly they reach as far as the **alar spine**, external which the spheno-squamosal suture, separating the great wing of the sphenoid fr

squamous portion of the temporal, curves forwards and upwards, internal to the mentia articularis, to reach the floor of the temporal fossa, along which its course

has been already traced (p. 155). On a level with the front of the foram magnum the **jugular process** of the occipital bone forms an irregular curved bon which sweeps outwards to terminate at a point just internal to the root of t styloid process. Here, in line with the spheno-squamosal suture, from which, h ever, it is separated by a considerable interval, its extremity turns backwards, may be traced at first internal to, and then turning upwards, behind the mast process of the temporal bone, separated from this latter by the occipito-mast suture. The bone behind the foramen magnum, which is included between two occipito-mastoid sutures, comprises the **nuchal surface** of the tabular portion the occipital bone, an area which is limited behind by the **superior curved** which separates it from the occipital surface of the same bone. The remain portions of the base of the calvaria, as at present exposed, are formed by **squamous** and **tympanic portions** of the **temporal bone** together with the **petro-mast part** of the same bone, the latter of which is wedged in between the great win the sphenoid in front and the occipital bone behind. Stretching forwards from squamous temporal in front is seen the **zygomatic process** which, by its union w the malar, completes the formation of the zygomatic arch.

Studying next the various parts in detail, the **hard palate** (palatum durum) m be first examined. Of horse-shoe shape as a rule, it presents many varieties of e line and size. Formed by the palatal processes (processus palatini) of the supe maxillæ in front and the horizontal plates (partes horizontales) of the palate bo behind, its circumference in front and at the sides corresponds to the sup **alveolar arch**, in which are embedded the sixteen teeth of the upper j posteriorly the edge of the hard palate is thin, ending mesially in a poin process, the **posterior nasal spine** (spina nasalis posterior), on either side of which posterior free border is sharp and lunated. The vault of the palate, which concave from side to side, and from before backwards, varies in depth according the projection and development of the alveolar processes. When the teeth are s and the alveoli are absorbed, the palate becomes shallow and flat. Runni throughout its entire length in the middle line is the **middle palatine sut** (sutura palatina mediana), which separates the palatal processes of the supe maxillæ in front and the horizontal plates of the palate bones behind. A lit behind the central incisor teeth, and in the line of this suture, is a little pit, **anterior palatine canal** or **fossa** (foramen incisivum). At the bottom of this may seen the openings of some small canals, varying in number from one to four; th are usually described as arranged in two pairs, the one pair placed side by si the other lying mesially in front and behind. The former are called the inci foramina, or foramina of Stenson, and transmit the terminal twigs of the super or descending palatine arteries which ascend to reach the nasal fossæ. The latt called the foramina of Scarpa, open, the anterior into the left, the posterior into t right nasal fossa, and afford passage for the fine filaments of the left and right na palatine nerves respectively. About half an inch (12 mm.) in front of the poster nasal spine the middle palatine suture is crossed at right angles by the transve **palatine suture** (sutura palatina transversa). This, which indicates the line union of the palatal processes of the superior maxillæ with the horizontal plates the palate bones, passes transversely outwards on either side until it reaches t inner aspect of the base of the alveolar process, along which it turns backward, disappear within the **posterior palatine canal** (foramen palatinum majus), the apertu of which lies immediately internal to the root of the wisdom molar. Through th there pass the superior or descending palatine artery and the large descendi palatine nerve. Leading from this foramen is a groove which curves forward im mediately to the inner side of the alveolar arch; not unfrequently the inner edg of this groove forms a thin and sharp ridge on the surface of the palate. In thi groove are lodged the aforementioned vessels and nerves. The surface of the palat in front of the transverse suture is rough, pitted for the palatine glands, and pierced b numerous small vascular foramina; the part of the palate behind the suture, forme by the under surface of the horizontal plate of the palate bone, is much smoothe From this there rises, just posterior to the orifice of the posterior palatine canal, thin sharp crest which curves inwards immediately in front of the posterior fr

; to this are attached some of the tendinous fibres of the tensor palati cle.

Pterygoid Processes.—Buttressed against the hinder extremities of the alveolar are the pterygoid processes of the sphenoid. If carefully examined, these be seen not to lie in actual contact with the maxillæ, but to be separated from a by the triangular wedge-shaped **tuberosities** (proc. pyramidales) of the palate s. It is these latter which are pierced by the posterior and external **accessory tine canals** (foramina palatina minora) which lie just behind the posterior pala- canal, and through which pass the lesser palatine nerves. As here displayed, **pterygoid processes** (processus pterygoidei) of the sphenoid lie on either side of opening of the posterior nares; each consists of two plates, an internal (lamina ialis) and an external (lamina lateralis); the latter is the broader, and is cted backwards and slightly outwards. Its external surface has been already lied in connexion with the zygomatic fossa (p. 156). Internally it is separated n the inner pterygoid plate by the **pterygoid fossa** (fossa pterygoidea), wherein odged a considerable part of the internal pterygoid muscle. The floor of the a is formed in greater part by the coalescence of the two pterygoid plates; but he level of the hard palate the tuberosity of the palate bone appears wedged in ween the two plates, and so enters into the formation of the floor of the rygoid fossa. The internal pterygoid plate separates the nasal from the rygoid fossa; to the hinder edge of the internal pterygoid plate are attached the ryngeal aponeurosis, the superior constrictor of the pharynx, and the palato- ryngeus muscle. Above, the posterior border of this plate is channelled to m the small **scaphoid fossa** (fossa scaphoidea), which curves outwards over the mmit of the pterygoid fossa, and furnishes a surface for the origin of the tensor palati scle. The sharp inner margin of this fossa, continuous below with the posterior rder of the internal pterygoid plate, extends upwards, and on either side of the dy of the sphenoid forms a blunt pointed process, the **pterygoid tubercle**, which tends backwards towards the apex of the petrous part of the temporal bone. st external to this, and concealed by it, is the hinder extremity of the **Vidian nal** (canalis Vidianis), through which pass the Vidian vessels and nerve. The ner surface of the internal pterygoid plate is directed towards the nasal fossæ. periorly this surface curves inwards to meet the under surface of the body of the henoid, forming on either side a lipped edge, the **vaginal process** (processus vaginalis), tween which the alæ of the vomer, which here forms the nasal septum, are edged. Between the two a small interval, however, is occasionally left, which forms s either side the **basi-pharyngeal canal**. A little external to the line of union of he vaginal process with the vomer is the opening of the **pterygo-palatine canal** analis pharyngeus). This lies between the under surface of the vaginal process nd the sphenoidal process of the palate bone, which here articulates with the nferior surface of the body of the sphenoid. The pharyngeal branch of the pheno-palatine ganglion and the pterygo-palatine artery pass through this canal. nferiorly the pterygoid processes project below the level of the hard palate. The ner plate ends in a slender recurved process, called the **hamular process** (hamulus terygoideus), which turns backwards and outwards; this is frequently broken off in kulls which have been roughly handled. It reaches as low as the level of the lveolar margin, and lies just within and behind the posterior extremity of the lveolar process. It can readily be felt in the living by placing the finger against he soft palate behind and just within the gum around the root of the wisdom ooth. On the front of and below this process the tendon of the tensor palati nuscle glides in a groove.

The **posterior nares** (choanæ) lie within and between the pterygoid processes. f a shape much resembling two Gothic windows, their bases or inferior boundaries re formed by the horizontal plates of the palate bone. Externally they are ounded by the inner surfaces of the internal pterygoid plates, whilst above, the uter side of the arch is formed by the vaginal processes of the same plate; intern- lly they are separated by the thin vertical posterior border of the vomer, whilst bove the everted alæ of the same bone form the inner sides of the arch. The lane of these apertures is not vertical but oblique, corresponding usually to a

line drawn from the bregma above through the last molar tooth of the u jaw below. Their size varies considerably, but the height is usually equal to t the width.

The region of the cranium which lies external to the superior maxilla external pterygoid plate corresponds to the **zygomatic fossa**, which has been al described as seen from the side (norma lateralis, p. 156). Viewed from below zygomatic fossa is bounded in front by the posterior surface of the body of superior maxilla and the internal surface of the malar bone. The roof, whi traversed by the spheno-squamosal suture, is formed in front by the under su of the great wing of the sphenoid, and behind by a small triangular surface o under side of the squamous part of the temporal bone immediately in front of eminentia articularis.

Circumscribed externally and behind by the anterior root of the zygoma, w curves forward to become continuous in front with the infra-temporal crest cro the external surface of the great wing of the sphenoid, the roof of the fo separated from its anterior wall by the **spheno-maxillary fissure**, which is so inc that with its fellow of the opposite side it forms an angle of 90°. Superiorly zygomatic fossa communicates freely with the temporal fossa beneath the matic arch, though the student must bear in mind the fact that when the inf maxilla is in position the external limits of the space are very much reduced (p.

The under surface of the great wing of the sphenoid is here V-shaped. angle corresponds to the spine, the outer limb to the spheno-squamosal su whilst the inner limb corresponds to a narrow cleft, the fissura spheno-pet which separates it from the petrous portion of the temporal bone to which united in the recent condition by a synchondrosis. Along the line of this l fissure the edges of the adjacent bones (sphenoid and petrous temporal) bevelled so as to form a groove, which extends from the root of the inner pter plate internally, to the inner side of the base of the alar spine externally, w the groove ends by entering an osseous canal. In the groove (sulcus tubæ audit is lodged the cartilaginous part of the **Eustachian tube**, whilst the osseous c includes the bony part of the same tube, together with the tensor tympani mu which is lodged in a separate compartment immediately above it. The ant extremity of the cartilaginous part of the Eustachian tube is supported by posterior edge of the internal pterygoid plate, which is often notched for its re tion. Between the root of the external pterygoid plate and the alar spine t are two foramina which lie immediately in front of the sulcus tubæ audit Of these the larger and anterior is the **foramen ovale**, through which pass motor root and inferior maxillary division of the fifth nerve, together with small meningeal artery. The smaller, which from its position immediately front of the alar spine is called the **foramen spinosum**, transmits the middle me geal artery and sympathetic plexus surrounding that vessel. The lesser superf petrosal nerve here passes through the base of the skull to join the otic gangl either through a small foramen (canalis innominatus) placed between the fora ovale and the foramen spinosum, or through the foramen ovale or through spheno-petrosal fissure. The position of the suture between the basi-occipital a basi-sphenoid corresponds to a line connecting the tips of the pterygoid tubercles the root of the internal pterygoid plates.

Occasionally in the centre of this line there is a small pit with a foramen leading from it. T probably represents the lower end of the cranio-pharyngeal canal.

The under surface of the **basi-occipital** (pars basilaris) stretches between t body of the sphenoid in front and the anterior margin of the foramen magnu behind; projecting from its centre is a slight elevation, the **pharyngeal tuber** (tuberculum pharyngeum), to which the pharyngeal aponeurosis, together with t central part of the anterior occipito-atlantal ligament, is attached. It should b noted, that when the atlas is in position the pharyngeal tubercle lies in line wit the tubercle on the anterior arch of that bone. Curving outwards and backward from the pharyngeal tubercle, on either side, is an irregular ridge (**crista muscularis**) in front and behind which are attached the rectus capitis anticus **major and mino**

cles. On either side of the basi-occipital, in front, there is an irregular opening ariable size; this is placed between the root of the pterygoid process anteriorly, apex of the petrous portion of the temporal bone externally, and the outer e of the basi-occipital and basi-sphenoid internally. It is called the **foramen rum medium**. Opening into it in front, just external to the pterygoid tubercle, he **Vidian canal**, whilst in correspondence with the apex of the petrous temporal large orifice of the **carotid canal** may be seen entering it behind and from the er side. In the recent condition the lower part of the foramen lacerum is upied by fibro-cartilage, over the upper surface of which the internal carotid ery and great superficial petrosal nerve pass to reach their respective foramina, ilst a small meningeal branch of the ascending pharyngeal occasionally enters cranium through it. Leading outwards from the foramen lacerum in the ection of the alar spine of the sphenoid is the spheno-petrosal fissure, which lies the bottom of the **sulcus tubæ auditivæ**, and disappears from view within the y **Eustachian canal**. Passing backwards from the foramen lacerum there is a sure between the outer side of the basi-occipital and the posterior and inner rder of the petrous part of the temporal bone. This, which is called the **petro-ipital fissure** (fissura petro-occipitalis), opens posteriorly into the **jugular foramen**. the recent condition the fissure is filled up with cartilage. The under surface the petrous bone included between these two fissures is rough and irregular, and ords attachments near its apex to two small muscles, the levator palati and the nor tympani. Immediately behind the alar spine the petrous temporal is rced by a circular hole, the inferior opening of the **carotid canal** (canalis caroticus). is passes upwards, and then turns inwards and forwards towards the apex of the ne, where it may again be seen opening into the outer and upper side of the ramen lacerum. Externally the wall of the vertical part of this canal which is ually very thin, separates it from the cavity of the tympanum, as may be seen by lding the skull up to the light and looking into the external auditory meatus . 118). The carotid canal transmits the internal carotid artery, together with e sympathetic plexus around it. It is noteworthy that the two carotid canals e in line with the anterior edges of the two external auditory meatuses.

The **jugular foramen** is an opening of irregular shape and size placed between e petrous temporal in front and the jugular process of the occipital bone hind. The former is excavated into a hollow called the **jugular fossa**, which forms roof to the upper and outer part of the space, whilst the latter, by a curved edge, ther rounded or sharp, constitutes its posterior border. There is often considerable fference in the size of the jugular foramina; that on the right side (with the skull n its normal position) is usually the larger. The foramen is occasionally sub-ivided into two by spicules of bone which bridge across it. Lodged within the men is the sinus of the internal jugular vein, in front of which the inferior petrosal inus passes down to join the internal jugular vein below the foramen. Effect-ng an exit between the two veins, in order from before backwards, are the glosso-haryngeal, pneumogastric, and spinal accessory nerves. Small meningeal branches om the ascending pharyngeal and occipital arteries also enter the foramen. The wo jugular foramina lie in line with a line drawn through the centres of the two xternal auditory meatuses. Following the direction of a line connecting the alar pine of the sphenoid and the mastoid process of the temporal, and placed immedi-tely external to the apertures of the carotid canal and jugular foramen, is the aginal process of the tympanic plate of the temporal bone, the edge of which is harp and thin, and serves to separate the under surface of the petrous temporal from the non-articular part of the glenoid fossa. Springing from this crest im-mediately external to the jugular fossa, and in line with the middle of the external uditory meatus, is the **styloid process** (processus styloideum) of the temporal bone (p. 116). Its relation to the jugular foramen is of great importance, as the internal jugular vein lies immediately to its inner side.

Immediately behind the root of the styloid process, internal to and in line with the front of the mastoid process, is the **stylo-mastoid foramen** (foramen stylo-mastoideum), the lower aperture of the aquæductus Fallopii through which the facial erve passes out and the stylo-mastoid branch of the posterior auricular artery

passes in. The inner surface of the mastoid process is deeply grooved at its b for the origin of the posterior belly of the digastric muscle. Internal to this, running along, just wide of the occipito-mastoid suture, is a shallow groove in w the occipital artery is lodged. Immediately internal to the stylo-mastoid fora is the synchondrosis between the extremity of the **jugular process** (proc jugularis) of the occipital bone and the petrous temporal. The former is a ba bone which limits the jugular fossa posteriorly and abuts on the occipital cond internally; its under surface is convex from before backwards and affords attachm to the rectus lateralis muscle. The **occipital condyles** (condyli occipitales) placed between the jugular processes and the foramen magnum. Limited in fr by a rounded thickening which becomes confluent with the anterior border of foramen magnum, they form by their inner sides the lateral boundaries of t aperture on its anterior half. Externally they are continuous with the jug processes, in front of which they overhang a fossa which is pierced behind by **anterior condylic foramen** (canalis hypoglossi), through which passes the hypogl nerve, together with a small vein and occasionally a small meningeal bra derived from the ascending pharyngeal artery.

The **posterior condylic fossæ** are situated just behind the posterior extremiti the condyles. Not unfrequently their floor is pierced by the **posterior con foramen** (canalis condyloideus), through which the posterior condylic vein eme The base of the skull behind the jugular processes and condyles of the occip bone is formed by the nuchal surface (planum nuchale) of the tabular plate of t bone. Posteriorly this surface is bounded by the **superior curved line**, in the ce of which is placed the projecting external occipital protuberance. Laterally tabular plate is separated from the mastoid portion of the temporal bone by occipito-mastoid suture, which curves backwards and outwards, from the extre of the jugular process in front, around the base of the mastoid process behind. front and in the middle line this plate of bone is pierced by the **foramen magn** the anterior half of which has been already seen to lie between the occip condyles. Usually of oval form, though in some cases it tends to approach circular, the plane of this opening is inclined downwards and slightly forwa The extreme anterior edge of the foramen is sometimes called the **basion**, whilst extreme posterior margin is termed the **opisthion**. The lower border of the medu oblongata, where it becomes continuous with the spinal cord, is lodged within foramen, together with the meninges which cover it, whilst the vertebral arter and the spinal portions of the spinal accessory nerves pass upwards through The anterior and posterior spinal arteries, some small veins, and the roots of th first cervical nerves, also traverse it from above downwards.

The student will, no doubt, experience considerable difficulty in bearing in mind the rela positions of the various foramina and processes which he has studied on the under surface of base of the skull.

If a line be drawn on either side from the anterior palatine canal in front, through the st mastoid foramina posteriorly, it will be found to cut or pass near to the following objects:— the hard palate it will lie close to the posterior and accessory palatine canals. It will then between the hamular process and the external pterygoid plate overlying the foramen ovale, foramen spinosum, the opening of the osseous Eustachian canal and the spine of the sphen behind this it will cut through the root of the styloid process and define externally the limit the jugular fossa. After passing through the stylo-mastoid foramen, if the line be prolon backwards it will usually be found to pass over the mastoid foramen in the occipito-mast suture. Another line of much value is one drawn across the base of the skull from the ce of one external auditory meatus to the other. This will be found to pass through the root the styloid process, the jugular foramen, the anterior condylic foramen; it then crosses the fro of the occipital condyles, and corresponds with the anterior edge of the foramen magnum.

A line which may be found useful is one drawn from the stylo-mastoid foramen of one side the posterior palatine canal of the opposite side. This will be seen to overlie, from behin forwards, the outer part of the jugular foramen and the inferior opening of the carotid can The line indicates the direction of the carotid canal, and cuts the foramen lacerum medi anteriorly; in front of this it usually corresponds to the position of the posterior aperture of t pterygo-palatine canal.

The examination of the base of the skull is incomplete unless the student examin it with the lower jaw and atlas vertebra in position. The relation of the ramus the lower jaw to the zygomatic fossa has been already sufficiently studied (p. 157

e or two points, however, may be emphasised. The **alar spine** of the sphenoid s just internal to the condyle of the jaw when that structure is in position in the ticular part of the glenoid fossa, and it is noteworthy that immediately to the ner side of the alar spine is the commencement of the **osseous Eustachian tube.** he root of the **styloid process** occupies the centre of the interval between the andibular ramus and the front of the mastoid process.

Anteriorly the arcade formed by the **body** of the **lower jaw** adds greatly to the pth of the hard palate. In this space are lodged the tongue and the structures hich form the floor of the mouth. The inner surface of each side of the body of e mandible is traversed by the **internal oblique line** (linea mylo-hyoidea), which mmences posteriorly just behind the root of the last molar tooth and runs downards and forwards towards the symphysis in front.

When the **atlas vertebra** is in articulation with the occipital bone it is well to cognise the relation of its **transverse processes** to the surrounding structures. The xtremities of these processes lie in line with the ends of the jugular processes of e occipital bone, and thus come to be placed just internal to and immediately below id slightly in front of the tips of the **mastoid processes.** They can thus be easily felt the living. Anteriorly they are separated by a short interval from the **styloid rocesses,** and the **stylo-mastoid foramina** lie immediately in front and slightly to he outer side of their extremities. The student will note that there is no hole in he jugular process of the occipital bone corresponding to the arterial foramen in he transverse process of the atlas through which the vertebral artery passes. The ourse of this vessel over the upper surface of the posterior arch behind the perior articular processes of the atlas will be seen to coincide with the posterior ondylic fossæ and the margins of the foramen magnum immediately internal hereto, where a slight grooving of the edge often indicates the course of the artery. n front the anterior tubercle of the atlas falls in line with the **pharyngeal tubercle** n the under surface of the basi-occipital, and the student must not overlook the ct that the anterior surface of the cervical column does not coincide with the nterior margin of the foramen magnum, but lies nearly half an inch in front of hat, in a coronal plane passing immediately in front of the external auditory neatus. Behind, the upper surface of the posterior arch of the atlas overlaps the nder margin of the foramen magnum, and it is by the apposition of these two rfaces that extension is checked at the occipito-atlantal articulation.

THE SKULL IN SECTION.

By the removal of the skull-cap the interior of the cranial cavity is exposed. The deep surface of the cranial vault is grooved mesially for the **superior longitudinal inus,** on either side of which are seen numerous depressions for the lodgment of Pacchionian bodies. On holding the bone up to the light, the floor of these little hollows is oftentimes seen to be very thin. A short distance in front of the lambda, and on either side of the saggital suture, are the internal openings of the **parietal foramina.** The inner tables of the frontal and parietal bones are grooved for the meningeal arteries. The principal branch of the **middle meningeal** runs more or less parallel to and at a variable distance behind the line of the coronal suture. Along the bottom of these grooves small foramina may be seen for the passage of nutrient arteries to the bone, and the floor of the longitudinal sinus is likewise pierced by small apertures for the transmission of veins.

The Upper Surface of the Base of the Skull.

Cranial Fossæ.—The upper surface of the base of the skull is divided into three fossæ, of which the cerebrum occupies the anterior and middle, whilst in the posterior is lodged the cerebellum.

The **anterior fossa** is defined posteriorly by the sharp, thin edge of the lesser wings of the sphenoid, which curve outwards and slightly upwards as well as backwards to reach the region of the **pterion** externally. The floor is formed from before backwards, in the middle line, by the upper surface of the ethmoid and the forepart of the body of the sphenoid; laterally it is constituted by the orbital plates

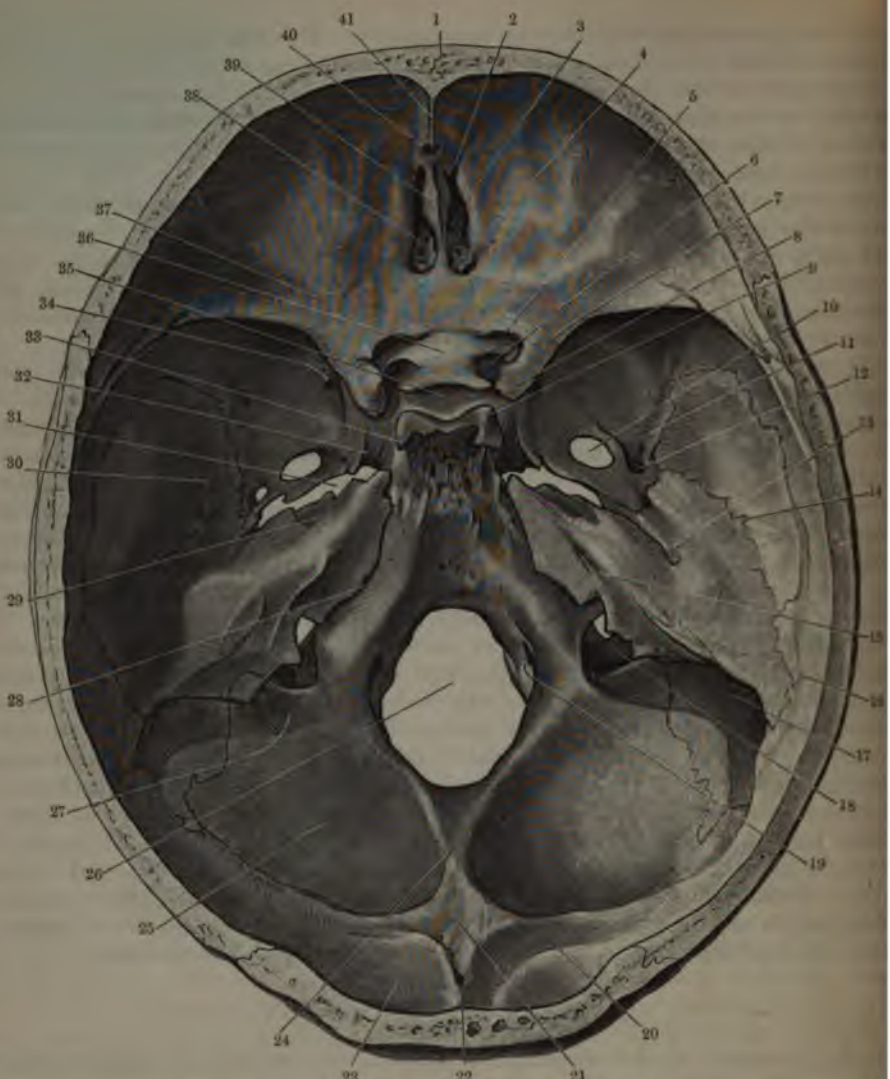

FIG. 122.—BASE OF THE SKULL AS SEEN FROM ABOVE.

1. Frontal bone.
2. Slit for nasal nerve.
3. Anterior ethmoidal foramen.
4. Posterior ethmoidal foramen.
5. Optic foramen.
6. Foramen for internal carotid artery formed by anterior and middle clinoid process.
7. Lesser wing of sphenoid.
8. Anterior clinoid process, in this case united on its inner side to the middle clinoid processes.
9. Posterior clinoid process.
10. Foramen ovale.
11. Groove for middle meningeal artery.
12. Foramen spinosum.
13. Hiatus Fallopii.
14. Line of petro-squamosal suture.
15. Internal auditory meatus.
16. Groove for superior petrosal sinus.
17. Groove for sigmoid part of lateral sinus.
18. Jugular foramen.
19. Anterior condylic foramen.
20. Groove for lateral sinus.
21. Internal occipital protuberance.
22. Ridge for attachment of falx cerebri.
23. Fossa for the lodgment of the occipital lobes of cerebrum.
24. Ridge for the attachment of the falx cerebelli
25. Fossa for the lodgment of the left cere bemisphere.
26. Foramen magnum.
27. Groove for the sigmoid sinus turning int jugular foramen.
28. Groove for the inferior petrosal sinus ru along the line of suture between the pe temporal and the basi-occipital.
29. Depression for the Gasserian ganglion.
30. Middle cranial fossa for lodgment of tem lobe of cerebrum.
31. Foramen lacerum medium.
32. Carotid groove.
33. Dorsum sellæ of sphenoid.
34. Leads into foramen rotundum.
35. Pituitary fossa.
36. Olivary eminence of sphenoid.
37. Anterior cranial fossa for lodgment of frontal of cerebrum.
38. Cribriform plate of ethmoid.
39. Crista galli of ethmoid.
40. Foramen cæcum.
41. Crest for attachment of falx cerebri.

the frontal and the lesser wings of the sphenoid. On these the under surface the frontal lobes of the cerebrum rests. In front the fossa is divided mesially the **frontal crest**, to which the falx cerebri is attached. This is confluent below h the fore part of the **crista galli**, from which, however, it is separated by the **amen cæcum**, which usually transmits a small vein from the nose. On either e of the crista galli there are grooves which vary considerably in depth and ith: therein are lodged the olfactory lobes. The floor and sides of the groove pierced by numerous foramina; of these the largest number transmit the actory nerves to the nasal fossæ. In front an elongated slit, placed on either e of the crista, affords a passage to the nose for the internal nasal nerve and a all branch of the anterior ethmoidal artery which accompanies it. To the outer e of the olfactory groove and the cribriform plate, the anterior fossæ communi- e on either side by means of the two **ethmoidal foramina** with the cavities of the bits. The anterior foramen transmits the internal nasal nerve and the anterior thmoidal artery; the posterior affords passage to the posterior ethmoidal artery d the small spheno-ethmoidal nerve of Luschka. External to the olfactory ove, the floor of the fossa, which here corresponds to the roof of the orbit, is ry thin, as may be seen by holding the skull up to the light; it is convex from le to side, and bears the impress of the convolutions of the under surface of the ntal lobes of the cerebrum which rest upon it. In front and at the side there e a number of vascular grooves for the branches of the anterior and middle eningeal arteries respectively.

The **middle fossa**, which in form may be compared to the wings of a bird nited by the body, is bounded in front by the curved thin posterior edge of the ser wings of the sphenoid; posteriorly, by the line of attachment of the tentorium rebelli, extending from the **posterior clinoid process** along the superior border of e petrous portion of the temporal bone. The median part of the fossa, which is arrow, corresponds to the **sella turcica** and the **olivary eminence** of the **sphenoid.** t is limited anteriorly by a line connecting the anterior margins of the two optic amina, and is overhung behind by the **dorsum sellæ.** In this area are lodged he structures which lie within the interpeduncular space on the base of the brain. The floor of the lateral parts of the fossa on each side is formed by the great wing f the sphenoid in front, the squamous part of the temporal bone to the outer side, nd the superior surface of the petrous temporal behind. In the hollows so formed he t-mporal lobes of the cerebrum are lodged. On either side of the olivary minence are seen the **optic foramina**; these pass into the orbital cavities and ransmit the optic nerves and ophthalmic arteries. Immediately behind these penings the anterior and middle clinoid processes are sometimes united, so as to nclose a foramen. Through this the internal carotid artery passes upwards. Leading backwards from this, along the side of the body of the sphenoid, is the **arotid groove**, which turns downwards near the apex of the petrous temporal, to become continuous with the carotid canal, which here opens on the posterior wall of an irregular aperture, placed between the side of the body of the sphenoid and the summit of the petrous temporal, called the **foramen lacerum medium.** Through the inner angle of this opening the carotid artery accompanied by its plexus of veins and sympathetic nerves passes upwards. Running through the fibrous tissue, which in life blocks up this opening, the large superficial petrosal nerve coming from the hiatus Fallopii passes downwards and forwards to reach the posterior orifice of the **Vidian canal**, which is placed on the anterior and inferior border of the foramen lacerum medium. A small meningeal branch of the ascending pharyngeal artery also passes upwards through this foramen. In front and to the outer side of the foramen lacerum, and separated from it by a narrow bar of bone, is the **foramen ovale**; through this pass both roots of the inferior maxillary nerve, the small meningeal artery, and some emissary veins. A little external and posterior to this is the **foramen spinosum** for the transmission of the middle meningeal vessels, together with a recurrent branch from the inferior maxillary nerve. Leading from the external extremity of the foramen lacerum there is a groove which passes outwards, backwards, and slightly upwards on the superior surface of the petrous temporal to end in the **hiatus Fallopii** (a cleft opening into

the **aquæductus Fallopii**), which gives passage to the large superficial petrosal b derived from the geniculate ganglion on the seventh nerve, together with the petrosal branch of the middle meningeal artery. Just external to the hiatus Fa there is another small foramen for the transmission of the lesser supe petrosal nerve. Overhung by the posterior border of the lesser wing of the sph is the **sphenoidal fissure**, the cleft which separates the lesser from the sphenoidal wings, and which opens anteriorly into the hollow of the orbit; thr this pass the third, fourth, ophthalmic division of the fifth, and sixth n together with the ophthalmic veins as well as the sympathetic filament to lenticular ganglion. Just below its inner extremity is the **foramen rotundu** the passage of the superior maxillary nerve to the spheno-maxillary fossa. B this, and between it and the foramen ovale, the **foramen Vesalii** may occasio be seen, through which a vein passes to reach the pterygoid plexus.

The lateral parts of the middle fossa are moulded in conformity with convolutions of the temporal lobes, but towards their inner sides the splitti the dura mater in the region of the cavernous sinus serves to separate the c base from the under surface of the cerebrum. As may be seen by transmitted the floor of the lateral parts of the fossa is thin as it overlies the te **zygomatic**, and **glenoid fossæ**. The grooves for the lodgment of the branches middle meningeal artery leading from the foramen spinosum are readily seen; coursing backwards a little below the line of the squamoso-parietal sutu specially well marked. Amongst other features may be noticed the depressio the lodgment of the **Gasserian ganglion** overlying the summit of the pe temporal; behind and to the outer side of the hiatus Fallopii, the a **eminence**, indicating the position of the superior semicircular canal; and immedi anterior and slightly to the outer side of this the **tegmen tympani**, which ro the cavity of the tympanum, the thinness of which can readily be demonst if light be allowed to fall through the external auditory meatus.

The **posterior fossa** is larger and deeper than the others. In front it is li by a line on either side leading backwards and outwards from each **posterior c process** along the superior border of the petrous part of the temporal bone, w externally and posteriorly it becomes confluent with the superior lip of transverse groove for the **lateral sinus**, ending posteriorly in the middle lin the **internal occipital protuberance**. Along the line thus indicated the proc dura mater called the **tentorium cerebelli**, which roofs in the posterior fos attached. The floor of the fossa, in which the cerebellar lobes, the pons, medulla are lodged, is formed by the petrous and mastoid portions of the temp bone, with part of the body of the sphenoid and the basilar portion of the occi bone wedged in between them. Above the mastoid temporal a small part of posterior inferior angle of the parietal enters into the constitution of the wall of the fossa. Behind and within these the lateral parts and lower portio the squamous occipital complete the floor. In the middle line the floor of the is pierced by the **foramen magnum**, in which lies the lower part of the med together with its membranes, and through which pass upwards the verte arteries and the spinal accessory nerves. On either side of the foramen magn and a little in front of a transverse line passing through its centre, is the ope of the **anterior condylic foramen** for the passage of the hypoglossal nerve, a m meningeal branch from the ascending pharyngeal artery and an emissary v Overhanging the opening of the anterior condylic foramen there is a thicke rounded bridge of bone, to the outer side of which is placed the irregular openin the **jugular foramen** (foramen lacerum posterius). The size of this is apt to vary the two sides, and the lumen is frequently subdivided by a spicule of bone wh runs across it; the posterior and external rounded part of the foramen is occup by the lateral sinus, which here joins the internal jugular vein. A mening branch from the ascending pharyngeal or occipital artery also enters the sk through this compartment. The fore and internal part of the foramen is conflu with the groove for the **inferior petrosal sinus**, which turns downwards in front the spicule above referred to. The interval between the portions of the foram occupied by the two veins allows the transmission of the glosso-pharyngeal, vag

spinal accessory nerves in order from before backwards. About a quarter of inch above and to the outer side of the fore part of the foramen jugulare the erior surface of the petrous portion of the temporal bone is pierced by the **rnal auditory meatus**, through which the facial and auditory nerves, together h the pars intermedia of Wrisberg, and the auditory branch of the basilar artery ve the cranial cavity. Behind the jugular foramen and close to the margin of foramen magnum the opening of the **posterior condylic foramen**, when pre- t, may be seen. This gives passage to a vein which joins the vertebral vein eriorly. The internal aperture of the **mastoid foramen** is noticed opening into groove for the lateral sinus, a little below the level of the superior border of the rous temporal. Through it passes an emissary vein which joins the occipital externally; the mastoid branch of the occipital artery also enters the cranial ity through this foramen.

The posterior fossa is divided into two halves posteriorly by the **internal occipital** , to which the falx cerebelli is attached, the floors of the hollows on either side hich are often exceedingly thin and are for the lodgment of the lateral lobes of cerebellum. The grooves for the following blood sinuses are usually distinct— **superior petrosal** running along the superior border of the petrous temporal, **inferior petrosal** lying along the line of suture between the petrous temporal basilar process of the occipital bone; the **occipital sinus** grooving the internal pital crest; and the **lateral sinus** curving forwards and outwards from the rnal occipital protuberance, across the internal surface of the squamous pital, to reach the posterior inferior angle of the parietal bone, in front of which rns downwards and inwards to reach the jugular foramen, describing a sigmoid re, and grooving deeply the inner surface of the mastoid and posterior aspect of petrous portions of the temporal bone. Before it terminates at the jugular men it again reaches the occipital bone and channels the upper surface of the ular process of that bone. Slight grooves for meningeal arteries are also seen— e pass upwards, whilst others turn downwards and are occupied by branches m the posterior offsets of the middle meningeal arteries.

Mesial Sagittal Section of the Skull.

Such a section should be made a little to one or other side of the mesial plane, as to pass through the nasal fossæ lateral to the septum; one-half will then splay the nasal septum in position, whilst in the other the outer wall of the sal fossa of that side will be exposed.

The form of the cranial cavity is, of course, subject to many variations dependent individual and racial peculiarities. The following details are, however, worthy note. The hinder border of the foramen magnum (**opisthion**), and consequently e floor of the posterior cranial fossa, occupies the same horizontal plane as the rd palate. The anterior border of the foramen magnum (**basion**) lies a little gher, so that the plane of the foramen is, in the higher races at least, oblique, and directed downwards and slightly forwards. From the basion a line passing wards and forwards to reach the suture between the sphenoid and ethmoid ses through the **basi-cranial axis** formed by the basi-occipital, the basi-sphenoid, d the presphenoid. The basi-cranial axis is wedge-shaped on section posteriorly, whilst anteriorly it is of considerable width, and has within it the large sphenoidal r sinus. Its upper surface leads upwards and forwards with a varying degree of bliquity from the basion to the overhanging edge of the dorsum sellæ, in front of which the **pituitary fossa**, the floor of which is quite thin, is well seen in the ection.

From the olivary eminence the floor of the anterior fossa follows a more or less horizontal direction, corresponding pretty closely to the level of the axis of the orbital cavity. The roof of the orbit is seen to bulge upwards to a considerable extent into the floor of the anterior fossa; whilst the floor of the middle fossa sinks to a level corresponding to that of the under surface of the basi-cranial axis, where it forms the roof of the posterior nares. The maximum length of the skull is measured from the **glabella** (a point between the superciliary ridges) to the occipital point posteriorly. It is noteworthy that the

maximum occipital point does not necessarily correspond to the external occipital tuberance (**inion**). The greatest vertical height usually corresponds to the distance the **basion** to the **bregma** (point of union of the sagittal with the coronal suture), th to this rule there are many exceptions. On looking into the posterior fossa the sut

41. Fossa for lodgment of cerebellar hemisphe
42. Internal occipital protuberance.

condylic and jugular foramina and the internal auditory meatus are seen in line, sl from below upwards. The **internal auditory meatus** lies in a vertical plane, p through the basion. The grooves for the middle meningeal artery and its branch very obvious. The anterior groove curves forwards and outwards, and reaching the surface of the pterion, passes towards the vertex at a variable distance behind and or less parallel to the coronal suture. From this grooves pass forwards across the s

a the frontal bone. Another groove curves upwards and backwards a little below e of the parieto-squamosal suture. From this an upwardly-directed branch s on the inner surface of the parietal bone, in the region of the parietal eminence, a lower branch passes backwards some little distance above the lambdoid suture, res offsets which curve downwards and inwards over the inner surface of the us portion of the occipital bone.

sal Fossæ.—In the section through the **nasal fossa** the structures which form *r wall* can now be studied. These are—the nasal bone; the nasal process of erior maxilla; the lachrymal bone; the lateral mass of the ethmoid, compris- superior and middle turbinated bones; the vertical plate of the palate bone; erior turbinated bone; and the mesial surface of the internal pterygoid plate. *of* as seen in the section is formed by the nasal and frontal bones, the cribri- late of the ethmoid, the body of the sphenoid and the sphenoidal turbinals, henoidal process of the palate and the ala of the vomer. The *floor*, which is horizontal from before backwards, is formed by the palatal processes of the r maxilla and palate bones. On sagittal section the **nasal fossa** appears hat triangular in shape with the angles cut off; the base corresponds to the the anterior and posterior nares to the truncated anterior and posterior respectively; the superior angle is cut off by the cribriform plate; whilst the orrespond to the frontal and nasal bones anteriorly, and the sphenoidal ds, sphenoidal process of the palate, and the ala of the vomer posteriorly. rity is therefore deep towards its middle, but gradually becomes shallower in nd behind where the openings of the nares are situated. The opening of erior naris, which is of half-heart shape, is larger than that of the posterior nd is directed forwards and downwards; the opening of the posterior is hboidal form, and slopes backwards and downwards. The inferior meatus is nnel which is overhung by the inferior turbinated bone, and its floor is by the side-to-side concavity of the upper surface of the hard palate. g into it above, under cover of the fore part of the inferior turbinated bone, anal for the nasal duct; whilst its floor is pierced in front near the middle the anterior palatine canal. The middle meatus is the hollow between the and inferior turbinated bones; it slopes from above downwards and back- and is overhung by the free curved edge of the middle turbinal, beneath here is a passage called the infundibulum, leading upwards and forwards to periorly into the frontal sinus, as well as into some of the anterior ethmoidal Under cover of the centre of the middle turbinated bone there is an irregular leading into the maxillary sinus or antrum of Highmore, and there quently independent openings for the middle and some of the anterior dal cells. The superior meatus, about half the length of the middle meatus, ed between the superior and middle turbinated bones in the back and upper f the fossa; it receives the openings of the posterior ethmoidal cells. Near terior extremity the spheno-palatine foramen pierces its outer wall, and brings elation with the spheno-maxillary fossa. The sphenoidal sinus opens on the the nose, above the level of the superior turbinated bone, into a depression the spheno-ethmoidal recess.

sal Septum.—If the opposite half of the section in which the osseous nasal is retained be now studied, it will be seen to be formed by the crests of the r maxillary and palate bones below, on which rests the vomer, the posterior of which being free, forms the posterior edge of the nasal septum, which obliquely upwards and backwards towards the under surface of the body of henoid. Here the vomer articulates with the rostrum of the sphenoid. In f this the vomer articulates with the perpendicular plate of the ethmoid, n which anteriorly there is an angular recess into which the cartilaginous fits. Superiorly and anteriorly the osseous septum is completed by the ation of the perpendicular plate of the ethmoid with the nasal process of ntal, together with the nasal crest formed by the union of the nasal bones; posteriorly and superiorly the perpendicular plate of the ethmoid articulates he mesial ethmoidal crest of the sphenoid. In most instances the osseous is not perfectly vertical, but is deflected towards one or other side.

Air-sinuses in connexion with the Nasal Fossæ.—Connected with the n
fossæ are a number of air-sinuses. These are found within the body of
sphenoid, the lateral mas
the ethmoid, the orbital p
cess of the palate bone,
body of the superior max
and the superciliary arch
the frontal bone.

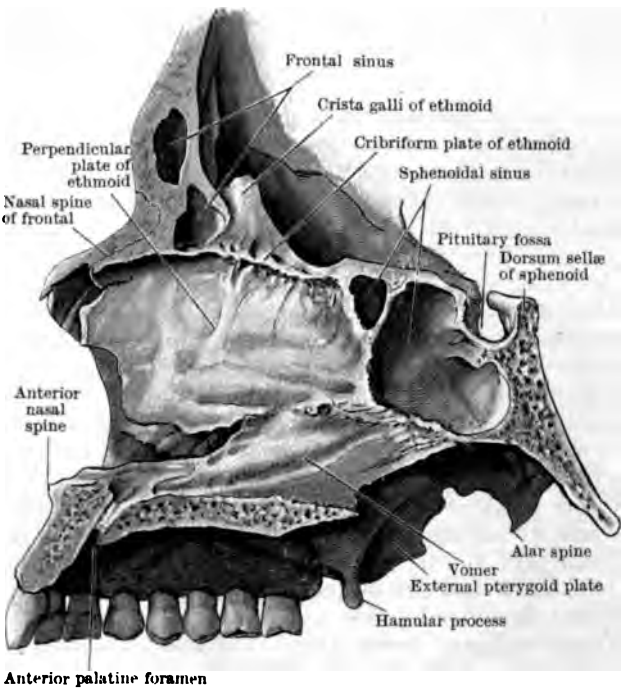

FIG. 124.—NASAL SEPTUM AS SEEN FROM THE LEFT SIDE.

front it is formed in part
the absorption of the sph
oidal spongy bones, and
divided up into two cavi
by a sagittally-placed pa
tion, which, however, is
quently displaced to one
other side. It opens
teriorly into the roof of
nose in the region of
spheno-ethmoidal recess.

The **ethmoidal sinuses**
placed between the lat
aspects of the upper part
the nasal fossæ, and
cavities of the orbit, from which they are separated by thin and papery w
These air spaces are completed by the articulation of the ethmoid with the supe
maxilla, lachrymal, frontal sphenoid, and palate bones, and are divided into th
groups—an anterior, middle, and posterior. The latter communicates with
superior meatus; the anterior and middle open either independently or in conju
tion with the infundibulum into the middle meatus.

The **sinus** in the orbital process of the **palate bone** either communicates w
the sphenoidal sinus, or else assists in closing in some of the posterior ethmoi
cells. Its communication with the nasal fossa is through one or other of th
spaces.

The **maxillary sinus** or **antrum** of **Highmore** lies to the outer side of the n
fossæ, occupying the body of the superior maxilla. Its walls, which are relati
thin, are directed upwards to the orbit, forwards to the face, backwards to
zygomatic and spheno-maxillary fossa, and inwards to the nose. In the la
situation the vertical plate of the palate bone, the uncinate process of the eth
the maxillary process of the inferior turbinated bone, and a small part of the l
rymal bone assist in the formation of the thin osseous partition which separat
from the nasal fossa. The floor corresponds to the alveolar border of the jaw,
differs from the other walls in being stout and thick; it is, however, deeply pi
inferiorly by the alveoli for the teeth. The antrum opens by a narrow orifice i
the middle meatus.

The **frontal sinuses** lie, one on either side, between the inner and outer tabl
the frontal bone over the root of the nose, and extend outwards under the s
ciliary arches. The partition which separates them is usually central, thou
may be deflected to one or other side. They communicate with the nose thr
a passage called the **infundibulum**, which opens inferiorly into the fore-part of
middle meatus.

The fact should not be overlooked that the air spaces within the temp
bone, viz. the tympanic cavity and the mastoid air cells, are brought into c
munication with the naso-pharynx through the Eustachian tubes. For fur

ırding the air sinuses and the mode of their growth, consult the descrip- individual bones.

Coronal Sections.

tions of many parts of the cranium are well displayed in a series of coronal

ng off a thin slice from the front of the lower part of the frontal bone carrying the section downwards through the inner wall of the orbit and

hard palate is arched below, whilst its superior surface is concave upwards on
de of the median crest which supports the nasal septum. The sides of the arch
rrespond to the inner surfaces of the alveolar processes and fall in line with the
lls of the nasal fossæ superiorly. The summit of the arch lies a quarter of an inch
ie level of the floor of the antrum.

SEXUAL DIFFERENCES IN THE SKULL.

lst it is a matter of difficulty, in all cases, to determine with certainty the sex of
the following points of difference are usually fairly characteristic. The female skull
rule, smaller than the male. In point of cranial capacity it averages about a tenth
n the male of corresponding race. It is lighter, smoother as regards the develop-
its muscular ridges, and possesses less prominent mastoid processes. In the frontal
the superciliary ridges are less pronounced, and this imparts a thinness and sharp-
the upper orbital margin, which is fairly characteristic, and can best be appre-
y running the finger along that edge of bone. For the same reason, the forehead
more vertical and the projections of the frontal eminences more outstanding, though
ted that the frontal and occipital regions are less capacious proportionately than in
e. The vertex in the female is said to be more flattened, and the height of the skull
ently somewhat reduced. In man the edge of the tympanic plate is generally
nd divides to form the sheath of the styloid process, whilst in the female the
nding border is described as being rounder and more tubercular.
ilst it is true that no one of these differences is sufficiently characteristic to enable
nounce with certainty on the matter of sex, it is the case that, taken together,
ually justify us in arriving at a conclusion which, as a rule, may be regarded as
ccurate. In some instances, however, it is impossible to express any definite

DIFFERENCES DUE TO AGE.

birth the face is proportionately small as compared with the cranium, constituting
one-eighth of the bulk of the latter. In the adult the face equals at least half the
n. About the age of puberty the development and expansion of some of the air-
, more particularly the frontal sinus, lead to characteristic differences in head and
rm.
e eruption of the teeth in early life and adolescence enables us to determine the
th fair accuracy. After the completion of the permanent dentition, the wear of the
nay assist us in hazarding an approximate statement. The condition of the sutures,
ay guide us, synostosis of the coronal and sagittal sutures not as a rule taking place
e in life. Complete obliteration of the synchondrosis between the occipital bone
phenoid may be regarded as an indication of maturity. In old age the skull
r becomes lighter and the cranial bones thinner. The alveolar borders of the
r and inferior maxillæ become absorbed owing to the loss of the teeth. This gives
a flattening of the vault of the hard palate and an alteration in the form of the
jaw, whereby the mandibular angle becomes more obtuse.

CRANIOLOGY.

The various groups of mankind display in their physical attributes certain features whi more or less characteristic of the stock to which they belong. Craniology deals with differences so far as they affect the skull. The method whereby these differences are re involves the accurate measurement of the skull in most of its details. Such procedure is in under the term craniometry. Here only the outlines of the subject are briefly refer for such as desire fuller information on the subject, the works of Broca, Topinard, Flow Turner may be consulted.

The races of man display great variations in regard to the size of the skull. Apart alto from individual differences and the proportion of head-size to body-height, it may be ge assumed that the size of the skull in the more highly civilised races is much in excess of displayed in lower types. The size of the head is intimately correlated with the de ment of the brain. By measuring the capacity of that part of the skull occupied b encephalon, we are enabled to form some estimate of the size of the brain. The **cranial c** is determined by filling the cranial cavity with some suitable material and then taki cubage of its contents. Various methods are employed, each of which has its advantage. T of fluids, which of course would be the most accurate, is rendered impracticable, without precautions, owing to the fact that the macerated skull is pierced by so many foramina matter of practice, it is found that leaden shot, glass beads, or seeds of various sorts are th serviceable. The results obtained display a considerable range of variation. For purp classification and comparison, skulls are grouped according to their **cranial capacity** in following varieties:—

Microcephalic skulls are those with a capacity below 1350 c.c., and include such well-k races as Andamanese, Veddahs, Australians, Bushmen, Tasmanians, etc.
Mesocephalic skulls range from 1350 c.c. to 1450 c.c., and embrace examples of the follo varieties: American Indians, Chinese, some African Negroes.
Megacephalic skulls are those with a capacity over 1450 c.c., and are most commonly with in the more highly civilised races: Mixed Europeans, Japanese, Eskimo, e

Apart from its size, the form of the cranium has been regarded as an important factor i classification of skulls; though whether these differences in shape have not been unduly phasised in the past is open to question.

The relation of the breadth to the length of the skull is expressed by means of the c **index** which records the proportion of the maximum breadth to the maximum length skull, assuming the latter equal 100, or—

$$\frac{\text{Max. breadth} \times 100}{\text{Max. length}} = \textbf{Cephalic index.}$$

The results are classified into three groups:—

1. **Dolichocephalic,** with an index below 75: Australians, Kaffirs, Zulus, Eskimo, Fi
2. **Mesaticephalic,** ranging from 75 to 80: Europeans (mixed), Chinese, Polynesians (m
3. **Brachycephalic,** with an index over 80: Malays, Burmese, American Indians, A manese.

In order to provide for uniformity in the results of different observers, some system is n sary by which the various points from which the measurements are taken must corres Whilst there is much difference in the value of the measurements insisted on by indivi anatomists, all agree in endeavouring to select such points on the skull as may be readily d mined, and which have a fairly fixed anatomical position. The more important of these " points" are included in the subjoined table:—

Nasion.—The middle of the naso-frontal suture.
Glabella.—A point midway between the two superciliary ridges.
Ophryon.—The central point of the narrowest transverse diameter of the forehead, measu from one temporal line to the other.
Inion.—The external occipital protuberance.
Maximum Occipital Point.—The point on the occipital squama in the sagittal plane m distant from the glabella.
Opisthion.—The middle of the posterior margin of the foramen magnum.
Basion.—The middle of the anterior margin of the foramen magnum.
Bregma.—The point of junction of the coronal and sagittal sutures.
Alveolar Point.—The centre of the anterior margin of the upper alveolar margin.
Subnasal Point.—The middle of the inferior border of the anterior nasal aperture at t centre of the nasal spine.
Vertex.—The summit of the cranial vault.
Obelion.—A point over the sagittal suture, on a line with the parietal foramina.
Lambda.—The meeting-point of the sagittal and lambdoid sutures.
Pterion.—The region of the antero-lateral fontanelle where the angles of the front parietal, squamous temporal, and alisphenoid lie in relation to one another. A

rule, the sutures are arranged like the letter H, the parietal and alisphenoid separating the frontal from the squamous temporal. In other cases the form of the suture is like an X; whilst in a third variety the frontal and squamous temporal articulate with each other, thus separating the alisphenoid from the parietal.

Asterion is the region of the postero-lateral fontanelle where the lambdoid, parieto-mastoid, and occipito-mastoid sutures meet.

Stephanion.—The point where the coronal suture crosses the temporal crest.

Dacryon.—The point where the vertical lachrymo-maxillary suture meets the fronto-nasal suture at the inner angle of the orbit.

Jugal Point.—Corresponds to the angle between the vertical border and the margin of the zygomatic process of the malar bone.

Gonion.—The outer side of the angle of the inferior maxilla.

ıe **measurements** of the length of the skull may be taken between a variety of points—the a, **glabella**, or ophryon in front, and the inion or maximum occipital point behind. Or the mum **length** alone may be taken without reference to any fixed points. In all cases it is r to **state** precisely where the measurement is taken. The maximum breadth of the head is **variable as regards** its position; it is advisable to note whether it occurs above or below the to-squamosal suture. The inter-relation of these measurements as expressed by the cephalic ı has been already referred to. The width of the head may also be measured from one asterion e other, **biasterionic width**, or by taking the **bistephanic diameter**.

he **height** of the cranium is usually ascertained by measuring the distance from the basion ıe bregma. The relation of the height to the length may be expressed by the **height** or ical **index**, thus—

$$\frac{\text{Height} \times 100}{\text{Length}} = \textbf{Vertical index.}$$

Skulls are classified in accordance with the relations of length and height as follows:—

Tapeinocephalic index below 72.		**Chamæcephalic** index up to 70.
Metriocephalic index between 72 and 77.	or	**Orthocephalic** index from 70·1 to 75.
Akrocephalic index above 77 (Turner).		**Hypsicephalic** index 75·1 and upwards (Kollmann, Ranke, and Virchow).

The horizontal circumference of the cranium, which ranges from 450 mm. to 550 mm., is sured around a plane cutting the glabella or ophryon anteriorly, and the maximum occipital int posteriorly. The **longitudinal arc** is measured from the nasion in front to the opisthion hind; if to this be added the basi-nasal length and the distance between the basion and the isthion, we have a record of the vertico-mesial circumference of the cranium. This may further ı divided by measuring the lengths of the frontal, parietal, and occipital portions of the perior longitudinal arc. In this way the relative proportions of these bones may be pressed.

The measurements of the skeleton of the face are more complex, but, on the whole, of greater lue than the measurements of the cranium. It is in the face that the characteristic features of ce are best observed, and it is here that osseous structure most accurately records the form and roportions of the living.

The form of the face varies like that of the cranium in the relative proportions of its length id breadth. Generally speaking, a dolichocephalic cranium is associated with a long face, whilst he brachycephalic type of head is correlated with a rounder and shorter face. This rule, how-ver, is not universal, and there are many exceptions to it.

The determination of the facial index varies according to whether the measurements are made ith or without the mandible in position. In the former case the length is measured from the phryon or nasion above to the mental tubercle below, and compared with the maximum ygomatic width. This is referred to as the **total facial index**, and is obtained by the rmula—

$$\frac{\text{Ophryo-mental length} \times 100}{\text{Bizygomatic width}} = \textbf{Total facial index.}$$

More usually, however, owing to the loss of the lower jaw, the proportions of the face are xpressed by the **superior facial index**. This is determined by comparing the ophryo-alveolar or aso-alveolar length with the bizygomatic width, thus—

$$\frac{\text{Ophryo-alveolar length} \times 100}{\text{Bizygomatic width}} = \textbf{Superior facial index.}$$

The terms **dolichofacial** or **leptoprosope** and **brachyfacial** or **chamœprosope** have been mployed to express the differences thus recorded.

Uniformity in these measurements, however, is far from complete since many anthropologists ompare the width with the length = 100.

The proportion of the face-width to the width of the calvaria is roughly expressed by the use of he terms **cryptozygous** and **phænozygous** as applied to the skull. In the former case the ygomatic arches are concealed, when the skull is viewed from above, by the overhanging and

projection of the sides of the cranial box; in the latter instance, owing to the narrowne calvaria, the zygomatic arches are clearly visible.

The projection of the face, so characteristic of certain races (Negroes for example) estimated on the living by measuring the angle formed by two straight lines, the one pass the middle of the external auditory meatus to the lower margin of the septum of the n other drawn from the most prominent part of the forehead above to touch the inci below. The angle formed by the intersection of these two lines is called the **faci** (Camper), and ranges from 62° to 85°. The smaller angle is characteristic of a mu projection of the lower part of the face. The larger angle is the concomitant of a more profile. The degree of projection of the upper jaw in the macerated cranium is most ac expressed by employing the **gnathic** or **alveolar index** of Flower. This records the proportions of the basi-alveolar and basi-nasal lengths, the latter being regarded thus—

$$\frac{\text{Basi-alveolar length} \times 100}{\text{Basi-nasal length}} = \textbf{Gnathic index.}$$

The results are conveniently grouped into three classes:—

Orthognathous, index below 98: including mixed Europeans, ancient Egyptians,
Mesognathous, index from 98 to 103: Chinese, Japanese, Eskimo, Polynesians (m
Prognathous, index above 103: Tasmanians, Australians, Melanesians, various Negroes.

Unfortunately, however, little reliance can be placed on the results obtained by this since it takes no account of the proportion of the third or facial side of the gnathic For a further discussion of this matter see Thomson and MacIver, *Races of the Thebaid* Clarendon Press, 1905).

The form of the nasal aperture in the macerated skull is of much value from a standpoint, as it is so intimately associated with the shape of the nose in the livi greatest width of the nasal aperture is compared with the nasal height (measured from t to the lower border of the nasal aperture) and the **nasal index** is thus determined:—

$$\frac{\text{Nasal width} \times 100}{\text{Nasal height}} = \textbf{Nasal index.}$$

Skulls are—

Leptorhine, with a nasal index below 48: as in mixed Europeans, ancient E American Indians, etc.
Mesorhine, with an index ranging from 48 to 53: as in Chinese, Japanese, Malay
Platyrhine, with an index above 53: as in Australians, Negroes, Kaffirs, Zulus, e

The form of the orbit varies considerably in different races, but is of much less value standpoint of classification. The **orbital index** expresses the proportion of the orbital the orbital width, and is obtained by the following formula:—

$$\frac{\text{Orbital height} \times 100}{\text{Orbital width}} = \textbf{Orbital index.}$$

The orbital height is the distance between the upper and lower margins of the orbi middle; whilst the orbital width is measured from a point where the ridge which f posterior boundary of the lachrymal groove meets the fronto-lachrymal suture (Fl from the dacryon (Broca) to the most distant point from these on the anterior edge of t border of the orbit.

The form of the orbital aperture is referred to as—

Megaseme, if the index be over 89;
Mesoseme, if the index be between 89 and 84;
Microseme, if the index be below 84.

The variations met with in the form of the palate and dentary arcade may be expr the **palato-maxillary index** of Flower. The length is measured from the alveolar pc line drawn across the hinder borders of the superior maxillary bones, whilst the width between the outer borders of the alveolar arch immediately above the middle of th molar tooth. To obtain the index, the following formula is employed:—

$$\frac{\text{Palato-maxillary width} \times 100}{\text{Palato-maxillary length}} = \textbf{Palato-maxillary index.}$$

For purposes of classification Turner has introduced the following terms:—

Dolichuranic, index below 110.
Mesuranic, index between 110 and 115.
Brachyuranic, index above 115.

As is elsewhere stated (p. 183), the size of the teeth has an important influenc architecture of the skull. Considered from a racial standpoint, the relative size of the

ngth of the cranio-facial axis has been found by Flower to be a character of much value.
ental length is taken by measuring the distance between the anterior surface of the first pre-
: and the posterior surface of the third molar of the upper jaw.
o obtain the **dental index** the following formula is used :—

$$\frac{\text{Dental length} \times 100}{\text{Basi-nasal length}} = \textbf{Dental index.}$$

ollowing the convenient method of division adopted with other indices, the dental indices be divided into three series, called respectively—

Microdont, index below 42 : including the so-called Caucasian or white races.
Mesodont, index between 42 and 44 : including the Mongolian or yellow races.
Megadont, index above 44 : comprising the black races, including the Australians.

Many complicated instruments have been devised to take the various measurements required, for all practical purposes the calipers designed by Flower or the *compas glissière* of Broca are cient.

s an aid to calculating the indices, the tables published in the *Osteological Catalogue of the al College of Surgeons of England*, Part I., Man. ; *Index-Tabellen zum Anthropometrischen uche*, C. M. Furst, Jena, 1902 ; or the index calculator invented by Dr. Waterston will be d of much service in saving time.

DEVELOPMENT OF THE CHONDRO-CRANIUM AND MORPHOLOGY OF THE SKULL.

As has been already stated (p. 24), the chorda dorsalis extends forwards to a point ediately beneath the anterior end of the mid-brain. In front of this the head takes end so that the large fore-brain overlaps the anterior extremity of the notochord. At stage of development the cerebral vesicles are enclosed in a membranous covering ived from the mesenchyme surrounding the notochord ; this differentiated mesodermal er is called the primordial membranous cranium. From it the meninges which invest brain are derived. In lower vertebrates this membranous capsule becomes converted o a thick-walled cartilaginous envelope, the primordial cartilaginous cranium. In mmals, however, only the basal part of this capsule becomes chondrified, the roof and t of the sides remaining membranous. In considering the chondrification of the skull mammals, it must be noted that part only of the base is traversed by the notochord, . that portion which extends from the foramen magnum to the dorsum sellæ of the enoid. It is, therefore, conveniently divided into two parts—one posterior, surrounding : notochord, and hence called **chordal**, and one in front, into which the notochord does t extend, and hence termed **prechordal**. These correspond respectively to the vertebral d evertebral regions of Gegenbauer. In the chordal region a pair of elongated cartilages, lled the **parachordal cartilages**, appear one on either side of the notochord ; these soon but completely envelop the chorda, and expand so as to form the basilar or occipital ate, which ossifies later to form the basilar process of the occipital bone, and the dorsum lle of the sphenoid. By backward extension from the occipital plate on either side and ound the foramen magnum the cartilaginous ex-occipitals and supra-occipitals are also rmed. In the prechordal region two curved strips of cartilage, the **trabeculæ cranii** of sthke, arise and pass forwards from the anterior extremity of the notochord, one on ther side of the cranio-pharyngeal canal. In front these trabeculæ spread out and timately fuse to form the **ethmoidal plate**, which constitutes the fore part of the ndro-cranium. Posteriorly the trabeculæ unite with the basilar plate and thus surround e cranio-pharyngeal canal, the lumen of which is subsequently closed to form the floor ! the pituitary fossa, in which rests the hypophysis cerebri. Owing to the presence of e nasal capsules, the fore-part of the ethmoidal plate becomes differentiated into an **sino-vomerine region**, from which the nasal septum and its associated cartilages are rived, whilst the remainder of the ethmoidal plate by expansion and subsequent ossifica-on develops to form the pre-sphenoid, the orbito-sphenoids, and the ali-sphenoids, which ter assist in completing the orbital cavity for the lodgment of the eyeball. The membranous ear capsules which lie lateral to the parachordal cartilages become chondrified nd form the **cartilaginous ear capsules**. These soon unite with the lateral aspects of e basilar plate, but are separated in front from the cartilaginous alisphenoid of the thmoidal plate by a membranous interval, which is subsequently occupied by the quamosal, a bone of dermic origin. This disappearance of the cartilage under the squa-mosal was regarded by Parker as the diagnostic mark of the mammalian chondro-cranium.

From the ventral surface of this cartilaginous *platform*—formed, as described, by the

union of the trabeculæ, parachordal cartilages, and cartilaginous ear capsules—is su the cartilaginous framework of the visceral arches, which play so important a pa development of the face, an account of which is elsewhere given (p. 36).

A consideration of the facts of comparative anatomy and embryology appears to the assumption that the mammalian skull is of two-fold origin—that, in fa composed of two envelopes, an outer and an inner, primarily distinct, but whicl process of evolution have become intimately fused together. The inner, cal primordial skull, is that which has just been described, and consists of the c cranium and the branchial skeleton. The outer, which is of dermic origin, inclu bones of the cranial vault and face which are developed in membrane. This se skull, which first appears in higher fishes as ossified dermal plates overlying the skull, acquires a great importance in the mammalia, as owing to the expansion

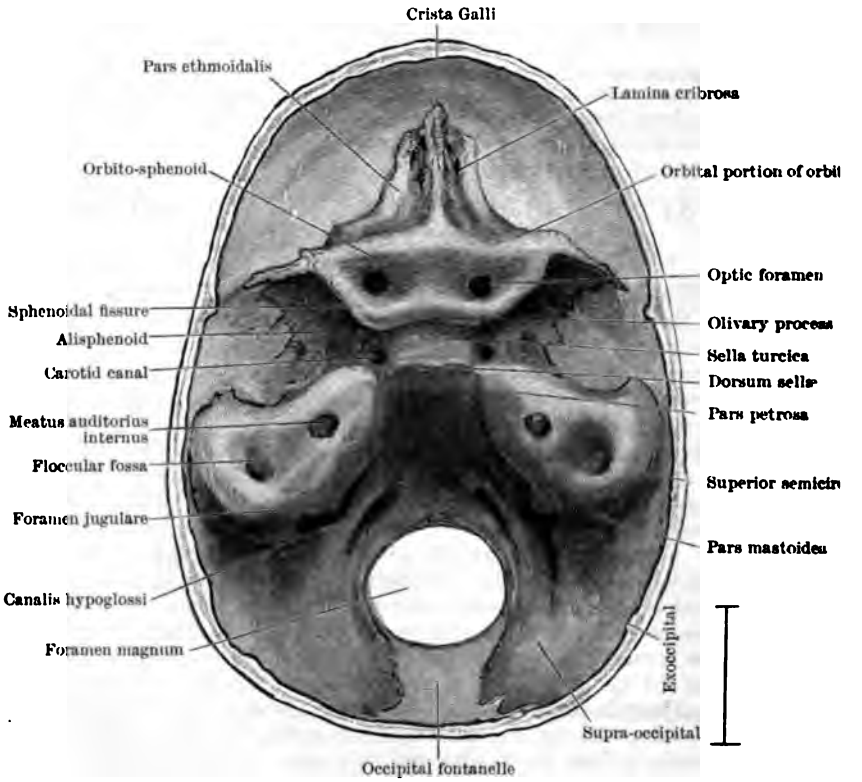

FIG. 127.—VIEW OF THE CHONDRO-CRANIUM OF A HUMAN FŒTUS 5 CM. IN LENGTH FROM V. COCCYX (about the middle of the third month); the cartilage is coloured blue. The line to of the drawing shows the actual size.

brain and the progressive reduction of the chondro-cranium, these dermal bones engrafted on and incorporated with the primordial skull, and act as covering bone cavities of the cranium and face; for it may be well to point out that these de membrane bones are not necessarily external in position, as over the cranial va also develop in the tissues underlying the mucous membrane of the cavities of the

Advantage is taken of this difference in the mode of development of the bone skull to classify them according to their origin into **cartilage** or **primordial bo membrane** or **secondary bones**. These differences in the growth of the bone must too much insisted on in determining the homologies of the bones of the skull, as it generally recognised that all bone is of membranous origin, and that whilst i cases cartilage may become calcified, it never undergoes conversion into true bone replaced by ossific deposit derived from a membranous source. In the subsequent of the skull parts of the cartilaginous cranium persist as the septal and alar carti the nose, whilst for a considerable period the basi-sphenoid and basi-occipital a united by cartilage. The cartilage also which blocks the foramen lacerum medi be regarded as a remnant of the chondro-cranium.

Till two years after birth there are membranous intervals between the ed

jes of the bones of the cranial vault. These are termed the **fontanelles**. Normally y are six in number, and correspond in the adult to the position of the bregma and bda in the middle line and the pterion and asterion on either side. The **anterior** or matic **fontanelle** is diamond-shaped, and corresponds to the converging angles of the etals and two halves of the frontal bone. The **posterior fontanelle** is triangular in n, and lies between the two parietals and the summit of the occipital squama. The ero-lateral **fontanelle** lies between the contiguous margins of the frontal, parietal, amous temporal, and great wing of the sphenoid, whilst the **postero-lateral fontanelle** ituated between the adjacent borders of the parietal, occipital, and mastoid portion of temporal. The term occipital fontanelle is applied to a membranous interval which urs in the fœtal condition posterior to the foramen magnum, and between the lateral ves of the cartilaginous supra-occipital. Its persistence accounts for the occasional urrence of a cerebral meningocele.[1]

Whilst in many instances the primordial and secondary bones remain distinct in the ly-developed condition, they sometimes fuse to form complex bones, such as the temporal l sphenoid (see pp. 120 and 127).

Various theories have been advanced to account for the mode of formation of the ull. The earliest of these was called the vertebrate theory, which assumed that the nium was built up of a series of modified vertebræ, the centra of which corresponded to basi-cranial axis, whilst the neural arches were represented by the covering bones of cranium. In view of the more recent researches regarding the composite origin of the ull above referred to, this theory was necessarily abandoned. It gave way to the ggestion of Gegenbauer that the primordial cranium has arisen by the fusion of several gments equivalent to vertebræ, the number of which he determined by noting the tameric arrangement of the cranial nerves, of which he concluded there were nine pairs, anged much like spinal nerves, both as to their origin and distribution. The olfactory d optic nerves, though frequently referred to as cranial nerves, are excluded, since from e nature of their development they are to be regarded as metamorphosed parts of the ain itself. Gegenbauer therefore assumed that that portion of the cranial base which is aversed by the nine pairs of segmentally arranged cranial nerves must be formed by the sion of nine vertebral segments; and as the region where the nerves escape corresponds the part of the chondro-cranium traversed by the notochord, he calls it the vertebral rtion of the cranial base, in contradistinction to the trabecular or non-vertebral part hich lies in front. This latter he regards as a new formation adapted to receive the reatly-developed brain and afford protection to the organs of sight and smell.

As has been pointed out by Hertwig, there is an essential difference between the evelopment of the axial cartilaginous skeleton of the trunk and head. The former becomes gmented into distinct vertebræ alternating with intervertebral ligaments; whilst the tter, in order to attain the rigidity necessary in this part of the skeleton, is never so ivided. It follows from this that the original segmentation of the head is only expressed three ways, viz. in the appearance of several primitive segments (myotomes), in the rrangement of the cranial nerves, and in the fundament of the visceral skeleton (visceral rches). According to Froriep the mammalian occipital corresponds to the fusion of four ertebræ, and there is some reason for supposing that in some classes of vertebrates the ccipital region of the primordial cranium is increased by fusion with the higher cervical egments.

The form of skull characteristic of man is dependent on the large proportionate evelopment of the cranial part, which contains the brain, and the reduction in size of the isceral part (face), which protects the organs of special sense. This leads to a decrease in the mass and projection of the jaws, as well as a reduction in the size of the teeth. Associated with the smaller mandible there is a feebler musculature, with a reduced area of attachment to the sides of the skull. In this way the disappearance of the muscular crests and fossæ, so characteristic of lower forms, is accounted for. At the same time the fact that the skull is poised on the summit of a vertical column, leads to important modifications in its structure. The disposition of parts is such that the occipito-vertebral articulation is so placed that the fore and hind parts of the head nearly balance each other, thus obviating the necessity for a powerful muscular and ligamentous mechanism to hold the head erect.

Another noticeable feature in connexion with man's skeleton is the prolonged period during which growth may occur before maturity is reached; this is associated with a more complete consolidation of the skull, since bones, which in lower forms remain throughout

[1] For further information regarding anomalous conditions of the fontanelles and the occurrence of Wormian r sutural ossicles, see F. Frassetto, *Ann. des Sci. Nat. Zool.* 8e sér. xviii. 1903.

life distinct, are in man fused with each other, as exemplified in the case of the presph and postsphenoid, the occipital and the interparietal, to mention one or two inst among many. It is noteworthy, however, that during ontogeny the morphological s cance of these bones is clearly demonstrated by their independent ossification.

The points of exit of the various cranial nerves remain remarkably constant, a their primitive condition serve to suggest the segmental arrangement of the cartilag chondro-cranium already referred to. Owing to the very great modifications whic mammalian skull has undergone in the process of its evolution, it may be pointed out the passage of the nerves through the dura mater—a derivative, the readers m reminded, of the primordial membranous cranium (see *ante*)—alone represents the pri disposition of the nerves. Their subsequent escape through the bony base is a late secondary development. In some cases the two, membranous or primary and the o or secondary foramina, correspond. In other instances the exit of the nerves throug dura mater does not coincide with the passage through the bone.

Of interest in this connexion it may be pointed out that the foramina and which traverse the skull are either situated in the line of suture between adjacent or in the line of fusion of the constituent parts of which the bone pierced is ma For example, the sphenoidal fissure is situated between the orbito and alisphenoids anterior condylic between the basi and exoccipitals; the jugular between the pe basi, and exoccipital; the optic between the orbito-sphenoid and the presphenoid Vidian between the alisphenoid, internal pterygoid plate, and the lingula.

THE BONES OF THE UPPER EXTREMITY.

The Clavicle.

The **clavicle** (clavicula), or collar bone, one of the elements in the form of the shoulder girdle, consists of a curved shaft, the extremities of whic enlarged. The inner end, since it articulates with the sternum, is calle sternal end: the outer extremity, from its union with the acromion process o scapula, is known as the acromial end.

The **sternal end** (extremitas sternalis) is enlarged, and rests upon the me

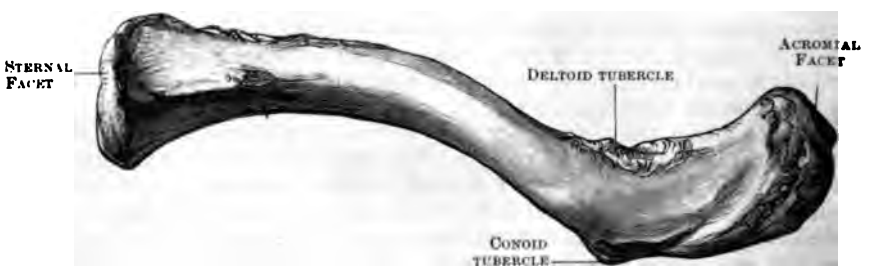

Fig. 128.—Right Clavicle as seen from Above.

of fibro-cartilage which is interposed between it and the clavicular facet o upper and external angle of the manubrium sterni. It is also supported by a part of the inner end of the cartilage of the first rib. Its *articular surface*, w broader from above downwards than from side to side, displays an antero-pos convexity, whilst tending to be slightly concave in a vertical direction. The around the articular area which serves for the attachment of the capsule o sterno-clavicular articulation is sharp and well defined, except below where rounded.

The **shaft** is so curved that its anterior outline is convex in its inner two-t whilst concave in the outer third of its length. Rounded or prismatic in towards its sternal extremity, the shaft becomes compressed and flattened to its outer end. Its *superior surface*, which is smooth and subcutaneous throu its whole length, is directed upwards and forwards; the *inferior surface* is in downwards and backwards. The *anterior border*, which separates the upper the under surface in front, is rough and tubercular towards its inner end fo attachment of the clavicular fibres of the pectoralis major, whilst exter

it becomes continuous with the anterior margin of the acromial end, it is defined, and bears the imprint of the origin of the fibres of the deltoid ; here, not uncommonly, a projecting spur of bone, called the **deltoid le**, may be seen. The *posterior border* is broad internally, where it is lipped

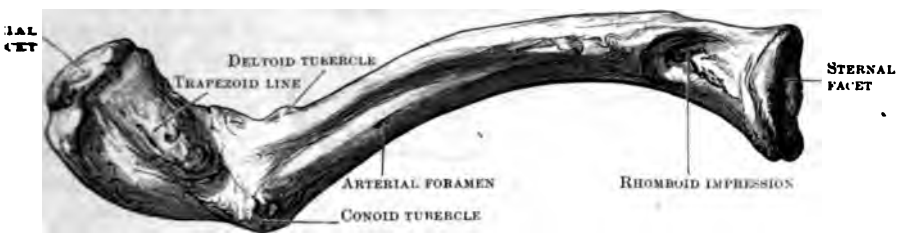

Fig. 129.—Right Clavicle as seen from Below.

iorly to furnish an attachment for the clavicular fibres of the sterno-id muscle; behind and below this the sterno-hyoid and sterno-thyroid es are attached to the bone. Externally, the posterior border becomes more ed, and is confluent with the posterior edge of the acromial end at a point there is a marked outgrowth of bone from its under surface, **the conoid le** (tuberositas coracoidea). Into the outer third of this border are inserted pper and anterior fibres of the trapezius muscle. The *inferior surface* of the close to the sternal end is marked by an irregular elongated impression rositas costalis), often deeply pitted, for the attachment of the rhomboid ent, which unites it to the cartilage of the first rib. External to this the is channelled by a groove which terminates close to the conoid tubercle; into groove the subclavius muscle is inserted.

he **acromial end** of the bone is flattened and compressed from above down-, and expanded from before backwards; its anterior edge is sharp and well d, and gives attachment to the deltoid muscle, which also spreads over part upper surface. Its posterior margin is rougher and more tubercular, and les a surface for the insertion of the trapezius. The area between these two ular attachments is smooth and subcutaneous. The outer edge of this rd-turned part of the bone is provided with an oval facet (facies articularis ialis) for articulation with the acromion process of the scapula; the margins d this articular area serve for the attachment of the capsule of the joint. inferior surface of the acromial end of the bone is traversed obliquely from d forwards and outwards by a rough ridge or line called the **trapezoid** or e ridge. The posterior extremity of this ridge, as it abuts on the posterior r of the bone, forms a prominent process, the **conoid tubercle** (tuberositas oidea); to each of these, respectively, are attached the trapezoid and conoid ons of the coraco-clavicular ligament.

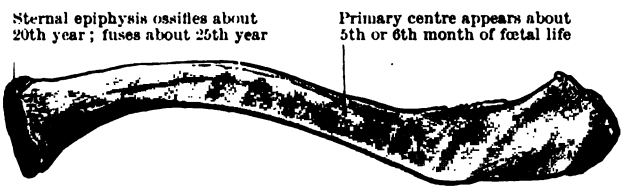
trient Foramina.—The foramina for the larger nutrient vessels, of which there may be two directed outwards, are usually found about the middle of the posterior border, or it e opening into the floor of the groove for the subclavius muscle.

chitecture.—The shaft consists of an outer layer of compact bone, thickest towards the , but gradually thinning towards the extremities, the investing envelope of which consists of a thin shell. Within the shaft the cancellous tissue displays a longitudinal striation, internally assumes a more cellular appearance. At the acromial end the general arrange-of the fibres resembles the appearance of the sides of a Gothic arch. The curves of the impart an elasticity to it, which is of much service in reducing the effects of the shocks to it is so frequently subjected.

ariations.—The clavicles of women are more slender, less curved, and shorter than those of In the latter the bone is so inclined that its outer end lies slightly higher or on the same with the sternal end. In women the bone usually slopes a little downward and outward. more pronounced curves of some bones are probably associated with a more powerful pment of the pectoral and deltoid muscles, a circumstance which also affords an explana-f the differences usually seen between the right and left bones, the habitual use of the right limb reacting on the form of the bone of that side. The influence of muscular action, er, does not wholly account for the production of the curves of the bone, since the bone en shown to display its characteristic features in cases where there has been defective

development or absence of the upper limb (Reynault). Partial or complete absence clavicle has been recorded. W. S. Taylor exhibited an interesting case of this kind Clinical Society of London, October 25, 1901.

Ossification.—Phylogenetically of dermic origin, the clavicle in man is remark commencing to ossify any other bone in the this occurs as early fifth or sixth week of life. The **primitive** from which the shaf outer extremity are dev appears prior to the tion of any cartila matrix; and it is not later stage that cartilage plays a part in the development of the bone by assisting growth of its extremities.



Sternal epiphysis ossifies about 20th year; fuses about 25th year
Primary centre appears about 5th or 6th month of fœtal life

FIG. 130.—OSSIFICATION OF THE CLAVICLE.

A **secondary centre** or **epiphysis** appears at the sternal end about the age of t or later, and fusion rapidly occurring between it and the shaft, ossification is com at the age of twenty-five or thereabouts.

THE SCAPULA.

The **scapula** (scapula), shoulder blade or blade bone, is of triangular shap flattened form. It has two surfaces, ventral and dorsal. From the latter springs a triangular process called the **spine**, which ends externally in the **acro** whilst from its superior border there arises a beak-like projection calle **coracoid** process.

The **body** of the bone, which is thin and translucent, except along its ma and where the spine springs from it, has three borders and three angles. Of borders the *internal* or *vertebral* (margo vertebralis) is the longest; it stre from the superior angle above to the inferior angle below. Of curved or some irregular outline, it affords a narrow surface for the insertion of the levator a scapulæ, rhomboideus minor, and rhomboideus major muscles.

The *superior border* (margo superior), which is thin and sharp, is the short the three. It runs from the superior angle towards the root of the coracoid pr before reaching which, however, it is interrupted by the **suprascapular notc** cisura scapulæ), which lies immediately to the inner side of the base of that pr This notch, which is converted into a foramen by a ligament, or occasionally spicule of bone, transmits the suprascapular nerve. Attached to the su border, close to the notch, is the posterior belly of the omo-hyoid. The *exter axillary border* (margo axillaris), so called from its relation to the hollow o armpit (axilla), is much stouter than either of the others; it extends fro external angle above to the inferior angle below. The upper inch or so o border, which lies immediately below the glenoid articular surface, is roug tubercular (tuberositas infraglenoidalis), and affords attachment to the long of the triceps. Below this it is usually crossed by a groove which mark position of the dorsal artery of the scapula. The *superior angle* (angulus me is sharp and more or less rectangular; the *inferior angle* (angulus inferi blunter and more acute; whilst the *external angle* (angulus lateralis) corres to that part of the bone which is sometimes called the **head**, and which su the **glenoid surface** and the **coracoid process**.

The **glenoid surface** is a pyriform articular area, slightly concave from above d wards and from side to side; its border is but slightly raised above the general s and affords attachment in the recent condition to the glenoid ligament, which to deepen the socket in which the head of the humerus rests. Below, the m of the glenoid fossa is confluent with the **infraglenoid impression** (tuberositas glenoidalis), whilst above it blends with a tubercle (tuberositas supraglenoi to which the long head of the biceps muscle is attached. Springing fro upper part of the head, in line with the superior border, is the **coracoid p** (processus coracoideus). The base of this is limited externally by the g

ilst internally it is separated from the superior border by the supra-
notch. Rising upwards for a short space, it bends on itself at nearly a
gle, and ends in a process which is directed outwards and slightly forwards,
ing the glenoid fossa above and in front. Compressed from above down-
has attached to its upper surface near its angle the conoid ligament, wide
there is a rough area for the trapezoid ligament. Attached to its
border is the coraco-acromial ligament, whilst at its extremity and
the front of its anterior border, is the combined origin of the biceps and
achialis, together with the insertion of the pectoralis minor. The **neck**

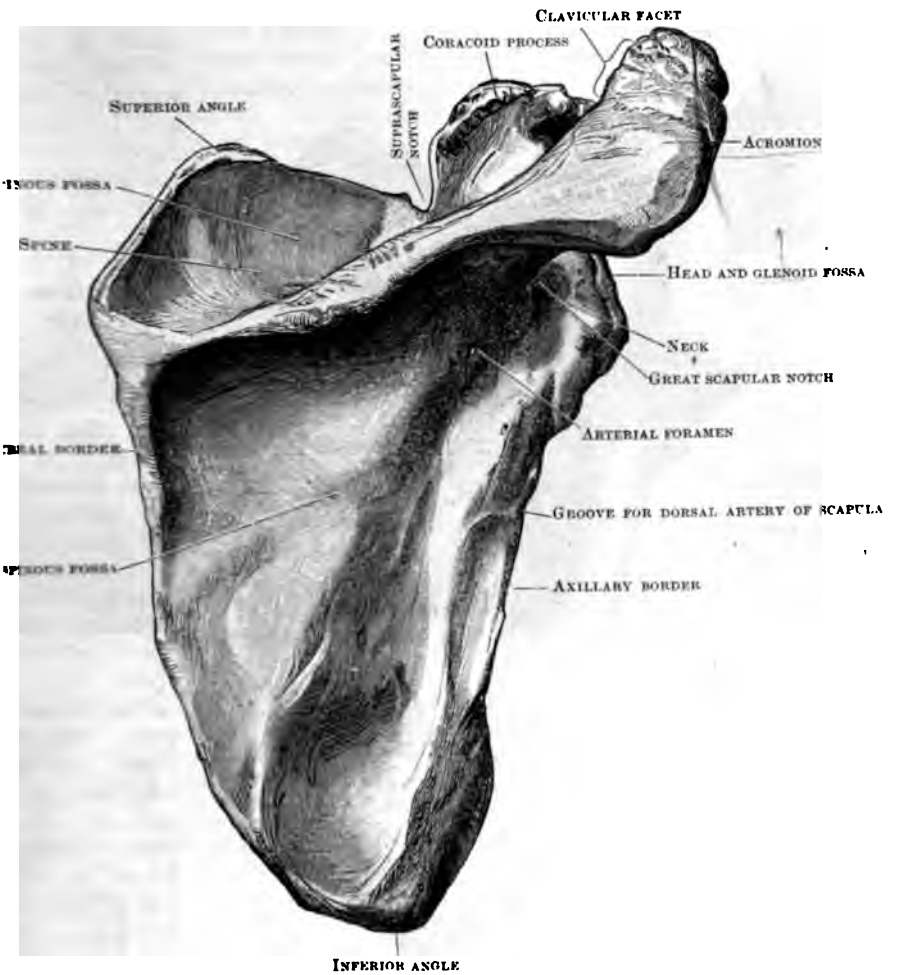


FIG. 131.—THE RIGHT SCAPULA AS SEEN FROM BEHIND.

scapulæ) is that somewhat constricted part of the bone which supports the
t corresponds in front and behind to a line drawn from the suprascapular
o the infraglenoid tubercle.

body of the bone has two surfaces, a **dorsal** (facies dorsalis) and a **ventral**
costalis). The former is divided into two fossæ by an outstanding process
gular form, called the **spine** (spina scapulæ). The attached border of this
the back of the body obliquely in a direction outwards and slightly
s, extending from the vertebral border near the lower limit of its upper
towards the centre of the posterior glenoid edge, from which, however, it
ated by the **great scapular notch**, which here corresponds to the posterior
of the neck. The surfaces of the spine, which are directed upwards and
rds, are concave, the upper entering into the formation of the **supraspinous**
hich lies above it, the lower forming the upper wall of the **infraspinous fossa**,

which lies below it. The two fossæ are in communication with each oth the free external concave border of the spine, where that curves over t scapular notch. The posterior free border of the spine is subcutaneous thr its entire length. Its upper and lower edges are strongly lipped, and se superior, for the attachment of the trapezius; the inferior, for the origi deltoid. The intervening surface varies in width—broad and triangular becomes confluent with the vertebral border, it displays a smooth surf which the tendinous fibres of the trapezius play; narrowing rapidly, it surface of varying width which blends externally with a flattened process,

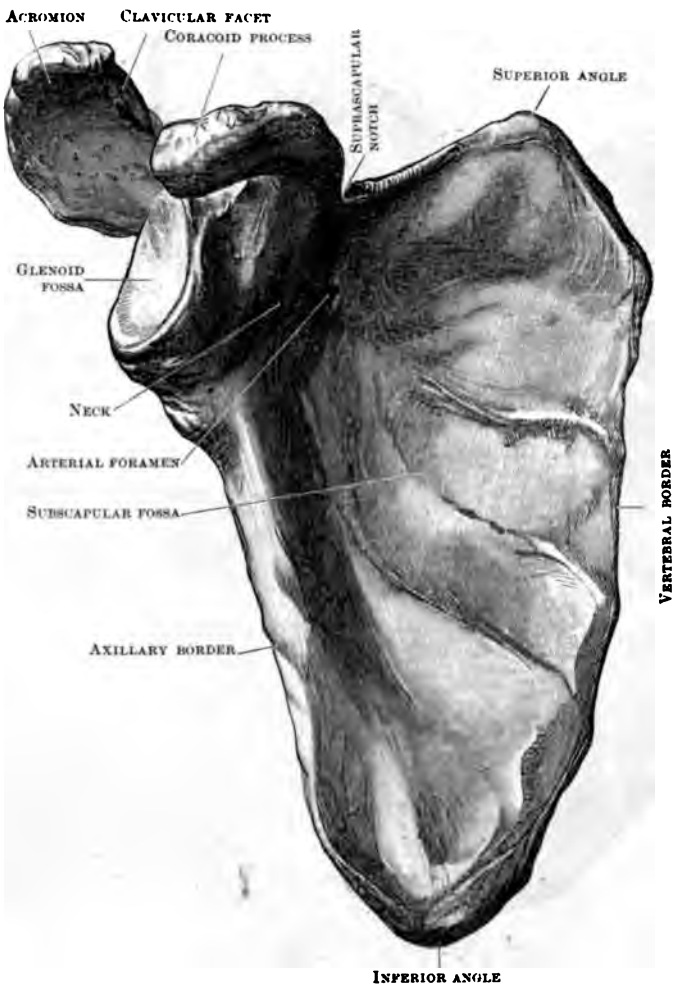

Fig. 132.—The Right Scapula as seen from the Front.

forming a co plate of bon arches acr scapular notc and behind, a curves forwa wards, and out overhang the fossa. The border of thi is continuous upper margi spine, and i curved. The border, more than the in which it is u front, is conflu the inferior the spine, wi it forms an bend, term acrómial ang bone included these two b called the acro cess. Of co form, it m sembles the end of the with which i lates by mea facet (facies a acromii) w placed on its border near it extremity.

perior surfac acromion, which is broad and expanded, is subcutaneous, and is directed upw backwards, and in the normal position of the bone outwards as well. Its inte where not in contact with the clavicle, has attached to it the fibres of the t whilst its external margin affords origin to the central part of the deltoid. anterior extremity it is connected with the coracoid process by means of th acromial ligament. Its under surface is smooth and overhangs the should

The **supraspinous fossa**, of much less extent than the infraspinous, i above the spine, the upper surface of which assists in forming its curved it is lodged the supraspinatus muscle. The suprascapular notch opens into whilst below and externally it communicates with the infraspinous foss great scapular notch, through which the suprascapular artery and nerve reach the infraspinous fossa.

The infraspinous fossa, overhung by the spine above, is of triangular form. The illary border of the bone limits it in front, whilst the vertebral margin bounds it ind; the greater part of this surface affords origin to the infraspinatus muscle, epting a well-defined area which skirts the axillary border and inferior angle of bone, and which affords an attachment to the fibres of origin, of the teres minor. muscle extends along the posterior surface of the axillary border in its upper -thirds, reaching nearly as high as the glenoid edge; whilst a crescentic surface, ich occupies the lower third of the axillary border and curves backward round posterior aspect of the inferior angle, furnishes an origin for the teres major cle. Here also, near the inferior angle, are occasionally attached some of the es of the latissimus dorsi muscle.

The ventral aspect (facies costalis) of the body is hollow from above downwards d from side to side, the greatest depth being in correspondence with the spring of the e from the dorsal surface. Its inner boundary, which is formed by the anterior ed edge of the vertebral border, affords attachment to the fibres of insertion of serratus magnus along the greater part of its extent. The area of insertion of muscle is, however, considerably increased over the anterior aspects of the erior and inferior angles respectively. Running down from the head and neck ve to the inferior angle below, there is a stout rounded ridge of bone, which arts a fulness to the anterior aspect of the axillary border and increases the th of the ventral hollow; to this, as well as to the floor of the fossa, the sub-pularis muscle is attached. The tendinous intersections of this muscle leave r imprint on this surface of the bone in a series of three or four rough lines ich converge towards the neck.

Nutrient Foramina.—Foramina for the passage of nutrient vessels are seen in different parts the bone; the most constant in position is one which opens into the infraspinous fossa, about an or so from the scapular notch. Others are met with on the upper and under surfaces of the e, on the ventral aspect near its deepest part, and also around the glenoid margin.

Connexions.—The scapula is not directly connected with the trunk, but articulates with the r end of the clavicle, in union with which it forms the shoulder girdle supporting the erus on its glenoid surface. Placed on the upper and back part of the thorax, it covers the from the second to the seventh inclusive. Possessed of a wide range of movement, it alters position according to the attitude of the limb, rising or falling, being drawn inwards or wards, or being rotated upon itself according as the arm is moved in various directions. These anges in position can easily be determined by recognising the altered relations of the subcutaneous d bony prominences, more especially the former, which include the spine, the acromion process, the lower half of the vertebral border.

Architecture.—For so light and thin a bone, the scapula possesses a remarkable rigidity. This owing to the arrangement of its parts. Stout and thick where it supports the glenoid surface d coracoid process, the rest of the bone is thin, except along the axillary border; but strength is parted to the body by the manner in which the spine is fused at right angles to its posterior surface.

Variations.—The most common variation met with is a separated acromion process. In e cases there has been failure in the ossific union between the spine and acromion, the ion between the two being effected by a layer of cartilage or an articulation possessing a nt cavity. The condition is usually symmetrical on both sides, though instances are recorded ere this arrangement is unilateral. Very much rarer is the condition in which the coracoid ess is separable from the rest of the bone. The size and form of the suprascapular notch ies. In certain cases the superior border of the bone describes a uniform curve reaching the e of the coracoid without any indication of a notch. In some scapulæ, more particularly in e of very old people, the floor of the subscapular fossa is deficient owing to the absorption of thin bone, the periosteal layers alone filling up the gap. Congenital elevation of the scapula e to defective development of the muscles connected with it.

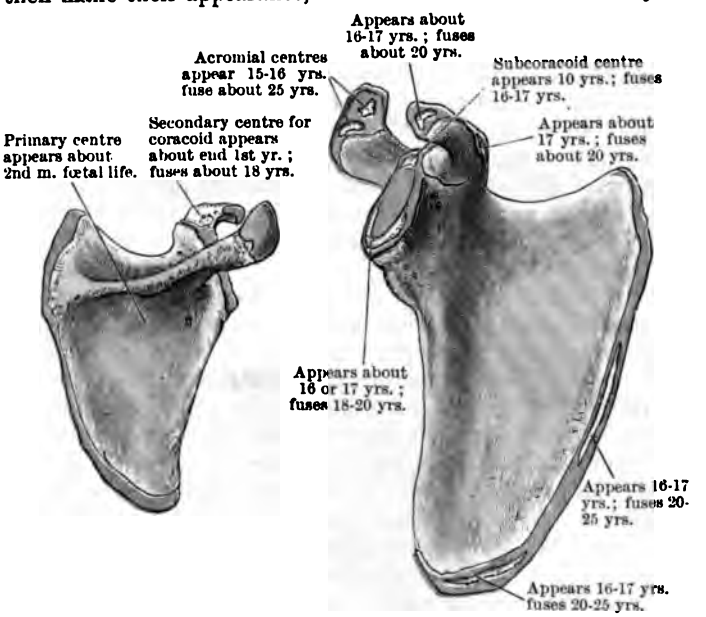
At birth the vertical length of the bone is less in proportion to its width than in the adult.

Ossification.—Ossification begins in the body of the cartilaginous scapula about the end of the second month of fœtal life. At birth the head, neck, body, spine, and base of the coracoid process are well defined; the vertebral border, inferior angle, glenoid fossa, acromion and coracoid processes, are still cartilaginous. The centre for the upper and part of the coracoid appears in the first year, and fusion along an oblique line leading the upper edge of the glenoid fossa to the conoid tubercle is complete about the enth year. A separate centre (subcoracoid), which ultimately includes the upper part glenoid fossa and external part of the coracoid process, makes its appearance about enth year, and fuses with the surrounding bone about sixteen or seventeen. Up till ge of puberty the acromion remains cartilaginous; centres, two or more in number,

then make their appearance, which coalesce and ultimately unite with the spin the twenty-fift Failure of unio however, persistt out life (see *ant* tions).

Ossificatio mences in the c in the inferio about puberty, dependently and later, along the v margin, fusion w body occurring twenty to twe years.

Small scal epiphyses mak appearance on th surface and at tremity of the c and are complete the twentieth y thin epiphysial p velops over the part of the fossa about six



Primary centre appears about 2nd m. fœtal life.
Secondary centre for coracoid appears about end 1st yr.; fuses about 18 yrs.
Acromial centres appear 15-16 yrs. fuse about 25 yrs.
Appears about 16-17 yrs.; fuses about 20 yrs.
Subcoracoid centre appears 10 yrs.; fuses 16-17 yrs.

seventeen, fusion being complete about eighteen or twenty years of age.

THE HUMERUS.

The **humerus**, or bone of the upper arm, articulates with the scapula abc with the bones of the forearm, the radius and ulna, below. Its upper en prises the **head** and **great** and **small tuberosities**; its **shaft**, which is longer th of the other bones of the upper extremity, is cylindrical above and flattened At the inferior extremity, which is expanded to form the **condyles** on eith it supports the **trochlear** and **capitellar** articular surfaces for the ulna and respectively.

The **superior extremity** is the thickest and stoutest part of the bone **head** (caput humeri), which forms about one-third of a spheroid and is cov articular cartilage, is directed upwards, inwards, and slightly backwards, and the glenoid fossa of the scapula; the convexity of its surface is most pronou its posterior half. Separating the head from the tuberosities externally is a groove, which fades away on the surface of the bone which supports the a part inferiorly. This is named the **anatomical neck** (collum anatomicu serves for the attachment of the capsule of the shoulder joint. The articular the groove opposite the small tuberosity is usually notched for the attachmen superior gleno-humeral ligament. The **great tuberosity** (tuberculum maju on the outer side of the head and becomes continuous with the shaft belo upper surface forms a quadrant, which is subdivided into three more or less areas of unequal size. Of these the highest and anterior is for the insertio supraspinatus muscle, the middle for the infraspinatus, whilst the low posterior serves for the insertion of the teres minor muscle. The outer su this tuberosity, which bulges beyond the line of the shaft, is rough and pie numerous foramina. Anteriorly the great tuberosity is separated from th **tuberosity** (tuberculum minus) by a well-defined furrow, called the **bicipital** (sulcus intertubercularis), from the circumstance that the tendon of origin long head of the biceps muscle is lodged within it. The **small tuberosity** front of the outer half of the head; it forms a pronounced elevation, whic into the shaft below. The surface of this tuberosity is faceted above and for the insertion of the sub-scapularis muscle, whilst externally it for

epicondyles. The **internal epicondyle** (epicondylus medialis) is the more p
of the two, and furnishes a surface for the origin of the **pronator radii t**

ial flexor muscles of the forearm. The **external epicondyle** (epicondylus unted and but little projecting, serves for the attachment of the common rigin of the extensor The brachialis anticus an extensive origin nterior surface of the f the shaft, including upper slips the inser- deltoid.

sterior surface of the of the shaft is smooth d from side to side; flattened below, where shaft tends to incline t becomes continuous ide with the posterior the epicondyles, the hich is grooved for the passage of the ulnar nerve, whilst the external supplies an origin for the anconeus muscle. The inner head of the triceps muscle has an extensive origin from the posterior surface of the lower two-thirds of the shaft, internal to and below the musculo-spiral groove.

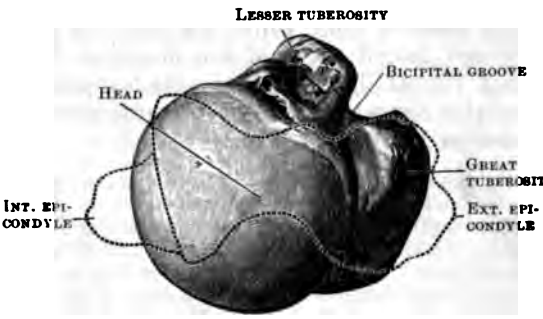

FIG. 136.—THE HEAD OF THE RIGHT HUMERUS AS SEEN FROM ABOVE (with the outline of the lower extremity in relation thereto shown in dotted line).

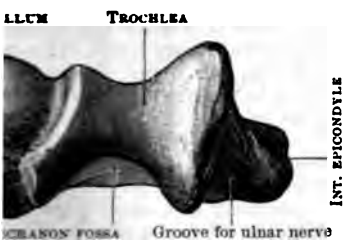

—THE LOWER EXTREMITY OF THE HUMERUS AS SEEN FROM BELOW.

The **lower extremity** of the humerus is furnished with two articular surfaces (the condyles proper), the outer of which, called the **capitellum** (capitulum), for articulation with the upper surface of the head of the radius, is a rounded eminence, the anterior surface and lower border, but not extending upwards sterior surface of the inferior end of the ove it, in front, there is a shallow de- ossa radialis), into which the margin of of the radius sinks when the elbow is lexed. A shallow groove separates the internally from the **trochlea**, which is a rticular surface, with prominent edges pirally round the lower extremity of the e spiral curves from behind forwards and nd its axis is slightly oblique to the long shaft. The inner lip is the more salient o, and forms a sharp and well-defined the articular area; its cartilage-covered slightly convex. The outer lip, much inent, is rounded off into the articular hich separates it from the capitellum, to which, however, it is carried up as a ss definite crest. It is by means of the hat the humerus articulates with the oid cavity of the ulna. On the anterior the bone, immediately above the trochlea, sion—the **coronoid fossa** (fossa coronoidea), n the coronoid process of the ulna slips in the joint, whilst in a corresponding position ack of the lower end of the shaft there , called the **olecranon fossa** (fossa olecrani), e the trochlea posteriorly. Into this the process sinks when the elbow is extended. The two fossæ are separated

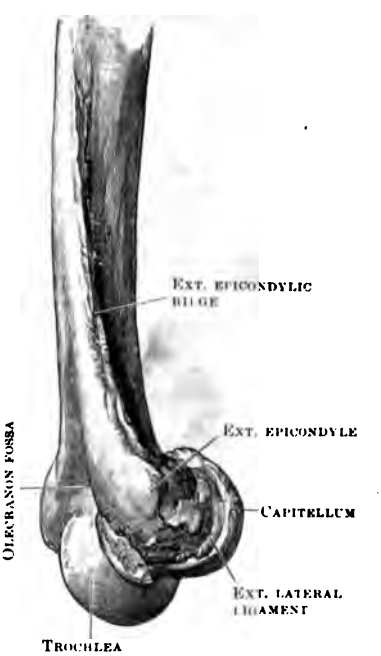

FIG. 138.—THE LOWER END OF THE RIGHT HUMERUS AS SEEN FROM THE OUTER SIDE.

by a thin translucent layer of bone which may be deficient, thus leading to the formation of a foramen between the two hollows in the macerated bone. The anterior of the capsule of the elbow-joint is attached to the superior margins of the radial coronoid fossæ in front, whilst the posterior ligament is connected with the border and lateral edges of the olecranon fossa behind. The strong internal external lateral ligaments are attached superiorly to the internal and external epicondyles respectively. The proportionate length of the humerus to the height is as 1 is to 4·93–5·25.

Nutrient foramina are usually to be seen, one at or near the surface for the insertion of coraco-brachialis, the other usually close to the hinder border of the deltoid eminence; have a downward direction. Numerous vascular foramina are scattered along the line of anatomical neck, the larger ones being situated near the upper end of the bicipital groove.

Connexions.—The humerus articulates with the scapula above, and radius and ulna Embedded as the humerus is in the substance of the upper arm, its shaft and head are surrounded on all sides. It is only at its lower part that it comes into direct relation with the surface internal epicondyle forming a characteristic projection on the inner side of the elbow; while external epicondyle, less prominent, and the external epicondylic ridge can best be recognised when the elbow is bent.

Architecture.—The shaft consists of a layer of compact bone surrounding a long medullary canal. The outer shell, thickest in the lower third of the bone, gradually thins until it reaches the superior epiphysial line, where it forms a layer no thicker than stout paper. Inferiorly the external shell is thicker and stouter than above, until it reaches the epicondyles, on which the articular surfaces are formed of a layer of compact spongy bone. The upper end of the medullary canal is surrounded by loose spongy tissue, the fibres of which arch inwards from the inner surface of the compact outer layer, whilst inferiorly the cancellous tissue which springs from the outer shell sweeps downwards in a radiating fashion on either side of the olecranon fossa towards the epicondyles. Above the olecranon fossa there are a number of laminæ of dense bone which arch across from one side to the other, the convexity of the arches being directed downwards. The superior epiphysis, formed of spongy bone, is united to the shaft by a wavy line, concave externally and convex internally, which from the base of the great tuberosity on the outer side to the inferior articular edge on the inner side. The mass above this includes the head and two tuberosities. The spongy tissue of the head is fine, and is arranged generally in lines radial to its surface; that of the great tuberosity is more open, and often displays large spaces towards its interior, which in old bones communicate freely with the medullary cavity of the shaft. The general direction of the fibres parallel to the outer surface of the tuberosity. The lower articular end is formed of fine spongy tissue, more compact towards the surface, and arranged in lines more or less at right angles to the articular planes. In the adult the principal nutrient canal, viz. that which opens on the surface near the insertion of the coraco-brachialis, traverses the outer compact wall of the shaft obliquely downwards for a distance of two and a quarter inches before it opens into the medullary cavity.

Variations.—As has been already stated, the olecranon and coronoid fossæ may communicate with each other in the macerated bone. The resulting supratrochlear foramen is commonly met with in the lower races of man, as well as in the anthropoid apes, and some other mammals. The occurrence of a hook-like spine, called the epicondylic process, which projects in front of the internal epicondylic ridge, is not uncommon. Its extremity connected with the internal epicondyle by means of a fibrous band, underneath which the ulnar nerve, accompanied by the brachial artery, or one of its large branches, may pass, or in some instances, the nerve alone, or the artery unaccompanied by the nerve. This process is the analogue in a rudimentary form of a canal present in many animals, notably in the carnivora and marsupials. In addition to the broad musculo-spiral groove already described, and which is no doubt produced by the twisting or torsion of the shaft, there is occasionally a distinct narrow groove posterior to it, which marks precisely the course of the musculo-spiral nerve as it winds round the outer side of the shaft of the bone.

Ossification.—At birth the shaft of the humerus is usually the only part of the bone ossified, if we except the occasional presence (22 per cent) of an ossific centre in the head. (H. R. Spencer, *Journ. Anat. and Physiol.* vol. xxv. p. 552.) The centre for the **shaft** makes its appearance early in the second month of intrauterine life. Within the first six months after birth a centre usually appears for the **head**; this is succeeded by one for the **great tuberosity** during the second or third year. These soon coalesce; a third centre for the **small tuberosity** begins to appear about the end of the third year, or may be delayed till the fourth or fifth year. These three centres are all blended by the seventh year, and form an **epiphysis**, which ultimately unites with the shaft at the age of twenty-five. It may be noticed that the superior end of the diaphysis is conical and pointed in the centre, over which the epiphysis fits as a cap, an arrangement which thus tends to prevent its displacement before union has occurred. The first centre to appear in the *lower extremity* is that for the **capitellum** about the second or

This extends inwards, and forms the outer half of the **trochlear surface**, the for the inner half not making its appearance till the eleventh or twelfth year. ste centres are developed in connexion with the **epicondyles**; that for the external rs about the twelfth year, and rapidly coalescing with the centres for the capitellum rochlea forms an **epiphysis**, which unites with the shaft about the sixteenth or eenth year. The centre for the **internal epicondyle** appears about the fifth year; ms a separate **epiphysis**, which unites with the shaft about eighteen or nineteen. two epiphyses at the lower end of the bone are separated by a down-growth of the

he epicondylic process when present is developed from the diaphysis, and has been ed to be already well ossified by the third year. ("Proc. Anat Soc." *Journ. Anat. Physiol.* 1898.)

THE ULNA.

f the two bones of the forearm, the **ulna**, which is placed internally, is the r. It consists of a large superior extremity supporting the **olecranon** and oid processes; a shaft tapering from above downwards; and a small rounded ior end called the **head**.

Superior Extremity.—The **olecranon process** (olecranon) lies in line with the . Its posterior surface, more or less triangular in form, is smooth and utaneous and covered by a bursa. Its superior aspect, which forms with the rior surface a nearly rectangular projection—the tip of the elbow—furnishes rface for the insertion of the tendon of the triceps muscle, together with a th area which is overlain by the same tendon, but separated from it by a al sac. To the anterior crescentic border of this process are attached the fibres he posterior part of the capsule and portion of the internal lateral ligament of elbow-joint. The anterior surface is articular, and enters into the formation of **great sigmoid cavity**.

The **coronoid process** (processus coronoideus) is a bracket-like process, wh forwards from the fore and upper part of the shaft, and is fused with the ol process superiorly. By its upper surface i into the formation of the great sigmoid whilst its anterior aspect, which is separat its upper side by a sharp irregular margin downwards and backwards to become cc with the anterior surface of the shaft. angular shape, this area, which is rou tubercular, terminates inferiorly in an oval e tubercle (tuberositas ulnæ), into which the of the brachialis anticus muscle is inserted. lateral margins of the coronoid process, th is usually the better defined. Above, w joins the superior border, there is gene salient tubercle, to which one of the h origin of the flexor sublimis digitorum m attached, whilst below this point the inner furnishes origins for the pronator radii te occasionally for the flexor longus pollicis i from above downwards. The smooth inner of the coronoid process merges with the ol behind, and with the internal surface of th below.

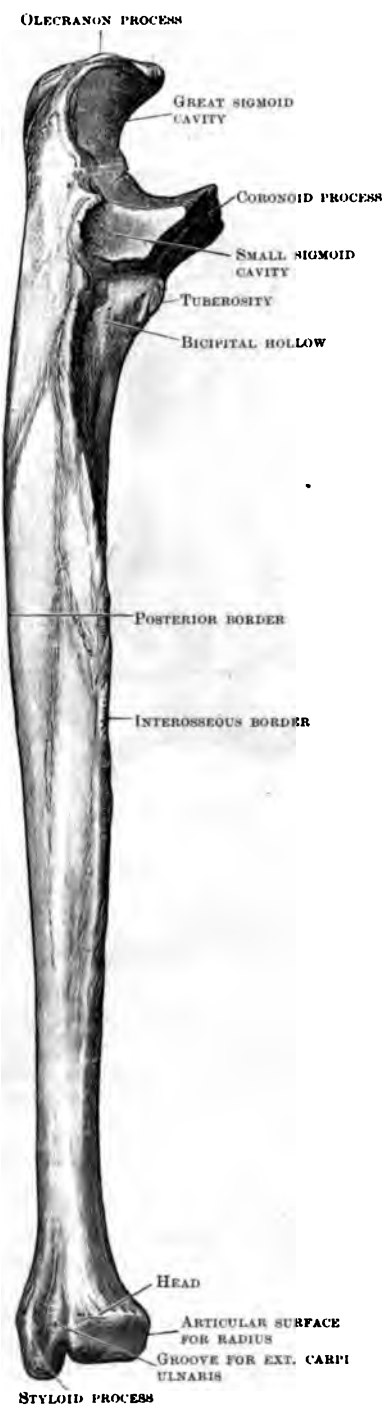

Fig. 140.—The Right Ulna as viewed from the Outer Side.

The **great sigmoid cavity** (incisura semil for articulation with the trochlea of the h is a semicircular notch, the upper part o is formed by the anterior surface of the ol whilst below it is completed by the upper of the coronoid process. Constricted tow deepest part by the notching of its lateral the articular surface is occasionally cro a narrow impression which serves to de olecranon process above from the coronoic The articular area is divided into an inner slightly concave transversely, and an out transversely convex to a slight degree, by tudinal smooth ridge which extends from t prominent part of the border of the ol above to the most outstanding point of the c process below. The margins of the great cavity are sharp and well defined, and ser the exception of the area occupied by th sigmoid cavity, for the attachment of the of the elbow-joint.

The **small sigmoid cavity**, placed on th side of the coronoid process, is an oblong s surface for the reception of the head of th It encroaches on the lower and outer the great sigmoid notch, so as to narrow siderably. Separated from it by a rec curved edge, it displays a surface which from above downwards, and concave fro backwards. Its anterior extremity is r and more pointed than its posterior, and confluent with the anterior edge of the process, at which point the orbicular ligament, which retains the head radius in position, is attached in front. Its posterior border, wider a outstanding, lies in line, and is continuous with the interosseous

shaft. Behind this border, the orbicular ligament is attached pos-

shaft of the ulna (corpus ulnæ), which is nearly straight, or but slightly
is stout and thick above, gradually tapering towards its lower extremity.
be divided into two surfaces, a flexor and an extensor, by two well-defined
, an **external** or **interosseous** (crista interossea), and a **posterior** (margo
), which latter is subcutaneous throughout its whole length.
outer, or **interosseous border** (crista interossea), is crisp and sharp in the
three-fourths of the shaft, but becomes faint and ill-defined in the lower
To this, with the exception only of the part which forms the posterior
ry of the bicipital hollow, is attached the interosseous membrane which
s the two bones of the forearm. The **posterior border** (margo dorsalis), of
outline, curving outwards above, and slightly inwards below, is continuous
rly with the triangular subcutaneous area on the back of the olecranon,
formed by the confluence of the borders which bound that surface; well
above, it becomes faint and more rounded below, but may be traced down-
o the posterior surface of the base of the styloid process. To this border is
d an aponeurosis common to the flexor carpi ulnaris, extensor carpi ulnaris,
tor profundus digitorum muscles. A noteworthy feature in connexion with
rt of the shaft is the fact that it is subcutaneous, and can easily be felt
the skin throughout its whole length.
flexor surface corresponds to the front and inner side of the shaft. It is
tly described as consisting of two surfaces, an anterior and an internal,
re separated by a rounded anterior border (margo volaris), which extends
e tubercle above towards the styloid process below. The prominence of
lge varies in different bones, being well marked in bones of a pronounced
t corresponding merely to the rounding of the surfaces in poorly developed
na. The flexor aspect of the bone affords an extensive origin to the flexor
lus digitorum muscle, which clothes its anterior and inner sides in its upper
rths, reaching as far back as the posterior border, and extending upwards
as the inner side of the coronoid process. Immediately below the small
l cavity there is a hollow triangular area, limited behind by the upper part
interosseous crest, and defined in front by an oblique line which extends
ards and backwards from the outer margin of the coronoid process. In this
the bicipital tubercle of the radius rests when the forearm is in the prone
n, and to its floor are attached the fibres of origin of the supinator radii brevis
. The lower fourth of the shaft is crossed by the fibres of the pronator
tus muscle, which derives its origin from a more or less well-defined crest,
winds spirally downwards and backwards towards the front of the root of the
l process, and is continuous above with the so-called anterior border.
e **extensor aspect** of the shaft lies posteriorly between the posterior border
e interosseous crest. At its upper part it is placed behind the great and
igmoid cavities, extending on to the outer side of the olecranon. Here an
orresponding to the upper third of the length of the bone is marked off
rly by an oblique ridge which leaves the interosseous crest about an inch or
below the hinder edge of the small sigmoid cavity. Into this somewhat
ular surface the fibres of the anconeus are inserted. Below this the
ior surface is subdivided by a faint longitudinal ridge, the bone between
and the interosseous crest furnishes origins for the extensor ossis metacarpi
s, extensor longus pollicis, and extensor indicis muscles, in order from above
wards. The surface of bone between the posterior border and the afore-men-
l longitudinal line is smooth and overlain by the extensor carpi ulnaris muscle.
he **inferior extremity** of the ulna presents a rounded head (capitulum ulnæ),
which, on its inner and posterior aspect, there projects downwards a cylindrical
ed process called the **styloid process** (processus styloideus). To the extremity
is latter is attached the internal lateral ligament, whilst in front it has con-
d with it the antero-internal portion of the capsule of the wrist-joint. The
o-external half of the circumference of the head is furnished with a smooth
w convex articular surface, which fits into the sigmoid cavity of the radius.

Its inferior surface, flat and semilunar in shape, and separated from the root ‹ styloid process by a well-marked groove, rests on the upper surface of the triai fibro-cartilage of the wris apex of which is attached groove just mentioned. margins of the head in fro behind the radial articulars have attached to them th terior and posterior in radio-ulnar ligaments. hinder and outer surface ‹ styloid process is channelle groove which separates it the posterior surface of the and extends some little w the posterior aspect of the end of the shaft. In this is l the tendon of the extenso ulnaris muscle. The propo ate length of the ulna to th height is as 1 is to 6·26–6·

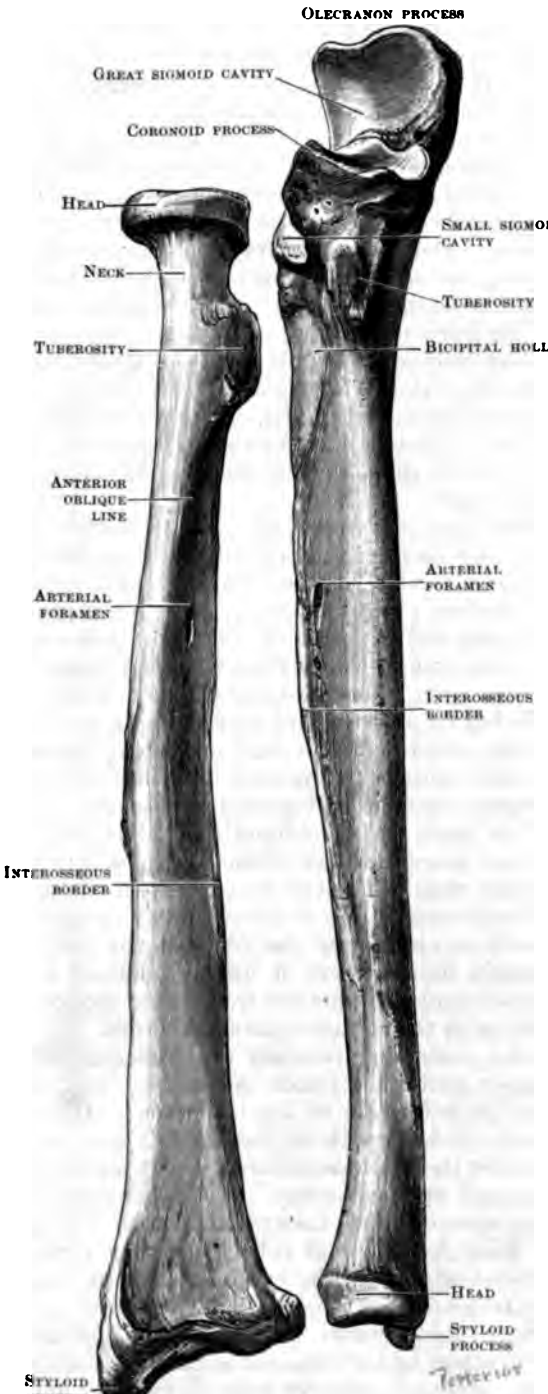

FIG. 141.—THE RADIUS AND ULNA AS SEEN FROM THE FRONT.

Nutrient Foramina. — A men, having an upward direct the nutrient artery of the shaft on the anterior surface of th from two to three inches bel tuberosity. Vascular canals o size are seen above and behi small sigmoid cavity, just post the notched external border great sigmoid cavity. At the end of the bone similar openi seen in the groove between the process and the inferior articul face of the head.

Connexions. — The ulna lates above with the trochlea humerus. On the outer side contact with the radius abo below, the superior radio-ul ticulation being formed by th of the radius and the small s cavity of the ulna, the inferio ulnar joint comprising the h the ulna, which fits into the s cavity of the radius. Betwee two joints the shafts of the bo united by the interosseous mer The inferior surface of the h the ulna does not articulate w carpus, but rests on the upper of the interposed triangular cartilage. The ulna is sup throughout its entire extent periorly the olecranon process readily recognised, particularl the elbow is bent, as in this p the olecranon is withdrawn fr olecranon fossa of the humc which it rests when the joint tended. Below this the subcu triangular area on the back olecranon can be easily dete

and from it the posterior border of the bone can readily be traced along the line of the furrow" to the styloid process below. With the hand supine this latter process can be fel inner side and slightly behind the wrist. When the hand is pronated, the lower end radius rolls round the lower extremity of the ulna, and the antero-external surface of the

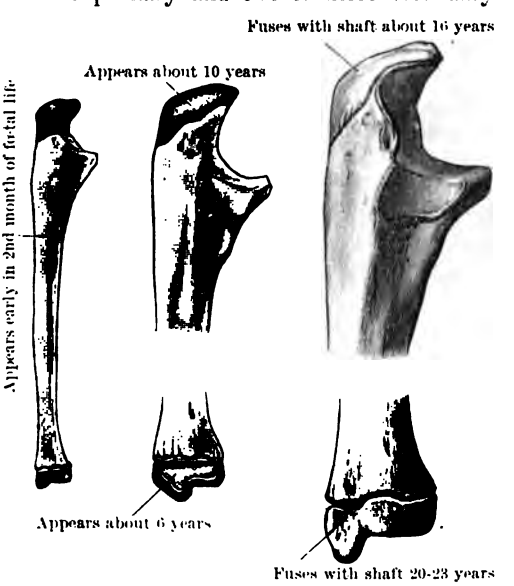
r bone now forms a well-marked projection on the back of the wrist in line with the ween the little and ring fingers.

itecture.—The weakest parts of the bone are the constricted portion of the great cavity, and the shaft in its lower third, the bone being most liable to fracture at these On section the medullary cavity is seen to extend upwards as high as the base of the process; inferiorly it reaches as low as the upper end of the lower fifth of the bone. The the **shaft**, which are formed of dense bone, are much thicker posteriorly than anteriorly. ney are continuous with the front of the coronoid process and the back of the olecranon, ne are composed of layers of looser texture, which, however, gradually become thinner as its of these processes are reached. Inferiorly they gradually taper until the head and rocess are reached, round which they form a thin shell, considerably thickened, however, egion of the groove for the extensor carpi ulnaris muscle. The bulk of the upper y is formed of loose cellular bone, arranged in a series of arcades, stretching from the to the posterior wall over the upper end of the medullary canal. Above the constricted the great sigmoid cavity the bone displays a different structure; here it is formed of one, of closer texture, arranged generally in lines radial to the articular surface. At the constriction of the great sigmoid cavity the layer immediately subjacent is much denser e compact.

lower fifth of the bone is formed of loose spongy bone, the fibres of which have a general inal arrangement; towards its extremity the meshes become smaller.

ations.—Cases of partial or complete absence of the ulna through congenital defect have orded. Rosenmüller has described a case in which the olecranon was separated from the d of the bone, resembling thus in some respects the patella. In powerfully developed ere is a tendency to the formation of a sharp projecting crest corresponding to the inser- he triceps.

ification.—The ulna is ossified from one primary and two or more secondary The centre for the shaft appears the second month of fœtal life. h the shaft and a considerable part upper extremity, including the l process, are ossified, as well as part lower extremity. The olecranon and the inferior surface of the head styloid process are cartilaginous. en years of age a secondary centre in the cartilage at the upper end bone, and forms an epiphysis nites with the shaft about sixteen. like centre appears in the cartilage head about the sixth year, from he under surface of that part of the developed, and by the extension of he styloid process is also ossified; physis does not unite with the shaft twentieth or twenty-third year. dent centres for the styloid process the extreme edge of the olecranon so been described. The student re be warned that the epiphysial ween the shaft and superior or n epiphysis does not correspond constricted part of the great sigmoid cavity, but lies considerably above it.



Fuses with shaft about 16 years

ated impression which marks the insertion of the pronator radii teres muscle.
e this, and on the outer surface of the neck, the supinator radii brevis muscle
rted, whilst inferiorly this border is overlain by the tendons of the brachio-
s and the extensor carpi radialis longior and brevior muscles.

e **anterior or flexor surface** (facies volaris) is crossed obliquely by a line which
rom the bicipital tubercle above, downwards, and outwards towards the
of the outer border of the shaft. This, oftentimes called the **anterior oblique**
rves for the attachment of the radial head of origin of the flexor sublimis
im muscle. Above it, the front of the bone has the fibres of the supinator
revis muscle inserted into it, whilst below and internal to it, extending
lown as the inferior limit of the middle third of the bone, is an extensive
for the origin of the flexor longus pollicis muscle. In the lower fourth
bone, where the shaft is broad and flat in front, there is a surface for the
n of the pronator quadratus muscle which also extends back to the inter-
ridge.

extensor or **posterior surface** (facies dorsalis) is also crossed by an oblique
s distinct than the anterior. This serves to define the superior limit of the
f the extensor ossis metacarpi pollicis muscle. Above this, the back of the
d upper part of the shaft is overlain by the fibres of the supinator radii brevis,
ecome attached to this surface of the bone in its outer half. Below the
r oblique line the posterior surface in the upper part of its inner half gives
o the extensor ossis metacarpi pollicis, and the extensor brevis pollicis
in order from above downwards.

lower extremity, which tends to be turned slightly forward when viewed
low, has a somewhat triangular form. Its inferior **carpal articular surface**,
from before backwards, and slightly so from side to side, is divided into two
y a slight antero-posterior ridge, best marked at its extremities where the
and posterior margins are notched; the external of these areas, of tri-
shape, is for articulation with the scaphoid, whilst the inner, quadrilateral in
for the semilunar bone. The anterior border, prominent and turned forward,
at its edge, where it serves for the attachment of the anterior part of the
of the wrist joint. The posterior border is rough, rounded, and tubercular,
rooved by many tendons: of these grooves the best marked is one which passes
y across its posterior surface. This is for the tendon of the extensor longus
muscle. The outer lip of this groove is often very prominent, and forms
anding tubercle. To the ulnar side of this oblique groove there is a broad
furrow in which the tendons of the extensor communis digitorum and
indicis muscles are lodged, whilst to its outer side and between it and the
process, there is another broad groove, subdivided by a faint ridge into two,
assage of the tendons of the extensor carpi radialis brevior and the extensor
lialis longior in that order from within outwards. The **styloid process** (pro-
tyloideus) lies to the outer side of the inferior extremity; broad at its base,
es narrow and pointed below where by its inner cartilage-covered surface
the summit of the inferior triangular articular area. The outer surface of
ess is crossed obliquely from above downwards and forwards by a shallow
he anterior lip of which is sharp and well marked, and serves to separate it
anterior surface of the bone, whilst the posterior lip is often emphasised
all tubercle above. The tendon of the brachio-radialis muscle is inserted
upper part of either lip, and also spreads out on to the floor of the groove,
e tendons of the extensor ossis metacarpi pollicis and the extensor brevis
muscles lie within the groove. To the tip of the styloid process is attached
rnal lateral ligament of the wrist. On the inner side of the lower extremity
the **sigmoid cavity** (incisura ulnaris) for the reception of the head of the
concave from before backwards, and plane from above downwards, it forms
nferior margin a rectangular edge which separates it from the inferior
rface. To this edge the base of the triangular fibro-cartilage is attached,
re which serves to separate the inferior articular surface of the head of

the ulna from the carpus. The anterior and posterior edges of the sigmoid cavit more or less prominent, serve for the attachment of ligaments.

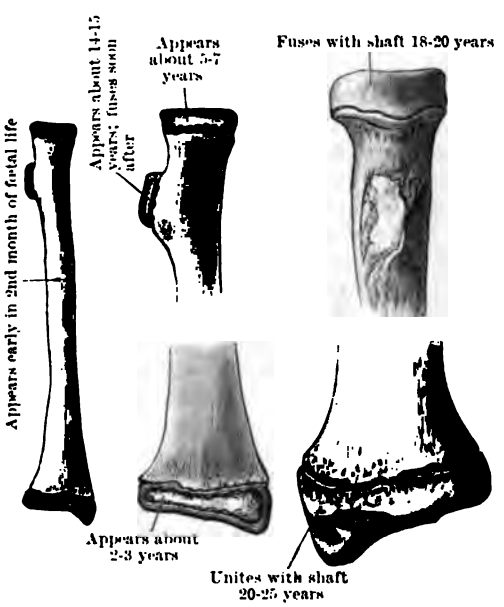
The proportionate length of the radius to the body height is as 1 is t 6·70–7·11.

Nutrient Foramina.—The openings of several small nutrient canals may be seen in th region of the neck. That for the shaft, which has an upward direction, is usually placed on th front of the bone, internal to the anterior oblique line, and from an inch and a half to two inch below the bicipital tubercle. The back of the lower extremity of the bone is pierced by mar small foramina.

Connexions.—The radius articulates with the capitellum of the humerus in the flex position of the elbow, with the ulna to its inner side by the superior and inferior radio-uln joints, and with the scaphoid and semilunar bones of the carpus below. Above, the head of t bone can be felt in the intermuscular depression on the outer side of the back of the elbow; he the bone is only covered by the skin, superficial fascia, and the thin common tendinous origin the extensor muscles, as well as the ligaments which support it. Its position can best be asc tained by pronating and supinating the bones of the forearm, when the head will be felt rotati beneath the finger. The lower end of the bone is overlain in front and behind by the flexor a extensor tendons, but its general form can be readily made out. The styloid process lying to t outer side of the wrist in line with the extended thumb can easily be recognised; note that reaches a lower level than the corresponding process of the ulna. The outer border of the low third of the shaft can be distinctly felt, as here the bone is only overlain by tendons.

Architecture.—The neck is the narrowest part of the bone; here fracture may occur, thou not commonly. The point at which the bone is usually broken is about one inch above t lower extremity. This is accounted for by the fact that the radius supports the hand at t radio-carpal articulation, and the shocks to which the latter is subjected, as in endeavouring save oneself from falling, are naturally transmitted to the radius. On section, the medulla canal is seen to extend as high as the neck; below, it reaches to the level of the inferior fifth the bone. Its walls are thick as compared with the diameters of the bone, particularly along t interosseous border, thus imparting rigidity to the curve of the shaft; these walls thin o above and below. Superiorly, the surface of the bicipital tubercle is formed of a th shell of bone, which, however, thickens again where it passes on to the neck. The upp extremity is formed of spongy bone arranged in the form of arcades, reaching below the lev of the bicipital tubercle internally, but not extending below the level of the neck e ternally. Beneath the capitellar articular surface there is a dense layer, thickest in t centre, and thinning towards the circumference; this is overlain by a very thin layer less compact bone.

The inferior fifth of the shaft and lower extremity are formed of loose spongy bo arranged more or less longitudinally. Im mediately subjacent to the carpal articul surface the tissue is more compact, and di plays a striation parallel to the articular pla The nutrient canal of the shaft pierces t anterior wall of the upper part of the medu lary cavity obliquely from below upwards i the space of half an inch.



Appears early in 2nd month of fœtal life
Appears about 14-15 years; fuses soon after
Appears about 5-7 years
Fuses with shaft 18-20 years
Appears about 2-3 years
Unites with shaft 20-25 years
At Birth.
About 12 years.
About 16 years.

Fig. 144.—The Ossification of the Radius.

Variations.—Cases of congenital absen of the radius are recorded; in these the thum is not infrequently wanting as well.

Ossification.—The centre for the sha makes its appearance early in the seco month of intrauterine life. At birth t shaft is well formed; its upper and low extremities are capped with cartilage, a the bicipital tubercle is beginning to appe A secondary centre appears in the cartila of the lower extremity about the second third year; this does not unite with t shaft until the twentieth or twenty-fif year, somewhat earlier in the female. Fr this the carpal and ulnar articular surfac are formed. The centre for the he appears from the fifth to the seventh ye and fuses with the neck about the age eighteen or twenty. It forms the capitell articular surface and combines with the neck to form the area for articulation with t small sigmoid cavity of the ulna. A scale-like epiphysis capping the summit of t bicipital tubercle has been described; this appears about the fourteenth or fifteenth ye and rapidly fuses with that process.

THE BONES OF THE HAND.

ıe bones of the hand, twenty-seven in number, may be conveniently divided ıree groups :—

The bones of the wrist or carpus—*eight* in number.
The bones of the palm or metacarpus—*five* in number.
The bones of the fingers and thumb or phalanges—*fourteen* in number.

The Carpus.

: **carpal bones** (ossa carpi) are arranged in two rows: the first, or proximal mprises from t inwards, **caphoid** (os are), **semi-** os lunatum), **m** (os tri- n), and **pisi-** s pisiforme); ond or distal ıcludes the **m** (os mul- ım majus), **d** (os mul- ım minus), **ıum** (os capi- and **unciform** ıatum). Ir- ly six-sided, these bones es non-ar- palmar and ıurfaces. In ı, the mar- ones are non- ır along their and radial according as rm the inner er members eries.

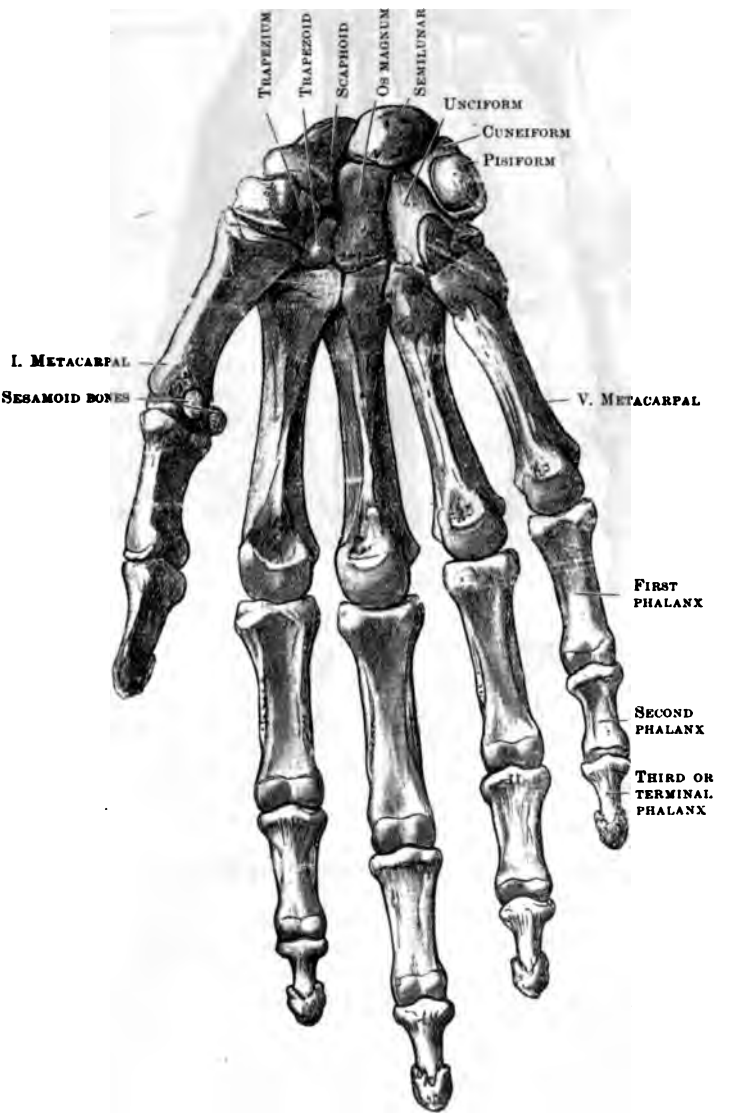


FIG. 145.—THE BONES OF THE RIGHT WRIST AND HAND AS SEEN FROM THE FRONT.

phoid Bone (os naviculare).—This is the largest as well as the outermost the first row. Its *palmar surface*, rough for the attachment of ligaments, ularly triangular. The inferior external angle forms a projection called

the **tuberosity**; this can be felt at the base of the root of the thumb. Its *s* *surface* is convex from side to side and before backwards for articulation wi radius. This area extends considerably over the posterior surface of the Its *inferior surface* is convex from before backwards, and extends on to the aspect of the bone, slightly convex from side to side; it is divisible into two the outer for articulation with the trapezium, the inner for the trapezoid.

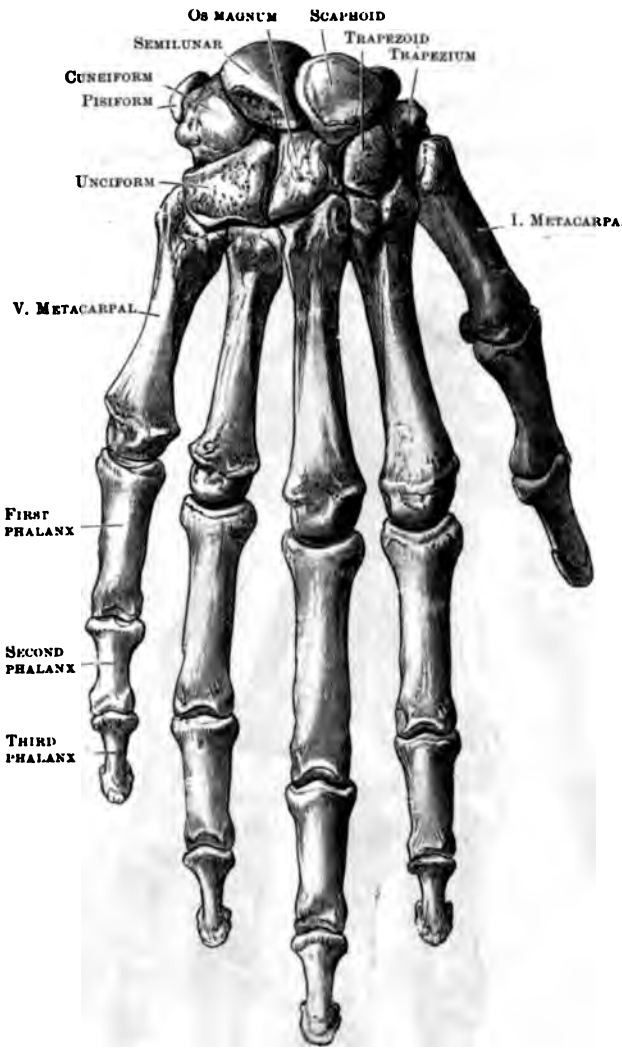

Fig. 146.—The Bones of the Right Wrist and Hand as seen from Behind.

outer surface is r and rounded and a non-articular l which extends fro radial articular s above to the tub below. The *inner s* is hollowed out in for articulation wit head of the os ma Above this it disp small semilunar-s facet for the sem bone. The *dorsal articular surface* li tween the radial ar surface above an surface for the tra and trapezoid belo is obliquely groov the attachment c posterior ligaments wrist. The scaphoi ulates with five b the radius, the sem the os magnum, the zoid, and the trape

Semilunar Bo lunatum).—So calle its deeply excavate the semilunar bon between the scaph the outer side an cuneiform on the Its *palmar surfa* rhombic form and siderable size, is rou the attachment o ments; its *superio face*, convex from to side and from backwards, articulates with the radius and in part with the under s of the triangular fibro-cartilage of the wrist. Its *inferior aspect*, deeply ho from before backwards, is divided into two articular areas, of which the is the larger; this is for the head of the os magnum; the inner, narrow side to side, articulates with the unciform. Its *external surface*, crescen shape, serves for articulation with the scaphoid, and also for the attachment interosseous ligaments which connect it with that bone. Its *inner surf* quadrilateral form, is cartilage-covered for articulation with the cuneiform the edge which separates this from the superior surface has attached to interosseous ligament which unites these two bones. The rough *dorsa articular surface* is much smaller than the palmar; by this means the and back of the bone can readily be determined. The semilunar artic

ve bones—the scaphoid, the radius, the cuneiform, the unciform, and the os
m.

neiform or Pyramidal Bone quetrum).—This bone may ognised by the small oval ular facet on its anterior for the pisiform. This ed towards the lower part *palmar surface*, which is ere rough for ligaments. one is placed obliquely, so ts surfaces cannot be ac- ly described as inferior, or, etc.; but for convenience cription, the method already d is adhered to. The *superior* e has a convex rhombic sur- r articulation with the under e of the triangular fibro- ge in adduction of the hand, h ordinarily it does not ap- o be in contact with that ure. To the ulnar side of t is rough for ligaments. *nferior surface* is elongated oncavo-convex from without ds; here the bone articulates with the unciform. The *external surface*, broader nt than behind, articulates with the semilunar. The *inner surface*, rounded ough, is confluent above and behind with the superior and dorsal aspects of the bone. The *dorsal surface*, rounded and smooth externally, is ridged and grooved internally for the attachment of ligaments. The cuneiform articulates with three bones, viz. the pisiform, the unciform, and the semilunar.

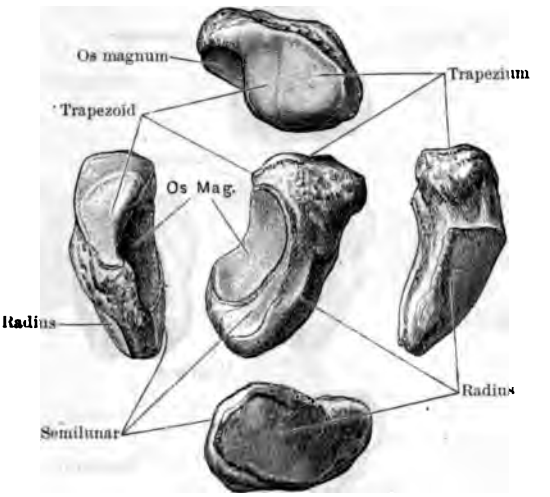

FIG. 147.—THE RIGHT SCAPHOID BONE.

NOTE.—The bone is represented in the centre of the figure in the position which it occupies in the hand viewed from the front. The views on either side, and above and below, represent respectively the corresponding surfaces of the bone turned towards the spectator.

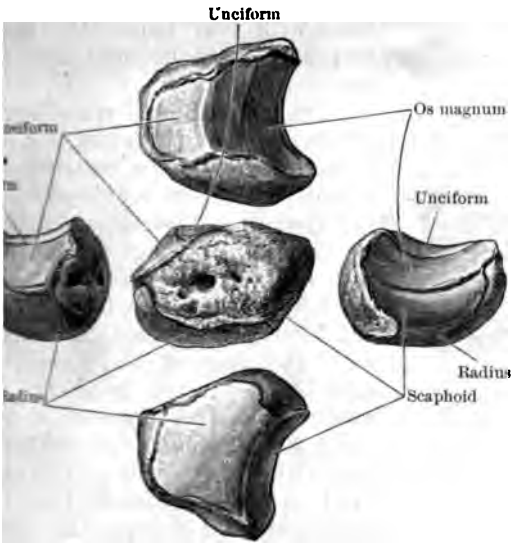

FIG. 148.—THE RIGHT SEMILUNAR BONE.

—The bone is represented in the centre of the figure in the sition which it occupies in the hand viewed from the ont. The views on either side, and above and below, present respectively the corresponding surfaces of the bone rned towards the spectator.

Pisiform bone (os pisiforme).—About the size and shape of a large pea, the pisiform bone rests on the anterior surface of the fore end of the cuneiform, with which it articulates by an oval or circular facet on its dorsal aspect. The rounded mass of the rest of the bone is non-articular, and inclines downwards and outwards so as to overhang the articular facet in front and externally. The mass of the bone is usually separated from the articular surface by a small but distinct groove. Into the summit of the bone the tendon of the flexor carpi ulnaris muscle is inserted, and here also the anterior annular ligament is attached.

rapezium (os multangulum majus).—The trapezium is the outermost bone of the d row of the carpus. It may be readily recognised by the oval saddle-shaped on its inferior surface for articulation with the metacarpal bone of the thumb.

From its *palmar aspect* there rises a prominent **ridge**, within which is a groov which the tendon of the flexc radialis muscle passes. The rid nishes an attachment for the a annular ligament, as well as fc of the short muscles of the The *superior surface* has a ha facet for the scaphoid, external t it is rough, and becomes cont with the non-articular *external* which serves for the attachm ligaments. On its *inner surfac* are two facets; the upper is oval, concave from above dow and very slightly convex from backwards, and is for articulation with the trapezoid. The lower, small and circular, and not always present, is for articulation with the outer side of the base of the second metacarpal bone. The *dorsal surface*, of irregular outline, is rough for the atta of ligaments. The trapezium lates with four bones, the sc trapezoid, and the first and metacarpal bones.

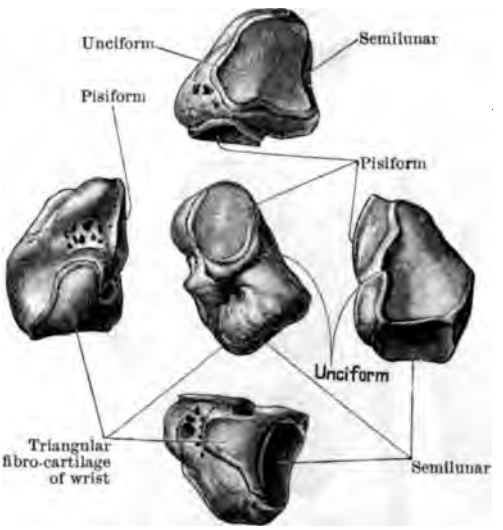

FIG. 149.—THE RIGHT CUNEIFORM BONE.

NOTE.—The bone is represented in the centre of the figure in the position which it occupies in the hand viewed from the front. The views on either side, and above and below, represent respectively the corresponding surfaces of the bone turned towards the spectator.

FIG. 150.—THE RIGHT I BONE.

NOTE.—The figure to th presents the palmar vi bone; that to the r dorsal view.

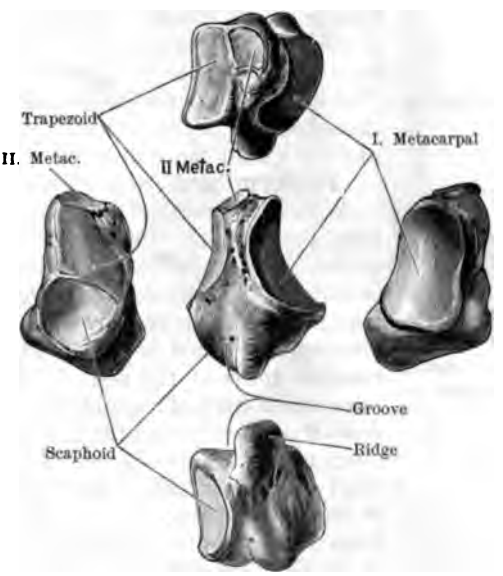

FIG. 151.—THE RIGHT TRAPEZIUM.

NOTE.—The bone is represented in the centre of the figure in the position which it occupies in the hand viewed from the front. The views on either side, and above and below, represent respectively the corresponding surfaces of the bone turned towards the spectator.

Trapezoid Bone (os multa minus).—With the exception pisiform, this is the smallest carpal bones. Its rough *palm face* is small and pentagonal in By a small oblong surface *superior aspect* it articulates w scaphoid. *Inferiorly*, by a sor saddle-shaped surface, it arti with the base of the second carpal. Separated from this rough V-shaped impression, surface on the *outer side* for a tion with the trapezium; this as if obliquely grooved from backwards and downwards. *ternal facet* for articulation w os magnum is narrow from downwards, and deeply curve before backwards. The *dorsal* of the bone, which is rough a articular, is much larger th palmar aspect. The mass bone, dorsally, is directed downwards and towards the ulnar side. The tr articulates with four bones—the trapezium, scaphoid, os magnum, and the metacarpal.

lagnum (os capitatum).—This is the largest of the carpal bones. Its *palmar* s rough and rounded. The *portion* of the bone forms l, and is furnished with rticular facets which fit hollows on the inferior of the scaphoid and semi- hat for the latter is in- and separated by a slight m the scaphoid articular ie *inferior surface*, narrow its palmar border and rsally, is subdivided usu- three facets by two ridges owards the radial side is ase of the second meta- he middle facet is for the tacarpal; whilst the in- facet of the three, not resent, very small and ear the dorsal side of the or the fourth metacarpal. *side* of the body has an surface for the trapezoid, equently separated from hoid surface on the head ugh line, to which the interosseous ligament connecting it with the scaphoid is attached. The *inner side* of the body has an elongated articular surface, usually deeply notched in front, or it may be divided anteriorly into a small circular area near the dorsal edge; and a larger posterior part. This latter articulates either singly or doubly with the unciform, the interosseous ligament which unites the two bones being attached either to the notch or to the surface separating the two articular facets. The *dorsal surface* is rough for ligaments; it is somewhat constricted below the head, the articular surface of which sweeps round its upper border.

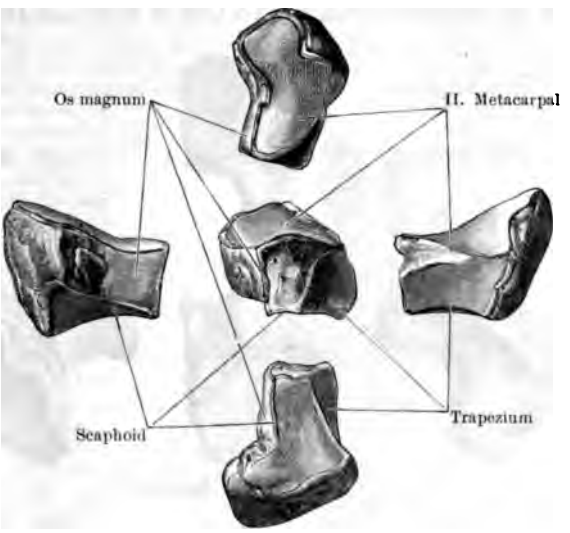

FIG. 152.—THE RIGHT TRAPEZOID.

NOTE.—The bone is represented in the centre of the figure in the position which it occupies in the hand viewed from the front. The views on either side, and above and below, represent respectively the corresponding surfaces of the bone turned towards the spectator.

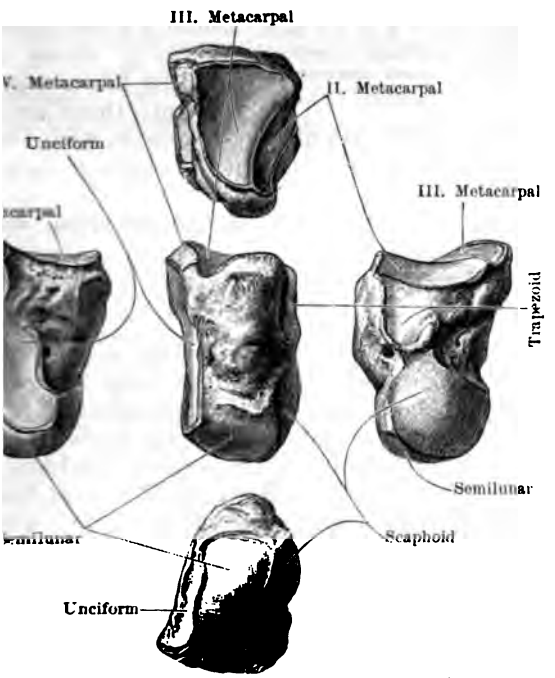

FIG. 153.—THE RIGHT OS MAGNUM.

ie bone is represented in the centre of the figure in the on which it occupies in the hand viewed from the front. iews on either side, and above and below, represent respectively orresponding surfaces of the bone turned towards the ator.

The os magnum articulates with seven bones—the unciform, the semilunar, the scaphoid, the trapezoid, and the second, third, and fourth metacarpal bones; occasionally the fourth metacarpal does not articulate with the magnum.

iform Bone (os hamatum).—The unciform can be readily distinguished by

the **hook-like process** (hamulus) which projects from the lower and inner asp
of its anterior surface. To this is attached the anterior annular ligament as w
as some of the fibres of ori
of the short muscles of
little finger. The *ulnar*
of the unciform proce
sometimes grooved by
deep branch of the u
nerve (Anderson, W., "R
Anat. Soc." *Journ. A*
and Physiol. vol. xxvii
11). The *palmar surf*

concave from before backwards, and are for articulation, the outer with the fou
and the inner with the fifth metacarpal bone. The *dorsal surface*, more or l
triangular in shape, is rough for ligaments.

The unciform articulates with five bones—viz. the os magnum, semilun
cuneiform, and the fourth and fifth metacarpals.

THE CARPUS AS A WHOLE.

When the carpal bones are articulated together they form a bony mass, t
dorsal surface of which is convex from side to side. Anteriorly they present
grooved appearance, concave from side to side. This arrangement is furth
emphasised by the forward projection, on the inner side, of the pisiform and ho
of the unciform, whilst externally the tuberosity of the scaphoid and the ridge
the trapezium help to deepen the furrow by their elevation. To these four poi
the anterior annular ligament of the wrist is attached, which stretches across fr
side to side, and thus converts the furrow into a canal through which the fle
tendons pass to reach the fingers.

Architecture.—The bones are formed of fairly compact spongy tissue, surrounded by a th
shell of denser bone. They are very vascular, and their non-articular surfaces are pierced
many foramina.

Variations.—Increase in the number of the carpal elements is occasionally met with, a
these have been ascribed to division of the scaphoid, semilunar, cuneiform, os magnum, tra
zoid, and unciform. In the last-mentioned case the hook-like process persists as a sepa
ossicle; but the researches of Thilenius (*Morph. Arbeiten*, Bd. v. Heft 3, S. 462), together with
observations of Pfitzner, prove that all these supernumerary bones are but the persistence of in
pendent cartilaginous elements which are met with in the hand of the human embryo betw
the second and fourth months, and which either disappear or become fused with adjac
elements. Of these the most interesting is the os centrale, first described by Rosenberg, a
subsequently investigated by Henke, Leboucq, and others. This is met with almost invaria

ıdependent cartilaginous element during the earlier months of fœtal life, and occasionally
s developed into a distinct ossicle placed on the back of the carpus between the scaphoid
magnum and the trapezoid. Its significance depends on the fact that it is an im-
component of the carpus in most mammals, and is met with normally in the orang
st monkeys. Ordinarily in man, as was pointed out by Leboucq, it becomes fused with the
d, where its presence is often indicated by
l tubercle, a condition which maintains
chimpanzee, the gorilla, and the gibbons.
has recently described a case in which
ras an os subcapitulum in both hands.
icle lay between the base of the middle
pal bone and the os magnum with the
id to its radial side. (*Anat. Anz.* vol. xxiv.)
addition to the number of the carpal
s may be due to the separation of the
process of the third metacarpal bone and
stence as a separate ossicle.
ıction in the number of the carpus has
ıet with, but this is probably due to
gical causes. Morestin (*Bull. Soc. Anat.*
, tome 71, p. 651), who has investigated
ject, finds that ankylosis occurs most fre-
between the bases of the second and
ıetacarpal bones and the carpus, seldom
between the carpus and the first meta-
or between the pisiform and cuneiform.
t Smith has recorded an instance of com-
ion between the semilunar and cuneiform
both wrists of a Soudanese negro. There
evidence of any pathological change.
nz. vol. xxiii. 1903.)

FIG. 155.—RADIOGRAPH OF THE HAND AT BIRTH.

It will be noticed that whilst the primary centres for the metacarpus and phalanges are well ossified, the carpus is still entirely cartilaginous.

Compare this with Fig. 197, in which the tarsus is shown in part already ossified.

ification.—At birth the carpus is
cartilaginous. An exceptional case
ed by Lambertz, in which the centres
os magnum and unciform were
present. The same authority states
is not uncommon to meet with these centres in the second month after birth.
ng to Debierre (*Journ. de l'Anat. et de la Physiol.* vol. xxii. 1886, p. 285),
on takes place approximately as follows:—

Os magnum	11 to 12 months.
Unciform	12 to 14 months.
Cuneiform	3 years.
Semilunar	5 to 6 years.
Trapezium	6 years.
Scaphoid	6 years.
Trapezoid	6 to 7 years.
Pisiform	10 to 12 years.

same observer failed to note the appearance of a separate centre for the apophysis
neiform, and records the occurrence of two centres for the pisiform.

THE METACARPUS.

metacarpal bones form the skeleton of the palm, articulating proximally
e carpus, whilst by their distal extremities or **heads** they support the bones
fingers. Five in number, one for each digit, they lie side by side and
divergent from each other, being separated by intervals, termed interosseous
Distinguished numerically from without inwards, they all display certain
n characters; each possesses a **body** or shaft, a **base** or carpal extremity, and a
phalangeal end.

shafts, which are *slightly curved towards the* palmar aspect, are narrowest
their middle. Their dorsal surface is marked by two divergent lines

which pass forward from the back of the base to tubercles on either side head. The surface included between the two lines is smooth and of elo triangular form. On either side of these lines two shallow grooves wind spirally forward on to the surface, where they are separated in front by a sharp which is continuous with a somewhat triangular which corresponds to the palmar aspect of the base grooved surfaces on either side of the shaft furnish orig the interossei muscles. Close to the palmar crest opening of the nutrient canal, which is directed towa carpal extremity, except in the case of the first meta bone.

FIG. 156.—FIRST RIGHT METACARPAL BONE.

The head (capitulum) is provided with a surfa articulation with the proximal phalanx. This area farther over its palmar than its dorsal aspect. Conve before backwards and from side to side, it is wider ant than posteriorly; notched on its palmar aspect, its edge two prominent tubercles, which are sometimes grooved small sesamoid bones which may occasionally be found anterior surface of the joint. On either side of the head bone there is a deep pit, behind which is a prominent tul to these are attached the lateral ligaments of the metacarpo-phalangeal joints.

The bases (basis), all more or less wedge-shaped in form, articulate with the carpus; they differ in size and shape according to their articulation.

Of the five metacarpal bones, the **first**, viz. that of the thumb, is the shortest and stoutest, the **second** is the longest, whilst the **third**, **fourth**, and **fifth** display a gradual reduction in length.

The four inner bones articulate by their bases with each other, and are united at their distal extremities by ligaments. They are so arranged as to conform to the hollow of the palm, being concave from side to side anteriorly, and convex posteriorly. The first metacarpal differs from the others in being free at its distal extremity, whilst its proximal end possesses only a carpal articular facet.

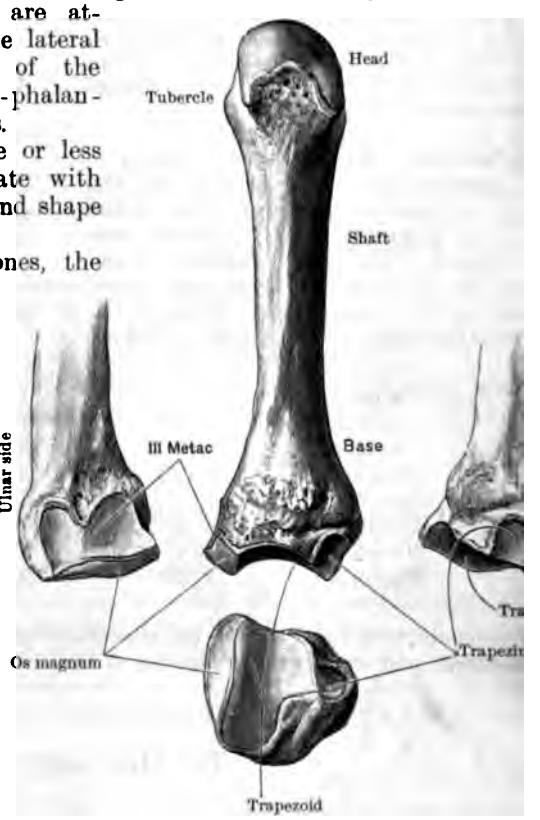

FIG. 157.—SECOND METACARPAL BONE.

NOTE.—The bone is represented in the centre of the figu position which it occupies in the hand viewed from t The views on either side, and below, represent re the corresponding surfaces of the bone turned tow spectator.

The first metacarpal bone is the shortest and stoutest of the series. Its shaft is compressed from before backwards. Its head, of large size, is but slightly convex from side to side, and is grooved in front for the sesamoid The base is provided with a saddle-shaped surface for articulation with the trap as no lateral facets. Externally there is a slight tubercle to whic

tor longus pollicis or extensor ossis mala-
pollicis muscle is attached. The canal for
ıtrient artery is directed towards the head of
ne.

ıe **second metacarpal bone** is recognised
s length and its broad and deeply-notched
for articulation with the trapezoid. It has
ll half-oval facet for the trapezium on the
side of its base,
; on its ulnar aspect
ents a narrow vertical
for the os magnum,
nt of which there are
alf-oval surfaces for
ird metacarpal. To
rsal aspect of the base
ched the tendon of
tensor carpi radialis
r muscle, whilst the
carpi radialis is in-
in front.

e **third metacarpal**
an usually be recog-
y the pointed **styloid**
s which springs from
ck of its base, and is
d radial-wards. Su-
ly there is a facet on
se for the os magnum.

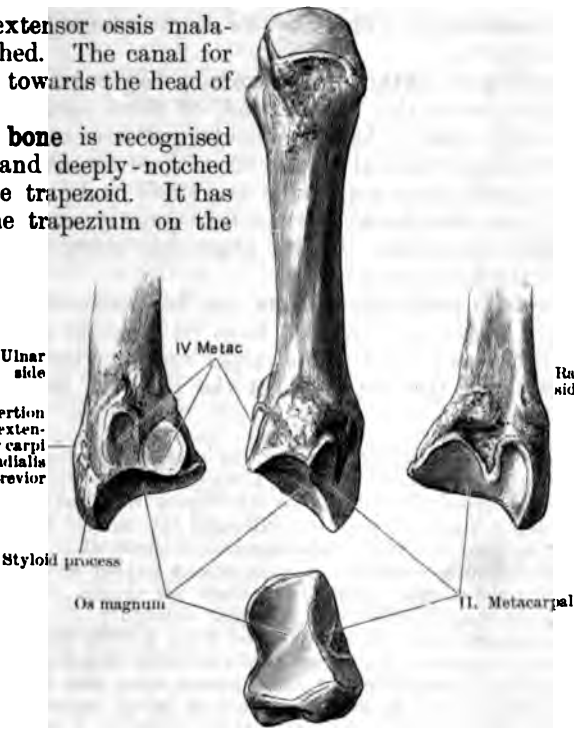

FIG. 158.—THIRD METACARPAL BONE.

NOTE.—The bone is represented in the centre of the figure in the position which it occupies in the hand viewed from the front. The views on either side, and below, represent respectively the corresponding surfaces of the bone turned towards the spectator.

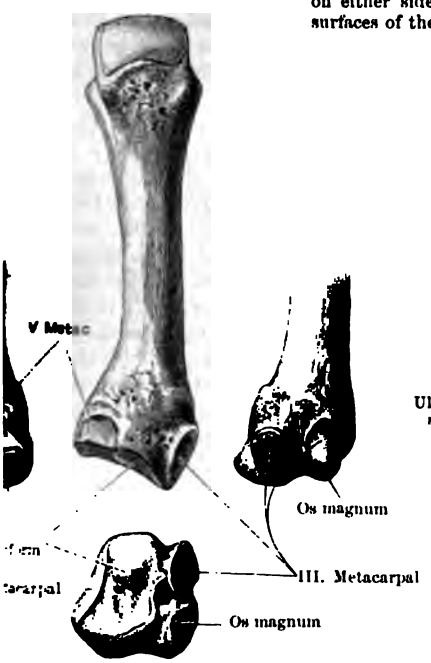

FIG. 159.—FOURTH METACARPAL BONE.

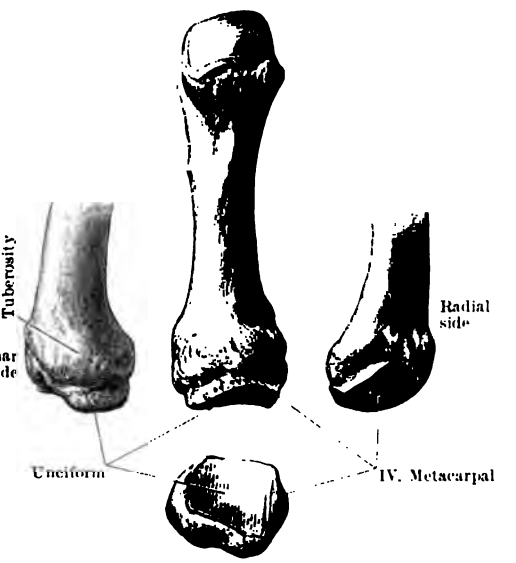

FIG. 160. FIFTH METACARPAL BONE.

—The bone in each figure is represented in the centre of the figure in the position which it occupies in the
d viewed from the front. The views on either side, and below, represent respectively the corresponding
rfaces of the bone turned towards the spectator.

ıe radial side there are two half-oval facets for the second metacarpal. To
ılnar side there are usually two small oval or nearly circular facets for the

fourth metacarpal. The extensor carpi radialis brevior muscle is inserted into back of the base.

The **fourth metacarpal bone** may be recognised by a method of exclusion. is unlike either the first, second, or third, and differs from the fifth, whi resembles in size, by having articular surfaces on both sides of its base. Super there is a quadrilateral surface on its base for articulation with the unciform. its radial side there are usually two small oval facets for the third metacarpal. these facets the dorsal one not infrequently has a narrow surface for articul with the os magnum. On the ulnar side there is a narrow articular strip for base of the fifth metacarpal.

The **fifth metacarpal bone** can be recognised by its size and the fact tha has only one lateral articular facet on its base, namely, that on its radial side the fourth metacarpal. The carpal articular surface is saddle-shaped, and the a **tubercle** on the ulnar side of the base for the insertion of the extensor c ulnaris muscle.

As has been already pointed out, the openings of the arterial canals are usually seen on palmar surfaces of the metacarpals, those of the four inner bones being directed upwards tow the base or carpal end, differing in this respect from that of the first metacarpal, which is dir downwards towards the head or phalangeal extremity. The opening of the latter canal us lies to the ulnar side of the palmar aspect of the shaft.

Architecture.—Similar in arrangement to that of long bones generally, though it ma noted that the compact walls of the shaft are thicker in proportion to the length of the than in the other long bones of the upper extremity.

Variations.—As previously stated (*ante*, p. 209), the styloid apophysis of the third m carpal bone appears as a separate ossicle in about 1·8 per cent of cases examined ("Fourth An Report of the Committee of Collect. Invest. Anat. Soc. Gt. Brit. and Ireland," *Journ. Anat. Physiol.* vol. xxviii. p. 64). In place of being united to the third metacarpal, the st apophysis may be fused with either the os magnum or the trapezoid, under which condition base of the third metacarpal bone is without this characteristic process.

Ossification.—The metacarpal bones are developed from primary and secon centres; but there is a remarkable difference between the mode of growth of the first the remaining four inner metacarpals, for whilst the **shaft** and **head** of the first metac are developed from the primary ossific centre, and its *base* from a secondary epiphys the case of the second, third, fourth, and fifth metacarpals, the **shafts** and **bases** are veloped from the primary centres, the *heads* in these instances being derived from secondary epiphyses. In this respect, therefore, as will be seen hereafter, the metac bone of the thumb resembles the phalanges in the manner of its growth, a circumst which has given rise to considerable discussion as to whether the thumb is to be reg as possessing three phalanges and no metacarpal, or one metacarpal and two phala The primary centres for the shafts and bases of the second, third, fourth, and fifth m carpals appear in that order during the ninth or tenth week of intrauterine life, a little time after the terminal phalanges have begun to ossify, that for the shaft and b of the metacarpal bone of the thumb a little later. At birth the shafts of the bones well formed. The secondary centres from which the heads of the second, third, fou and fifth metacarpals and the base of the first are developed, appear about the third y and usually completely fuse with the shafts about the age of twenty. There may b independent centre for the styloid process of the third metacarpal, and there is usual scale-like epiphysis on the head of the first metacarpal which makes its appearance ab eight or ten, and rapidly unites with the head.

The Phalanges.

The **phalanges** or finger bones (phalanges digitorum manus) are fourteen number—three for each finger, and two for the thumb.

Named numerically in order from the proximal toward the distal ends of t fingers, the **first phalanx** (phalanx prima), the longest and stoutest of the three, ha semi-cylindrical shaft which is curved slightly forwards. The palmar surface is and bounded on either side by two sharp borders to which the sheath of the fle tendons is attached. The dorsal surface, convex from side to side, is overlain the extensor tendons. The proximal end, considerably enlarged, has a simple ov concave surface, which rests on the head of its corresponding metacarpal bone. O either side of this the bone is tubercular, and affords attachment to the late

ıts of the metacarpo-phalangeal joint, and also to the interossei muscle. The nd is much smaller than the proximal; the convex ır surface is divided into two condyles by a central running from before backward. The **second phalanx** ıx secunda) resembles the first in general form, but maller size. It differs, however, in the form of its al articular surface, which is not a simple oval con- but is an oval area divided into two small, nearly : concavities by a central ridge passing from before ırds; these articulate with the condyloid surfaces of ɔximal phalanx. Into the margins of its palmar near the proximal end are inserted the split s of the tendon of the flexor sublimis digitorum, on the dorsal aspect of the proximal end the central the extensor communis digitorum muscle is at-

The **third, terminal** or **ungual phalanx** (phalanx is the smallest of the three; it is easily recognised spatula-shaped surface on its distal extremity which :s the nail. The articular surface on its proximal sembles that on the proximal end of the second x, but is smaller. On the palmar aspect of this end bone there is a rough surface for the insertion of don of the flexor profundus digitorum muscle. The surface of the same extremity has attached to it the al portions of the tendon of the extensor communis um muscle. The phalanges of the thumb resemble arrangement of their parts the first and third ges of the fingers.

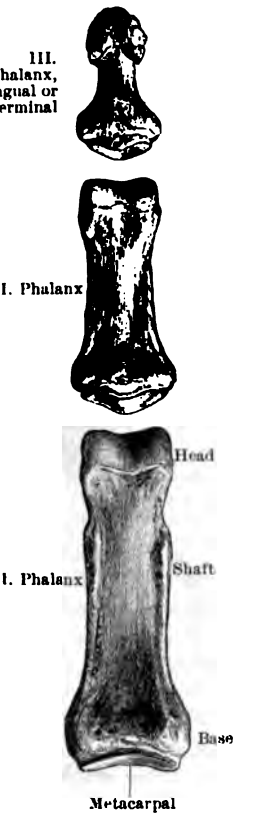

FIG. 161.—THE PHALANGES OF THE FINGERS (palmar aspect).

arterial canals, usually two in number, placed on either the palmar aspect and nearer the distal than the proximal he bone, are directed towards the finger-tips.

itecture.—Each phalanx has a medullary cavity, the walls shaft being formed of dense compact bone, especially thick ıe dorsal aspect. The extremities are made up of spongy bone within a thin dense shell.

iations.—Several instances have been recorded of cases in which there were three phalanges ıumb. Bifurcation of the terminal phalanges has occasionally been met with, and examples ression of a phalangeal segment or its absorption by another phalanx have also been de- (Hasselwander, *Zeits. F. Morph. u. Anthr.*, vol. vi. 1903).

sification.—The phalanges are ossified from primary and secondary centres. From the former, which appear as early as the ninth week of fœtal life, the shaft and distal extremities are developed; whilst the latter, which begin to appear about the third year, form the proximal epiphyses which unite with the shafts from eighteen to twenty. Dixey (*Proc. Roy. Soc.*, xxx. and xxxi.) has pointed out that the primary centre in the ungual phalanges commences to ossify in the distal part of the bone rather than towards the centre of the shaft. This observation has been confirmed by Lambertz, who further demonstrates the fact that ossification commences earlier in the distal phalanges than in any of the other bones of the hand. Of the other phalanges, those of the first row, beginning with that of the third finger, next ossify, subt to the appearance of ossific centres in the shafts of the metacarpal bones, whilst

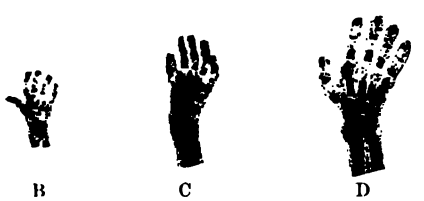

FIG. 162. -RADIOGRAPHS OF FŒTAL HANDS.

it 10 weeks. Here the ossific nuclei of the terminal ıanges and the four inner metacarpal bones are seen.
tle later. The centre for the metacarpal bone of the ımb is now appearing, and the centres for the first ılanges of the index and middle fingers are clearly seen.
it the beginning of the third month. The centres for all first row of phalanges are now distinct, and the centres the second phalanges of the index, middle, and ring fingers e made their appearance.
ween the third and fourth month. The primary centres all the phalanges and metacarpus are now well eloped.

the second or intermediate row of the phalanges is the last to ossify about the end third month.

Sesamoid Bones.

Two little oval nodules (ossa sesamoidea), which play in grooves on the p aspect of the articular surface of the head of the first metacarpal bone, are consi met with in the tendons and ligaments of that metacarpo-phalangeal articul Similar nodules, though of smaller size, are sometimes formed in the correspo joints of the other fingers, more particularly the index and little finger; as Thil has pointed out (*Morph. Arbeiten*, vol. v.), these are but the persistence of cartilag elements which have a phylogenetic interest.

THE LOWER LIMB.

THE PELVIC GIRDLE AND THE LOWER EXTREMITY.

The **pelvic girdle** is formed by the articulation of the two haunch bones the sacrum behind, and their union with each other in front, at the joint calle symphysis pubis.

The Innominate Bone.

The **innominate** or haunch bone (os coxæ) is the largest of the flat bones skeleton. It consists of three parts—the **ilium**, the **ischium**, and the **pu** primarily distinct, but fused together in the process of growth to form one irregular bone. The coalescence of these elements takes place in and aroun **acetabulum**, a large circular articular hollow which is placed on the outer side bone. The expanded wing-like part above this is the ilium; the stout V-sh portion below and behind it constitutes the ischium; while the >-shaped pa the inner side, and in front and below, forms the pubis. The two latter porti the bone enclose between them a large aperture of irregular outline, calle **thyroid** or **obturator** foramen (foramen obturatorum), which is placed in fron below, and to the inner side of the acetabulum.

The **ilium**, almost a quadrant in form, consists of an expanded plate of having a curved superior border, the **iliac crest** (crista iliaca). Viewed fron side, this forms a curve corresponding to the circumference of the circle of the bone is the quadrant; viewed from above, however, it will be seen to di a double bend—convex anteriorly and externally, and concave posteriorly externally. The iliac crest is stout and thick, and for descriptive purpo divided into an outer lip (labium externum), an inner lip (labium internum) an intermediate surface (linea intermedia) which is broad behind, narrowest its middle, and wider again in front. About 2½ inches from the anterior extr of the crest the outer lip is usually markedly prominent and forms a proje tubercle, which can readily be felt in the living. Attached to these surface lips anteriorly are the muscles of the flank, whilst from them posteriorly latissimus dorsi, quadratus lumborum, and erector spinæ muscles derive origins. The crest ends in front in a pointed process, the **anterior superior iliac** (spina iliaca anterior superior). To this the outer extremity of Poupart's liga is attached, as well as the sartorius muscle, which also arises from the edge of immediately below it, whilst from the same process and from the anterior ex the outer lip of the iliac crest externally the tensor fasciæ femoris muscle origin.

The **anterior border** of the ilium stretches from the anterior superior iliac to the margin of the acetabulum below. Above, it is thin; but below, it for thick tubercular process, the **anterior inferior iliac spine** (spina iliaca anterio ferior). From this the rectus femoris muscle arises, whilst the stout fibres o ilio-femoral ligament of the hip-joint are attached to it immediately above acetabular margin. Posteriorly, the crest terminates in the **posterior superior spine** (spina iliaca posterior superior). Below this, the posterior border of the is sharp and irregularly notched terminating in a prominent angle, the post

erior iliac spine (spina iliaca posterior inferior), in front of which the edge of the ne becomes thick and rounded, and forms a wide notch which sweeps forwards d downwards to join the mass of bone behind the acetabulum, where it becomes ed with the ischium; this is called the **ilio-sciatic** or **great sciatic notch** (incisura hiadica major).

The ilium has two surfaces, an inner and an outer. The *external surface* is

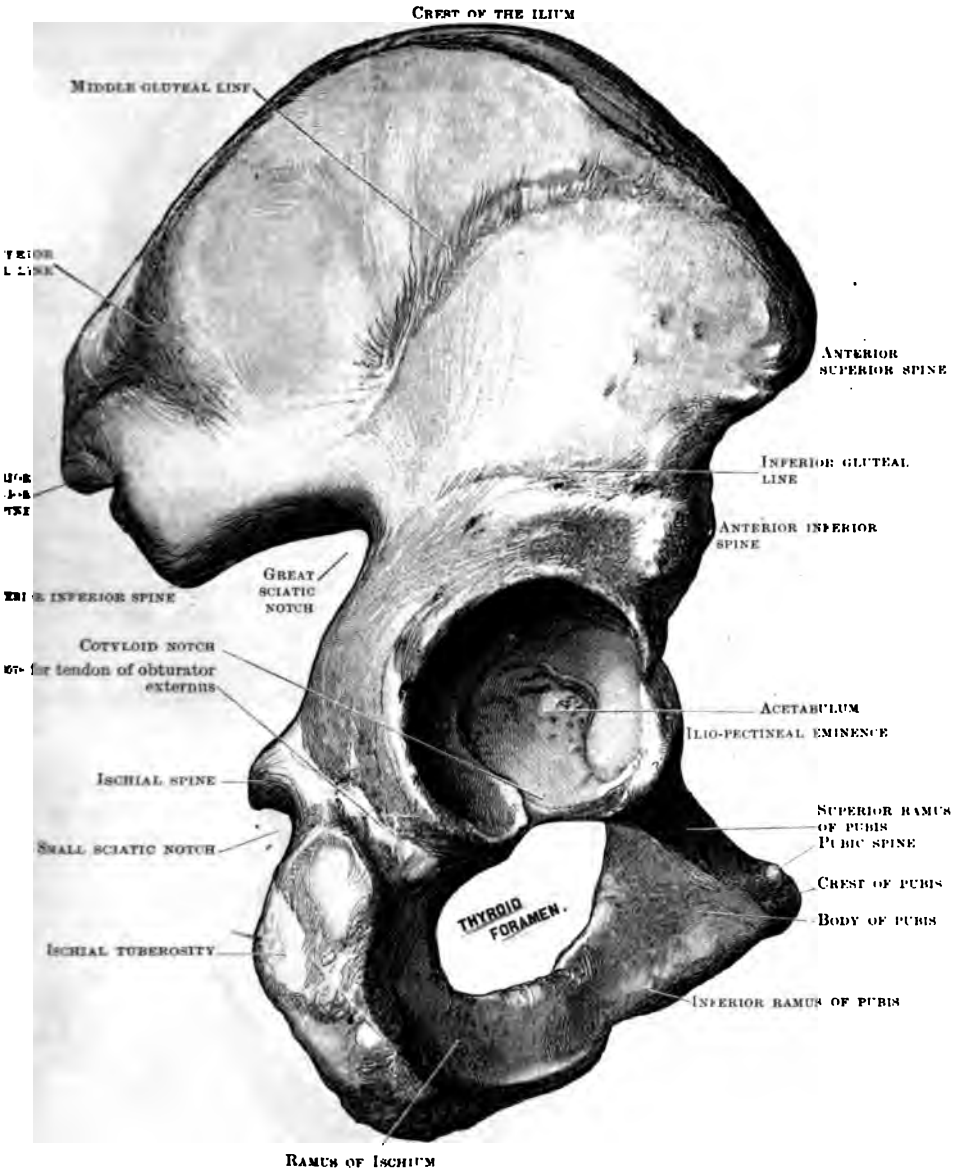

Fig. 163.—The Right Innominate Bone as seen from the Outer Side.

ided into two parts, viz. a lower acetabular, and an upper gluteal part. The er forms a little less than the upper two-fifths of the acetabular hollow, and is arated from the larger gluteal surface above by the upper prominent margin of e articular cavity. The **gluteal surface**, broad and expanded, is concavo-convex m behind forward. It is traversed by **three** rough **curved lines**, well seen in ngly developed bones, but often faint and indistinct in feebly marked specimens. Of these the **inferior curved line** (linea glutæa inferior) curves backwards m a point immediately above the anterior inferior spine towards the ilio-sciatic

notch posteriorly; the bone between this and the acetabular margin is mar
a rough shallow groove, from which the reflected head of the rectus femoris
arises. The **middle curved line** (linea glutæa anterior) commences at the c
the ilium, about one inch and a half behind the anterior superior iliac spi

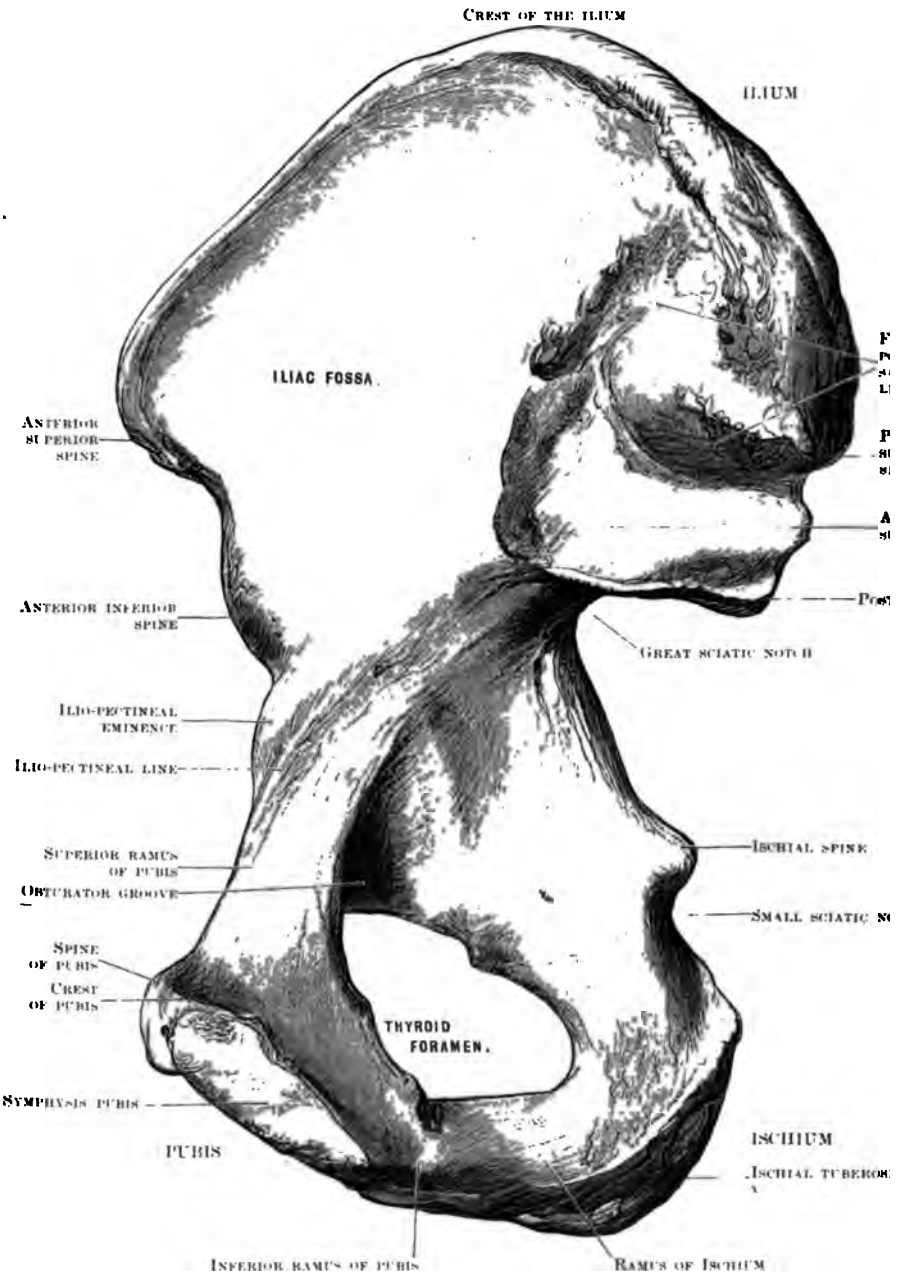

FIG. 164.—THE RIGHT INNOMINATE BONE (Inner Aspect).

sweeps backwards and downwards towards the upper and posterior part of t
sciatic notch. The surface between this line and the preceding furnishes an
sive origin for the gluteus minimus muscle. The **posterior** or **superior curv**
(linea glutæa posterior) leaves the iliac crest about two and a half inches i
of the posterior superior iliac spine, and bends downwards and slightly forw
a direction anterior to the posterior inferior spine. The area between this a
middle curved line is for the origin of the gluteus medius muscle, whilst th

rface immediately above and behind it is for some of the fibres of origin of the luteus maximus muscle.

The *inner surface* of the ilium is divided into two areas which present very haracteristic differences. The **posterior** or **sacral part**, which is rough, displays in ont a somewhat smooth, auricular surface (facies auricularis) which is cartilage-ated in the recent condition, and articulates with the sacrum. Above and behind his there is an elevated irregular area, the **tuberosity** (tuberositas iliaca), which is ere and there deeply pitted for the attachment of the strong posterior sacro-iliac gaments. Above this the bone becomes confluent with the inner lip of the iliac rest, and here it affords an origin to the erector spinæ and multifidus spinæ uscles. The anterior part of the inner aspect of the bone is smooth and exten-ive; it is subdivided by an oblique ridge, called the **ilio-pectineal line** (linea cuata), which passes forwards and downwards from the most prominent point of he auricular surface towards the inner side of the ilio-pectineal eminence which placed just above and in front of the acetabulum, and marks the fusion of the ium with the pubis. Above this the bone forms the shallow **iliac fossa** (fossa iaca), from the floor of which the iliacus muscle arises, whilst leading from the ssa, below and in front, there is a shallow furrow, passing over the superior etabular margin, between the anterior inferior iliac spine on the outer side and e ilio-pectineal eminence internally, for the lodgment of the tendinous and fleshy rt of the **ilio-psoas** muscle. If held up to the light the floor of the deepest part f the iliac fossa will be seen to be formed of but a thin layer of bone. A nutrient ramen of large size is seen piercing the bone towards the hinder part of the ssa. Below and behind the ilio-pectineal line the inner surface of the ilium rms a small portion of the wall of the true pelvis; the bone here is smooth, and nded off posteriorly into the ilio-sciatic notch, where it becomes confluent with e inner aspect of the ischium. Just anterior to the ilio-sciatic notch there are sually the openings of one or two large vascular foramina. From this surface ise some of the posterior fibres of the obturator internus muscle.

The **ischium** constitutes the lower and hinder part of the innominate bone. periorly its **body** (corpus) forms somewhat more than the inferior two-fifths of e acetabulum together with the bone supporting it behind and within. Below is, the **superior ramus** passes downwards and backwards as a stout three-sided ece of bone, from the inferior extremity of which a compressed bar of bone, called e **inferior ramus**, extends forwards at an acute angle. This latter unites in front nd above with the descending ramus of the pubis, and encloses the aperture called e obturator foramen.

Superiorly, and on the outer aspect of the ischium, the acetabular surface is parated from the bone below by a sharp and prominent margin, which is, owever, deficient in front, where it corresponds to the **cotyloid notch** (incisura cetabuli), leading into the articular hollow; the floor of this notch is entirely rmed by the ischium. Below the prominent acetabular margin there is a well-arked groove in which the tendon of the obturator externus lies. Beneath this e antero-external surface of the superior and inferior rami furnish surfaces for the tachments of the obturator externus, quadratus femoris, and adductor magnus uscles. The postero-external surface of the ischium forms the convex surface on e back of the acetabulum. The inner border of this is sharp and well defined, nd is confluent above with the border of the ilium, which sweeps round the great o-sciatic notch. From this border, on a level with the lower edge of the cetabulum, there springs a pointed process, the **spine** (spina ischiadica), to which is tached the lesser sacro-sciatic ligament and the superior gemellus muscle. Inferior this, the postero-external surface narrows rapidly, its inner border just below the ine being hollowed out to form the **small sciatic notch** (incisura ischiadica minor). he lower part of this surface and the angle formed by the two rami are capped by an irregularly rough pyriform mass called the **tuberosity** (tuber ischii). This is ivided by an oblique ridge into two areas, the upper and outer for the tendon of igin of the semimembranosus muscle, the lower and inner for the conjoined heads f the biceps and semitendinosus muscles. Its prominent inner lip serves for the ttachment of the great sacro-sciatic ligament, whilst its outer edge furnishes an

notch posteriorly; the bone between this and the acetabular margin is ma
a rough shallow groove, from which the reflected head of the rectus femoris
arises. The **middle curved line** (linea glutæa anterior) commences at the
the ilium, about one inch and a half behind the anterior superior iliac spi

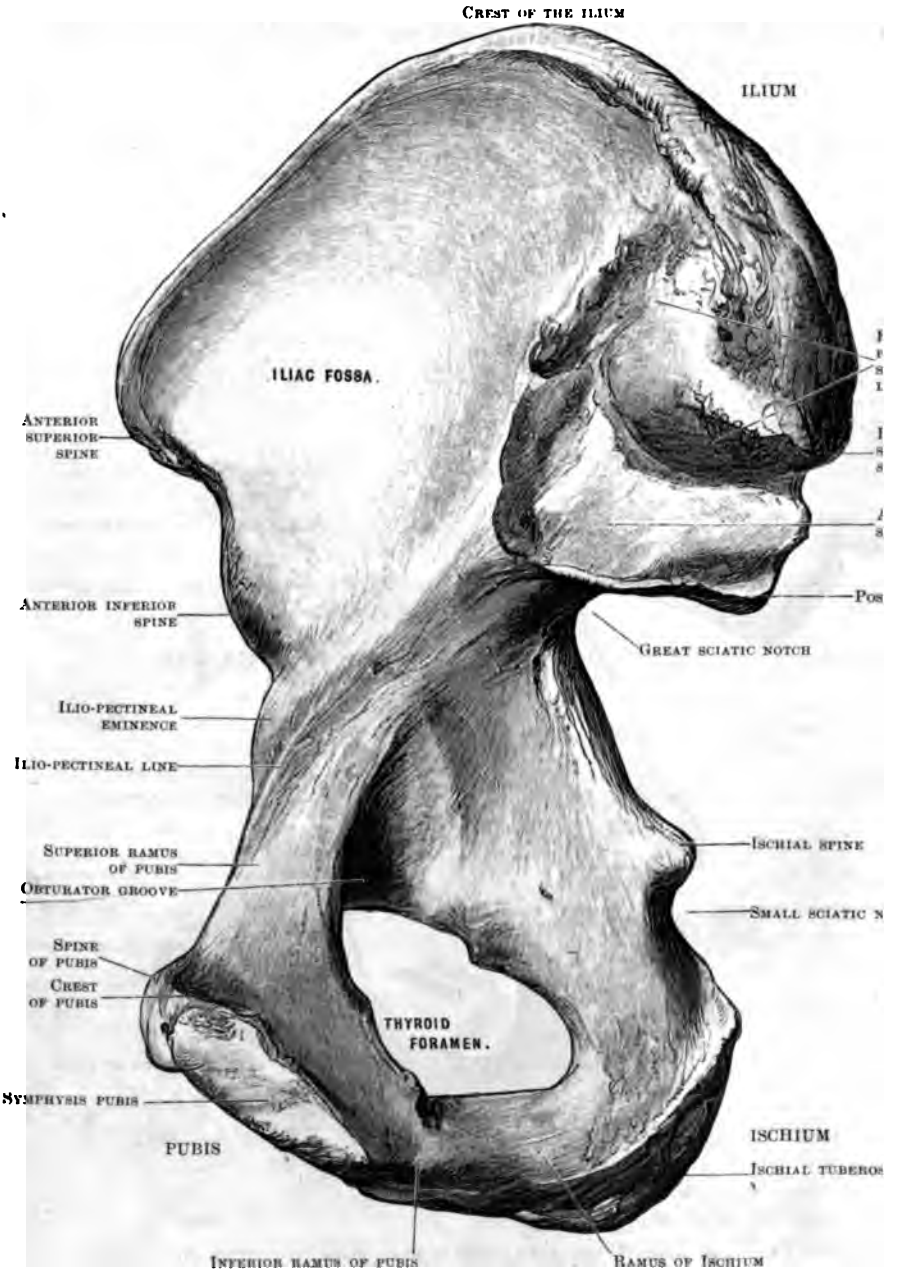

FIG. 164.—THE RIGHT INNOMINATE BONE (Inner Aspect).

sweeps backwards and downwards towards the upper and posterior part of
sciatic notch. The surface between this line and the preceding furnishes a
sive origin for the gluteus minimus muscle. The **posterior** or **superior cur**
(linea glutæa posterior) leaves the iliac crest about two and a half inches
of the posterior superior iliac spine, and bends downwards and slightly forv
a direction anterior to the posterior inferior spine. The area between this
middle curved line is for the origin of the gluteus medius muscle, whilst th

surface immediately above and behind it is for some of the fibres of origin of the gluteus maximus muscle.

The *inner surface* of the ilium is divided into two areas which present very characteristic differences. The **posterior** or **sacral part**, which is rough, displays in front a somewhat smooth, auricular surface (facies auricularis) which is cartilage-coated in the recent condition, and articulates with the sacrum. Above and behind this there is an elevated irregular area, the **tuberosity** (tuberositas iliaca), which is here and there deeply pitted for the attachment of the strong posterior sacro-iliac ligaments. Above this the bone becomes confluent with the inner lip of the iliac crest, and here it affords an origin to the erector spinæ and multifidus spinæ muscles. The anterior part of the inner aspect of the bone is smooth and extensive; it is subdivided by an oblique ridge, called the **ilio-pectineal line** (linea arcuata), which passes forwards and downwards from the most prominent point of the auricular surface towards the inner side of the ilio-pectineal eminence which is placed just above and in front of the acetabulum, and marks the fusion of the ilium with the pubis. Above this the bone forms the shallow **iliac fossa** (fossa iliaca), from the floor of which the iliacus muscle arises, whilst leading from the fossa, below and in front, there is a shallow furrow, passing over the superior acetabular margin, between the anterior inferior iliac spine on the outer side and the ilio-pectineal eminence internally, for the lodgment of the tendinous and fleshy part of the ilio-psoas muscle. If held up to the light the floor of the deepest part of the iliac fossa will be seen to be formed of but a thin layer of bone. A nutrient foramen of large size is seen piercing the bone towards the hinder part of the fossa. Below and behind the ilio-pectineal line the inner surface of the ilium forms a small portion of the wall of the true pelvis; the bone here is smooth, and rounded off posteriorly into the ilio-sciatic notch, where it becomes confluent with the inner aspect of the ischium. Just anterior to the ilio-sciatic notch there are usually the openings of one or two large vascular foramina. From this surface arise some of the posterior fibres of the obturator internus muscle.

The **ischium** constitutes the lower and hinder part of the innominate bone. Superiorly its **body** (corpus) forms somewhat more than the inferior two-fifths of the acetabulum together with the bone supporting it behind and within. Below this, the **superior ramus** passes downwards and backwards as a stout three-sided piece of bone, from the inferior extremity of which a compressed bar of bone, called the **inferior ramus**, extends forwards at an acute angle. This latter unites in front and above with the descending ramus of the pubis, and encloses the aperture called the obturator foramen.

Superiorly, and on the outer aspect of the ischium, the acetabular surface is separated from the bone below by a sharp and prominent margin, which is, however, deficient in front, where it corresponds to the **cotyloid notch** (incisura acetabuli) leading into the articular hollow; the floor of this notch is entirely formed by the ischium. Below the prominent acetabular margin there is a well-marked groove in which the tendon of the obturator externus lies. Beneath this the antero-external surface of the superior and inferior rami furnish surfaces for the attachments of the obturator externus, quadratus femoris, and adductor magnus muscles. The postero-external surface of the ischium forms the convex surface on the back of the acetabulum. The inner border of this is sharp and well defined, and is confluent above with the border of the ilium, which sweeps round the great or ilio-sciatic notch. From this border, on a level with the lower edge of the acetabulum, there springs a pointed process, the **spine** (spina ischiadica), to which is attached the lesser sacro-sciatic ligament and the superior gemellus muscle. Inferior to this, the postero-external surface narrows rapidly, its inner border just below the spine being hollowed out to form the **small sciatic notch** (incisura ischiadica minor). The lower part of this surface and the angle formed by the two rami are capped by an irregularly rough pyriform mass called the **tuberosity** (tuber ischii). This is divided by an oblique ridge into two areas, the upper and outer for the tendon of origin of the semimembranosus muscle, the lower and inner for the conjoined heads of the biceps and semitendinosus muscles. Its prominent inner lip serves for the attachment of the great *sacro-sciatic ligament*, whilst its outer edge furnishes an

origin for the quadratus femoris muscle; in front and below, the adductor magnus muscle is attached to it.

The *inner surface* of the body and superior ramus of the ischium form in part the wall of the true pelvis. Smooth and slightly concave from before backwards and nearly plane from above downwards, it is widest opposite the level of the ischial spine. Below this, its posterior edge is rounded and forms a groove leading to the small sciatic notch, along and over which the tendon of the obturator internus passes. To part of this surface the fibres of the obturator internus are attached, whilst the inner aspect of the spine supplies points of origin for the coccygeus and levator ani muscles, as well as furnishing an attachment to the "white line" of the pelvic fascia. The inner surface of the inferior ramus of the ischium is smooth, and so rounded that its inferior edge tends to be everted. To this, as well as to its margin, is attached the crus penis, together with the ischio-cavernosus, obturator internus, transversus perinei, and compressor urethræ muscles. In the female, structures in correspondence with these are also found.

The fore-part of the innominate bone is formed by the **pubis**; it is by means of the union of this bone with its fellow of the opposite side that the pelvic girdle is completed in front.

The **pubis** (os pubis) consists of two rami—a **superior, ascending,** or **horizontal** (ramus superior ossis pubis), and an **inferior** or **descending** (ramus inferior ossis pubis). The broad part of the bone formed by the fusion of these two rami is the **body.**

The body is sometimes described as that part of the bone which enters into the formation of the acetabulum, but the English nomenclature has here been followed.

The **body of the pubis** has two surfaces. Of these the *inner* or *posterior* is smooth, and forms the fore-part of the wall of the true pelvis; hereto are attached the levator ani muscle and puboprostatic ligaments. The *anterior* or *external surface* is rougher, and furnishes origins for the gracilis, adductor longus, adductor brevis, and some of the fibres of the obturator externus muscles. The *inner border* is provided with an elongated oval cartilage-covered surface by means of which it is united to its fellow of the opposite side, the joint being called the **symphysis pubis.** The *upper border,* thick and rounded, projects somewhat, so as to overhang the anterior surface. It is called the **crest.** Internally this forms with the inner border or symphysis the **angle,** whilst externally it terminates in a pointed process, the **spine** (tuberculum pubicum). From the crest arise the rectus abdominis and pyramidalis muscles, and to the spine is attached the inner end of Poupart's ligament. Passing upwards and outwards from the outer side of the body towards the acetabulum, of which it forms about the anterior fifth, is the **superior ramus** (ramus superior). This has three surfaces: an antero-superior, an antero-inferior, and an internal or posterior. The *antero-superior surface* is triangular in form. Its apex corresponds to the pubic spine; its anterior inferior border to the **obturator crest** (crista obturatoria), leading from the spine to the upper border of the cotyloid notch; whilst its sharp postero-superior border trends upwards and outwards from the spine, and is continuous with the iliac portion of the ilio-pectineal line just internal to the ilio-pectineal eminence, forming as it passes along the superior ramus the pubic portion of that same line (pecten ossis pubis). On this line, just within the ilio-pectineal eminence, there is often a short, sharp crest which marks the insertion of the psoas parvus. The base of the triangle corresponds to the ilio-pectineal eminence above and the upper margin of the cotyloid notch below. Slightly hollow from side to side, and convex from before backwards, this surface provides an origin for, and is in part overlain by, the pectineus muscle. The *internal* or *posterior surface* of the superior ramus is smooth, concave from side to side, and slightly rounded from above downwards; by its sharp inferior curved border it completes the thyroid foramen, as seen from behind. The *antero-inferior surface* forms the roof of the broad obturator groove (sulcus obturatorius) which passes obliquely downwards and forwards between the lower margin of the antero-superior surface in front and the inferior sharp border of the internal surface behind. The **inferior** or **descending ramus of the pubis** (ramus inferior) passes downwards and outwards from the lower part of the body.

Flattened and compressed, it unites with the inferior ramus of the ischium, and thus encloses the thyroid foramen, whilst in correspondence with its fellow of the opposite side it completes the formation of the pubic arch. *Anteriorly* it furnishes origins for the gracilis, adductor brevis, and adductor magnus muscles, as well as some of the fibres of the obturator externus muscle. Its *inner surface* is smooth, whilst its lower border, rounded or more or less everted, has attached to it the fore-part of the crus penis and the subpubic ligament.

The **acetabulum** or **cotyloid cavity** is the nearly circular hollow in which the head of the thigh bone fits. As has been already stated, it is formed by the fusion of the ilium and ischium and pubis in the following proportions: the ilium a little less than two-fifths, the ischium somewhat more than two-fifths, the pubis constituting the remaining one-fifth. It is so placed as to be directed downwards, outwards, and forwards, and is surrounded by a prominent margin, to which the capsule and cotyloid ligament of the hip-joint are attached. Opposite the obturator foramen this margin is interrupted by the **cotyloid notch** (incisura acetabuli); immediately external to the ilio-pectineal eminence the margin is slightly hollowed, whilst occasionally there is a feeble notching of the border above and behind. These irregularities in the outline of the margin correspond to the lines of fusion of the ilium and pubis, and the ilium and ischium respectively. The floor of the acetabulum is furnished with a horseshoe-shaped articular surface, which lines the circumference of the hollow, except in front, where it is interrupted by the cotyloid notch. It is broad above; narrower in front and below. Within this articular surface there is a more or less circular rough area (fossa acetabuli) continuous in front and below with the floor of the cotyloid notch. This, somewhat depressed below the surface of the articular area, lodges a quantity of fat, and provides accommodation for the interarticular ligament of the joint. As may be seen by holding the bone up to the light, the floor of this part of the acetabulum is not usually of great thickness. The major part of the non-articular area is formed by the ischium, which also forms the floor of the cotyloid notch.

The **thyroid** or **obturator foramen** (foramen obturatum) lies in front of, below, and internal to the acetabulum. The margins of this opening, which are formed in front and above by the pubis, and behind and below by the ischium, are sharp and thin, except above, where the under surface of the superior ramus of the pubis is channelled by the obturator groove. Below, and on either side of this groove, two tubercles can usually be seen. The one, situated on the edge of the ischium, just in front of the cotyloid notch, is named the **posterior obturator tubercle** (tuberculum obturatorium posterius); the other, placed on the lower border of the inner surface of the superior ramus of the pubis, is called the **anterior obturator tubercle** (tuberculum obturatorium anterius). Between these two tubercles there passes a ligamentous band, which converts the groove into a canal along which the obturator vessels and nerve pass. Elsewhere in the fresh condition the obturator or thyroid membrane stretches across the opening from margin to margin. The form of the foramen varies much, being oval in some specimens, in others more nearly triangular; its relative width in the female is greater than the male.

Nutrient foramina for the ilium are seen on the floor of the iliac fossa, just in front of the sacro-auricular surface; on the pelvic aspect of the bone, close to the great sciatic notch; and on the gluteal surface externally, near the centre of the middle curved line. For the ischium, on its pelvic surface, and also externally on the groove below the acetabulum. For the pubis, on the surface of the body, and deeply also from the acetabular fossa.

Connexions.—The innominate bone articulates with the sacrum behind, with the femur to the outer side and below, and with its fellow of the opposite side internally and in front. Each of its three parts comes into direct relation with the surface. Above, the iliac crest assists in forming the iliac furrow, which serves to separate the region of the flank from that of the buttock. In front, the anterior superior iliac spine forms a definite landmark; whilst behind, the posterior superior iliac spines will be found to correspond with dimples situated on either side of the middle line of the root of the back. The symphysis, the crest, and spine of the pubis can all be distinguished in front, though overlain by a considerable quantity of fat, whilst the position of the tuberosities of the ischia, when uncovered by the great gluteal muscles in the flexed position of the thigh, can readily be ascertained. In the perineal region the outline of the pubic and ischial rami *can easily be determined* by digital examination.

Architecture.—As a flat bone the os innominatum consists of spongy tissue between two compact external layers. These latter vary much in thickness, being exceptionally stout along the ilio-pectinal line and the floor of the iliac fossa immediately above it. The gluteal aspect of the ilium is also formed by a layer of considerable thickness. The spongy tissue is loose and cellular in the thick part of the ilium and in the body of the ischium; absent where the floor of the iliac fossa is formed by the coalescence of the thin dense confining layers; fine grained and more compact in the tuberosity of the ischium, the iliac crest, and the floor of the acetabulum, in which latter situation it is striated by fibres which are directed radially to the surface of that hollow, these again being crossed at right angles by others which are arranged circumferentially. This spongy tissue forms a more compact layer over the surface of the upper and back portion of the acetabular articular area. The bottom of the floor of the acetabulum varies in thickness; in most cases it is thin, and in exceptional instances the bone is here deficient. The same condition has been met with in the iliac fossa, where absorption of the thin bony plate has taken place.

Variations.—Some of the anomalies met with in the haunch bone are due to ossification of the ligaments connected with it; in other cases they depend on errors of development. Failure of union between the pubic and ischial rami has also been recorded. Cases have occurred where the obturator groove has been bridged across by bone, and one case is noted of absence of the cotyloid notch on the acetabular margin. In rare cases the os acetabuli (see Ossification) remains as a separate bone.

Ossification commences in the ilium about the ninth week of intrauterine life; about the fourth month a centre appears below the acetabulum for the ischium, the pubis being developed from a centre which appears in front of the acetabulum about the fifth or sixth month. At birth the form of the ilium is well defined; the body and part of the tuberosity of the ischium are ossified, as well as the horizontal ramus and part of the body of the pubis. All three parts enter into the formation of the sides of the acetabulum, and by the third year have converged to form the bottom of that hollow, being separated from each other by a triradiate piece of cartilage, in which, about the twelfth year, independent ossific centres make their appearance, which may or may not become fused with the adjacent bones. In the latter case they unite to form an independent ossicle, the os acetabuli, which subsequently fuses with and forms the acetabular part of the pubis. By the age of sixteen the ossification of the acetabulum is usually completed, whilst the rami of the ischium and pubis commonly unite about the tenth year. Secondary centres, six in number, make their appearance about the age of puberty, and are found in the following situations: one for the anterior inferior iliac spine, one for the iliac crest and the anterior and posterior superior iliac spines, a scale-like epiphysis over the tuberosity of the ischium, a separate epiphysis for the spine of the ischium, (?) a point for the spine and another for the angle of the pubis. Fusion between these and the primary centres is usually complete between the twenty-second and twenty-fifth years.

About 12 or 13 years.

FIG. 165.—OSSIFICATION OF THE INNOMINATE BONE.

Parsons (*Journ. Anat. and Physiol.*, vol. xxxvii. p. 315) regards the ischial epiphysis as the homologue of the hypo-ischium in reptiles, and suggests that the epiphysis over the angle of the pubis may represent the epipubic bone of marsupials.

THE PELVIS.

The **pelvis** is formed by the union of the innominate bones with each other in front, and with the sacrum behind. In man the dwarfed caudal vertebræ

(coccygeal) are curved forwards and so encroach upon the limits of the pelvic cavity inferiorly. The pelvis is divided into two parts by the ilio-pectineal lines, which curve forwards from the upper part of the lateral masses of the sacrum behind, to the roots of the spines of the pubes in front. The part above is called the **false pelvis** (pelvis major), and serves by the expanded iliac fossæ to support the

FIG. 166.—MALE PELVIS AS SEEN FROM THE FRONT.

abdominal contents; the part below, the **true pelvis** (pelvis minor) contains the pelvic viscera, and in the female forms the bony canal through which, at full term, the fœtus is expelled.

The **true pelvis** is bounded in front by the symphysis pubis in the middle line, and by the body and rami of the pubis on either side, laterally by the smooth inner surfaces of the ischia and ischial rami, together with a small part of the ilium

FIG. 167.—FEMALE PELVIS AS SEEN FROM THE FRONT.

below the iliac portion of the ilio-pectineal line. Springing from the posterior margin of the ischium are the inturned ischial spines. Behind, the broad curved anterior surface of the sacrum, and below it, the small and irregular coccyx, form its posterior wall. Between the sides of the sacrum behind, and the ischium and ilium in front and above, *there is a wide interval*, called the **sacro-sciatic notch**,

which is, however, bridged across in the recent condition by the great and small sacro-sciatic ligaments, which thus convert it into two foramina, the larger above the spine of the ischium—the great sacro-sciatic foramen, the lower and smaller below the spine, called the small sacro-sciatic foramen.

The **inlet** (apertura pelvis superior) of the pelvis is bounded in front by the symphysis pubis, with the body of the pubis on either side; laterally by the ilio-pectineal lines; and behind by the sacral prominence. The circumference of this aperture is often called the **brim of the pelvis**; in the male its shape is cordate, in the female more oval. The *antero-posterior* or *conjugate diameter* is measured from the sacro-vertebral angle to the symphysis pubis; the *oblique diameter* from the sacro-iliac joint of one side to the ilio-pectineal eminence of the other; whilst the *transverse diameter* is taken across the point of greatest width.

The **outlet** (apertura pelvis inferior) is bounded anteriorly by the **pubic arch** (arcus pubis), formed in front and above by the bodies of the pubis, with the symphysis between them, and the inferior pubic rami below and on either side. These latter are continuous with the ischial rami which pass backwards and outwards to the ischial tuberosities, which are placed on either side of this aperture. In the middle line and behind, the tip of the coccyx projects forward, and in the recent condition the interval between this and the ischial tuberosities is bridged across by the great sacro-sciatic ligament, the inferior edge of which necessarily assists in determining the shape of the outlet.

As the anterior wall of the cavity, formed by the symphysis pubis, measures from 1½ to 2 inches, whilst the posterior wall, made up of the sacrum and coccyx, is from 5 to 6 inches in length, it follows that the planes of the inlet and outlet are not parallel, but placed at an angle to each other. The term **axis of the pelvis** is given to lines drawn at right angles to the centre of these planes. Thus, with the pelvis in its true position, when the figure is erect, the axis of the inlet corresponds to a line drawn downwards and backwards from the umbilicus towards the tip of the coccyx below, whilst the axis of the outlet is directed downwards and slightly backwards, or downwards and a little forwards, varying according to the length of the coccyx. Between these two planes the axis of the cavity, as it passes through planes of varying degrees of obliquity, describes a curve repeating pretty closely the curve of the sacrum and coccyx.

Position of the Pelvis.—The position of the pelvis in the living when the figure is erect may be approximately represented by placing it so that the anterior superior iliac spines and the symphysis pubis lie in the same vertical plane. Under these conditions the plane of the inlet is oblique, and forms with a horizontal line an angle of from 50° to 60°. The position of the pelvis depends upon the length of the ilio-femoral ligaments of the hip-joint, being more oblique when these are short, as usually happens in women in whom the anterior superior iliac spines tend to lie in a plane slightly in advance of that occupied by the symphysis pubis. In cases where the ilio-femoral ligament is long, a greater amount of extension of the hip-joint is permitted, and this leads to a lessening of the obliquity of the pelvis. This condition, which is more typical of men, results in the anterior superior iliac spines lying in a plane slightly posterior to the plane of the symphysis, whilst the angle formed by the plane of the inlet and the horizontal is thereby reduced. Bearing in mind the oblique position of the pelvis, it will now be seen that the front of the sacrum is directed downwards more than forwards, and that the sacral promontory is raised as much as from 3½ to 4 inches above the upper border of the symphysis pubis, lying higher than the level of a line connecting the two anterior superior iliac spines. From the manner in which the sacrum articulates with the ilia, it will be noticed that the weight of the trunk is transmitted downwards through the thickest and strongest part of the bone (see Architecture) to the upper part of the acetabula, where these rest on the heads of the femora.

Sexual Differences.—The female pelvis is lighter in its construction than that of the male; its surfaces are smoother, and the indications of muscular attachments less marked. Its height is less and the splay of its walls not so pronounced as in the male, so that the female pelvis has been well described as a short segment of a long cone as contrasted with the male pelvis, which is a long segment of a short cone. The cavity of the true pelvis in the female is more roomy, and the ischial spines not so much inturned. The pubic arch is wide and rounded, and will usually admit a right-angled-set square

d within, so that the summit touches the under surface of the symphysis pubis, ides lie in contact with the ischial rami. In the male the arch is narrow and ming an angle of from 65° to 70°. The sacro-sciatic notch in the female is allow. The distance from the posterior edge of the body of the ischium to the ferior iliac spine is longer, measuring on an average 50 mm. (2 inches) in the ontrasted with 40 mm. (1⅝ inches) in the male.

t in the female is large and oval or reniform, as compared with the cribbed and l aperture in the male. The sacro-vertebral angle is more pronounced in the the obliquity of the inlet greater. The sacrum is shorter and wider. The perior iliac spines lie wider apart; the pubic crests are longer; and the pubic parated by a greater interval than in man. The outlet is larger; the tubero-ischia are farther apart; and the coccyx does not project forward so much. f the sacrum is liable to very great individual variation. As a rule the curve orm in the male, whilst in the female it tends to be flatter above and more below. There is a greater proportionate width between the acetabular he female than in the male. Of much importance from the standpoint of the are the various diameters of the true pelvis. In regard to this it is worthy the plane of "greatest pelvic expansion" extends from the union between the third sacral vertebræ behind, to the middle of the symphysis pubis in front, oundaries on either side corresponding with the mid-point of the inner surface bulum; whilst the plane of "least pelvic diameter" lies somewhat lower, and y lines passing through the sacro-coccygeal articulation, the ischial spines, er third of the symphysis pubis (Norris). Subjoined is a table showing the erage measurements in the two sexes:—

	Males.	Females.
listance between the iliac crests	11⅛ in., or 282 mm.	10¾ in., or 273 mm.
etween the anterior superior iliac	9½ in., or 240 mm.	9¾ in., or 250 mm.
etween the last lumbar spine and t of the symphysis pubis	7 in., or 176 mm.	7⅛ in., or 180 mm.

of the Pelvis.—From the close association of the pelvic girdle with the lower limb its growth takes place concurrently with the development of that member. At er limbs measure but a fourth of the entire body length; consequently at that time compared with the head and trunk, is relatively small. At this period of life the th sexes is in greater part an abdominal organ, whilst in the female the uterus has into the true pelvic cavity, and the ovaries and Fallopian tubes rest in the iliac sacro-vertebral angle, though readily recognised, is as yet but faintly marked. ith the remarkable growth of the lower limbs and the assumption of the erect n the child begins to walk, striking changes take place in the form and size of the e consist in a greater expansion of the iliac bones necessarily associated with the muscles which control the movements of the hip, together with a marked increase ertebral angle due to the development of a forward lumbar curve; at the same time, f the trunk being thrown on the sacrum causes the elements of that bone to sink to between the innominate bones. The cavity of the true pelvis increases in size y, and the viscera afore-mentioned now begin to sink down and have assumed a in the pelvis by the *fifth or sixth year*. The extension of the thighs in the

upright position necessarily brings about a more pronounced pelvic obliquity, whilst the st and thickness of the ilium over the upper part of the acetabulum is much increased to wit the pressure to which it is obviously sul Coincident with this is the gradual develo of the iliac portion of the ilio-pectinea which serves in the adult to separate s the false from the true pelvis. This part bone is remarkably strong, as has been (see Architecture), and serves to transm body weight from the sacrum to the thigl The sexual differences of the pelvis, so they refer to the general configuration part of the skeleton, are as pronounced third or fourth month of fœtal life as th in the adult (Fehling, *Ztschr. f. Gebur Gynaek.* Bd. ix. and x.; A. Thomson, *Anat. and Physiol.* vol. xxxiii. p. 359). rougher appearance of the male type related with the more powerful muscul velopment.

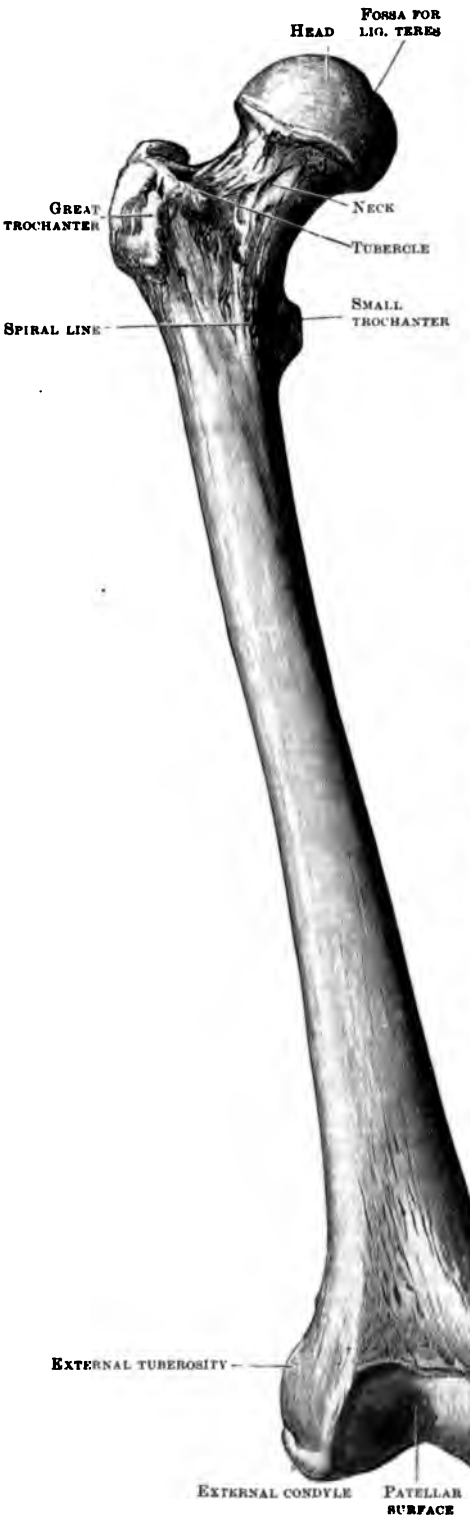

Fig. 168.—Right Femur as seen from the Front.

The Femur.

The **femur** or thigh bone is rem able for its length, being the longest in the body. Superiorly the femor separated by the width of the p Inferiorly they articulate with the and patellæ. In the military pos of attention, with the knees close toge the shafts of the thigh bones occu oblique position. For descriptive pur the bone is divided into an uppe tremity, comprising the **head**, **neck**, two **trochanters**; a **shaft**; and a **extremity**, forming the expansions k as the **condyles**.

The **head** (caput femoris) is the l spherical articular surface which, coated with cartilage, fits into the a bular hollow. Its pole is directed up and inwards and slightly forward little below the summit, and us somewhat behind it, is a hollow ov (fovea capitis femoris) for the attach of the ligamentum teres. The cir ference of the head forms a lip w wavy outline, more prominent abov behind than in front. The head is ported by a stout compressed bar of the **neck** (collum oris), which forms the upper end of shaft an angle of a 125 degrees, and i rected upwards, inw and a little forw Its vertical width ceeds its antero- terior thickness. stricted about its mi it expands internal support the head, whilst externally, where it joins the shaft, its vertical diame

much increased. Anteriorly it is clearly defined from the shaft by a rough ridge which commences above on a prominence, sometimes called the **tubercle** of the femur, and passes obliquely downwards and inwards. This constitutes the upper part of the **spiral line** (linea inter-trochanterica), and serves for the attachment of the ilio-femoral ligament of the hip-joint. Posteriorly where the neck unites with the shaft, there is a full rounded ridge passing from the trochanter major above to the trochanter minor below; this is the posterior **intertrochanteric line** or **ridge** (crista intertrochanterica). A little above the middle of this ridge there is usually a fulness which serves to indicate the upper limit of attachment of the quadratus femoris muscle, and is called the **tubercle for the quadratus**. Externally the neck is embedded in the inner surface of the trochanter major, by which, at its upper and back part, it is to some extent overhung. Here is situated the **digital fossa** (fossa trochanterica), into which the tendon of the obturator externus is inserted. Passing nearly horizontally across the back of the neck there is a faint groove leading into this depression; in this the tendon of the obturator externus muscle lies. Inferiorly the neck becomes confluent with the trochanter minor behind, and is continuous with the inner surface of the shaft in front. The neck is pierced by many vascular canals, most numerous at the upper and back part. Some are directed upwards towards the head, whilst others pass in the direction of the trochanter major.

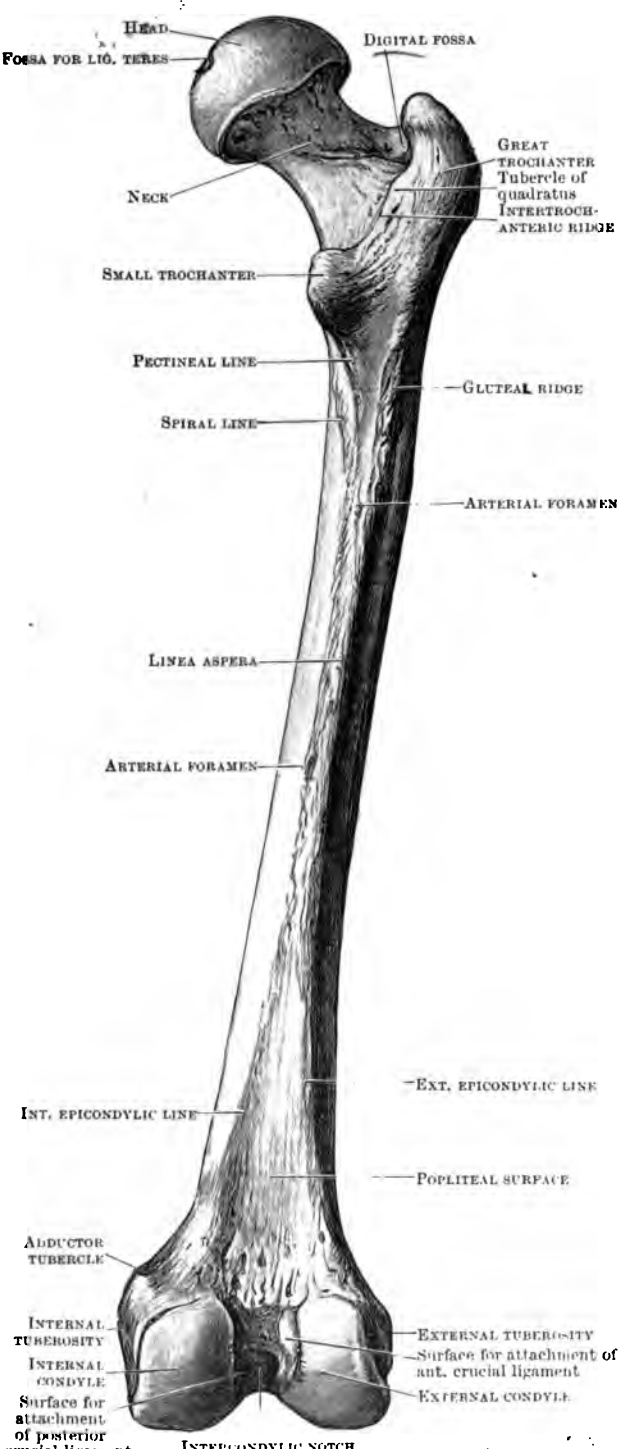

Fig. 169.—Right Femur as seen from Behind.

The **trochanter major** is a large quadrangular process which caps the upper and outer part of the shaft, and overhangs the root of the neck above and behind. Its *outer surface*, of rounded irregular form, slopes upwards

and inwards, and is separated from the external surface of the shaft below by a more or less horizontal ridge. Crossing it obliquely from the posterior superior to the anterior inferior angle is a rough line which serves for the insertion of the gluteus medius muscle; above and below this the surface of the bone is smoother and is overlain by bursæ. The *anterior surface*, somewhat oblong in shape, and inclined obliquely from below upwards and inwards, is elevated from the general aspect of the shaft below, from which it is separated in front by an oblique line leading upwards and inwards to the tubercle at the upper end of the superior part of the spiral line. This surface serves for the insertion of the gluteus minimus. The *superior border* is curved and elevated; into it are inserted the tendons of the obturator internus and gemelli muscles within and in front, and the pyriformis muscle above and behind. The *posterior border* is thick and rounded, and forms the upper part of the posterior intertrochanteric ridge. The angle formed by the superior and posterior borders is sharp and pointed, and forms the tip of the trochanter overhanging the digital fossa, which lies immediately below and within its inner surface.

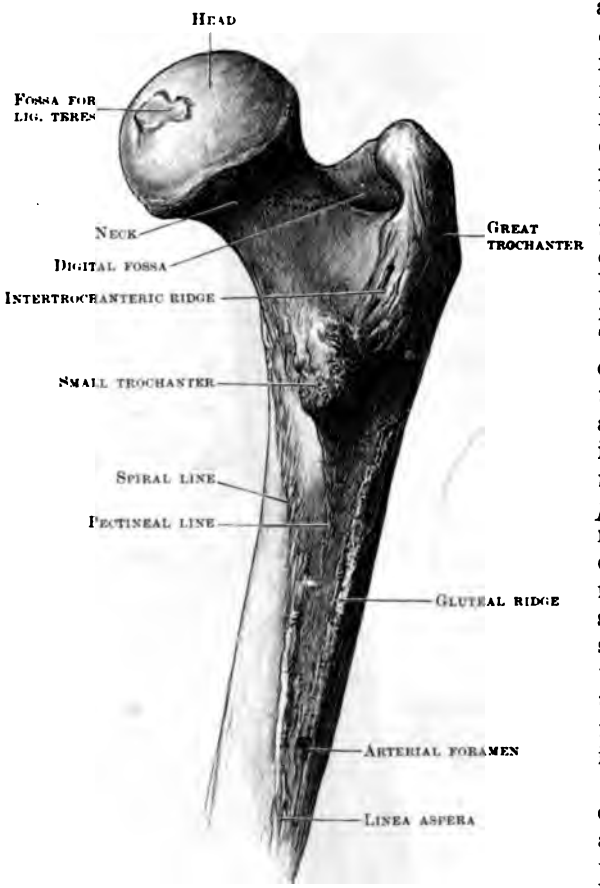

Fig. 170.—Back View of Upper End of Right Femur.

The **trochanter minor** is an elevated pyramidal process situated at the back of the inner and upper part of the shaft where that becomes continuous with the lower and posterior part of the neck. Confluent above with the posterior intertrochanteric ridge, it gradually fades away into the back of the shaft below. The combined tendon of the ilio-psoas is inserted into this process and the bone immediately below it.

The **shaft** (corpus femoris), which is characterised by its great length, is cylindrical in form. As viewed from the front, it is straight or but slightly curved; as seen in profile, it is bent forwards, the curve being most pronounced in its upper part. The shaft is thinnest at some little distance above its middle; below this it gradually increases in width to support the condyles inferiorly; its antero-posterior diameter, however, is not much increased below. Its surfaces are generally smooth and rounded, except behind, where, running longitudinally down the centre of its curved posterior aspect, there is a rough-lipped ridge, the **linea aspera** (linea aspera). Most salient towards the middle of the shaft, the linea aspera consists of an inner lip (labium mediale) and an outer lip (labium laterale), with a narrow intervening rough surface. Above, about 2 to 2½ inches from the trochanter minor, the linea aspera is formed by the convergence of three lines. Of these the outer is a rough, somewhat elevated, ridge, which commences above, on the back of the shaft, external to and on a level with the trochanter minor, and becomes continuous below with the outer lip of the linea aspera. This serves for the bony insertion of the gluteus maximus, and is occasionally developed into an outstanding process called the **trochanter tertius**. Internally the inner lip of the linea aspera is confluent above with a line which winds round the shaft upwards and forwards in front of the

chanter minor to become continuous with the rough ridge which serves to define
e neck from the shaft anteriorly (see *ante*). The whole constitutes what is known
the **spiral line**, and extends from the fore and upper part of the trochanter major
ove to the linea aspera below. Intermediate in position between the spiral line
front and internally, and the gluteal ridge externally, there is a third line,
e **pectineal line** (linea pectinea), which passes down from the trochanter minor
d fades away inferiorly into the surface between the two lips of the linea aspera.
to this the pectineus muscle is inserted. About the junction of the middle with
e lower third of the shaft the two lips of the linea aspera separate from one
other, each passing in the direction of the condyle of the corresponding side.
ie lines so formed are called the inner and outer epicondylic lines respectively, and
close between them a smooth triangular area corresponding to the back of the
ver third of the shaft; this, called the **popliteal surface** (planum popliteum), forms
e floor of the upper part of the popliteal space. The continuity of the upper part
the internal epicondylic line is but faintly marked, being interrupted by a wide
d faint groove along which the popliteal artery passes to enter the space of that
me. Below, where the line ends on the upper and inner surface of the internal
ndyle, there is a little spur of bone called the **adductor tubercle**, to which the
ndon of the adductor magnus is attached, and behind which the inner head of
e gastrocnemius muscle takes origin.

The **linea aspera** affords extensive linear attachments to many of the muscles of the thigh.
ie vastus internus arises from the spiral line above and the inner lip of the linea aspera below.
he adductor longus is inserted into the inner lip about the middle third of the length of the shaft.
he adductor magnus is inserted into the intermediate part of the line, extending as high as the
vel of the trochanter minor, where it lies internal to the insertion of the gluteus maximus.
elow, its insertion passes on the internal epicondylic ridge, reaching as low as the adductor
ubercle. The adductor brevis muscle is inserted into the linea aspera above, between the pec-
neus and adductor longus muscles internally and the adductor magnus externally. Below the
sertion of the gluteus maximus the short head of the biceps arises from the outer lip as well as
om the external epicondylic line; in front these also serve for the origin of the vastus externus
uscle.

The canals for the nutrient arteries of the shaft, which have an upward direction, are usually
o in number, and are placed on or near the linea aspera—the upper one about the level of the
nction of the middle and upper third of the bone, the lower some three or four inches below—
ually on the inner side of the shaft, immediately in front of the inner lip of the linea aspera.

The front and lateral aspects of the shaft are covered by, and furnish surfaces
, the origins of the vasti and crureus muscles.

The **lower extremity** of the femur comprises the two **condyles**. These are two
urved processes of bone, each provided with an articular surface, and separated
ind by a deep **intercondylic notch**. United in front, where their combined
icular surfaces form an area on which the patella rests, the two condyles differ
m each other in the following respects: If the shaft of the bone be held vertically,
internal condyle is seen to reach a lower level than the **external**; but, as the
nur lies obliquely in the thigh, the condyles are so placed that their inferior sur-
es lie in the same horizontal plane. Viewed from below, the internal condyle is
n to be the narrower and shorter of the two. The external condyle is broader,
l advances farther forward and higher up on the anterior surface of the shaft.
e **intercondylic notch** (fossa intercondyloidea) reaches forwards as far as a trans-
se line drawn through the centre of the external condyle. Its sides are formed
the inner and outer surfaces of the outer and inner condyles respectively, the
er being more deeply excavated, and displaying an oval surface near its lower
l anterior part for the attachment of the posterior crucial ligament of the knee-
nt. Placed high up, on the posterior part of the inner surface of the external
dyle, there is a corresponding surface for the attachment of the anterior crucial
ament. The floor of the notch, which is pierced by numerous vascular canals,
pes upwards and backwards towards the popliteal surface on the back of the
ft, from which it is separated by a slight ridge (linea intercondyloidea) to which
posterior part of the capsule of the knee-joint is attached.

The cutaneous aspect of each condyle (*i.e.* the outer surface of the external
ndyle and the inner surface of *the internal condyle*) presents an elevated rough

surface, called the **tuberosity** (epicondylus), that of the **internal** (epicondylus medialis) being the more pronounced and outstanding from the line of the shaft; capped above by the adductor tubercle, it affords attachment near its most prominent point to the fibres of the internal lateral ligament of the knee-joint. The **external tuberosity** (epicondylus lateralis), less pronounced and lying more in line with the outer surface of the shaft, is channelled behind by a curved groove, the lower rounded lip of which serves to separate it from the inferior articular surface. This groove ends in front in a pit which is placed just below the most salient point of the tuberosity; hereto is attached the tendon of the popliteus muscle, which overlies the lower lip of the groove in the extended position of the joint, but slips into and occupies the groove when the joint is flexed. Behind the most prominent part of the external tuberosity, and just above the pit for the attachment of the popliteus, the external lateral ligament of the knee-joint is attached, whilst superior to that there is a circumscribed area for the origin of the tendinous part of the outer head of the gastrocnemius muscle.

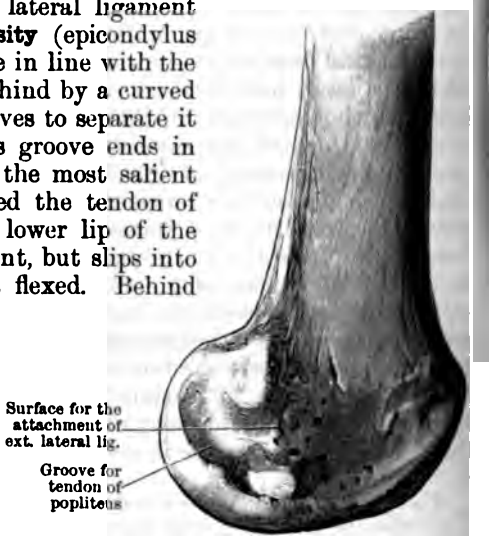

FIG. 171.—LOWER END OF RIGHT FEMUR (Outer Side).

The **articular surface** on the lower extremity is divisible into three parts—that which corresponds to the inferior surface of the shaft and which is formed by the coalescence of the two condyles in front, and those which overlie the under and hinder aspects of each of those processes. The former is separated from the latter by two shallow oblique grooves which traverse the articular surface from before backwards, on either side, in the direction of the anterior part of the intercondylic notch. These furrows are the impressions in which fit the fore-parts of the internal and external semilunar cartilages of the knee-joint respectively, when the knee-joint is extended. The anterior articular area or **trochlea** (facies patellaris) is adapted for articulation with the patella. Convex from above downwards, it displays a broad and shallow central groove, bounded on either side by two slightly convex surfaces. Of the two sides, the external is the wider and more prominent, and rises on the front of the bone to a higher level than the internal. The **condyloid or tibial surfaces** are convex from side to side, and convex from before backwards. Sweeping round the under surface and posterior extremities of the condyles, they describe a spiral curve more open in front than behind. The inner condyloid articular surface is narrower than the outer, and when viewed from below is also seen to describe a curve around a vertical axis. The articular surface of the external condyle is inclined obliquely from before backwards and slightly outwards. The surfaces of the condyles above the articular area posteriorly are confluent superiorly with the popliteal surface of the shaft; from these areas the heads of the gastrocnemius muscles arise. The bone from which the inner head of the muscle springs is often elevated in the form of a tubercle placed on the lower part of the popliteal surface of the shaft, just above the internal condyle. The proportionate length of the femur to the body height is as 1 is to 3·53–3·92.

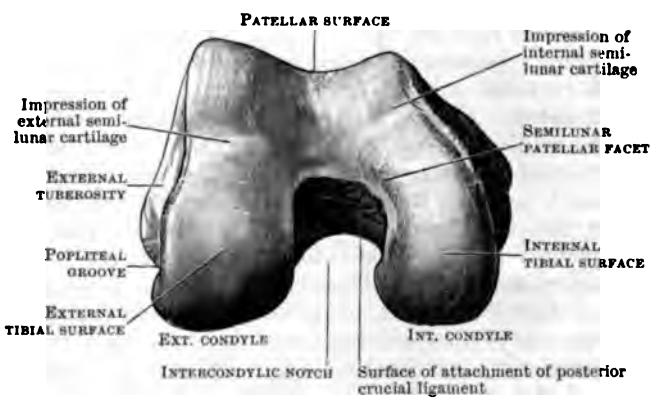

FIG. 172.—LOWER END OF RIGHT FEMUR AS SEEN FROM BELOW.

Arterial Foramina.—Numerous vascular canals are seen in the region of the neck, at the bottom of the digital fossa, on the posterior intercondylic ridge and on the external surface of the great trochanter. The nutrient arteries for the shaft pierce the bone on or near the linea aspera. Both back and front of the lower end of the shaft display the openings of numerous vascular canals, and the floor of the intercondylic notch is also similarly pierced.

Connexions.—The femur articulates with the os innominatum above and the tibia and patella below. The external surface of the great trochanter determines the point of greatest hip width in the male, being covered only by the skin and superficial fascia and the aponeurotic insertion of the gluteus maximus. In the erect position the tip of the trochanter corresponds to the level of the centre of the hip-joint. When the thigh is flexed the trochanter major sinks under cover of the anterior fibres of the gluteus maximus. In women the hip width is usually greatest at some little distance below the trochanter, due to the accumulation of fat in this region. The shaft of the bone is surrounded on all sides by muscles. Its forward curve, however, is accountable to some extent for the fulness of the front of the thigh. The exposed surfaces of the condyles determine to a large extent the form of the knee. In flexion the articular edges can easily be recognised on either side of and below the patella.

Architecture.—The shaft has a medullary cavity which reaches as high as the root of the small trochanter. Inferiorly it extends to within 3½ inches of the lower articular surface. In the upper half the outer compact wall is very thick, but below the middle of the shaft it gradually thins until it reaches the condyles inferiorly, over which it passes as a thin, hardly definable external layer. Above, it is especially thick along the line of the linea aspera, and here the large nutrient canal may be seen passing obliquely upwards in the substance of the dense bone for the space of two inches. In the upper end of the shaft the osseous lamellæ springing from the sides of the medullary cavity arch inwards towards the centre, intersecting each other in a manner comparable to the tracery of a Gothic window. The lower wall of the neck is thick below, near the trochanter minor, but thins rapidly before it reaches the head. From this aspect of the neck there spring a series of oblique lamellæ which pass upwards and inwards, spreading in fan-shaped manner into the under surface of the head. These are intersected above by lamellæ which arch inwards from the outer side of the shaft below the great trochanter, as well as from the under surface of the thin but compact outer shell of the upper surface of the neck, the whole forming a bracket-like arrangement which assists materially in adding to the strength of the neck. Further support is given by the addition of a spur of dense bone which springs from the inner surface of the under side of the neck, just in front of and above the trochanter minor: this is called the **calcar femorale**. From it stout lamellæ having a vertical direction arise. The spongy tissue of the head and great trochanter is finely reticulated, that of the lower part of the neck and upper part of the shaft being more open in its texture. Passing vertically downwards through this tissue there is a vascular canal, the orifice of which opens externally on the floor of the digital fossa.

The spongy tissue of the lower part of the shaft is more delicate and uniform in its arrangement, displaying a more or less parallel striation in a longitudinal direction. Subjacent to the articular surface the tissue is rendered more compact by the addition of lamellæ disposed in curves in harmony with the external aspect of the bone.

Variations.—Absence of the pit on the head of the femur for the attachment of the ligamentum teres has been recorded. This corresponds with the condition met with in the orang. Not infrequently there is an extension of the articular surface of the head on to the fore and upper aspect of the neck; this is a "pressure facet" caused by the contact of the iliac portion of the acetabular margin with the neck of the bone, when the limb is maintained for long periods in the flexed position, as in tailors, and also in those races who habitually squat (Lane, *Journ. Anat. and Physiol.*, vol. xxii. p. 606).

The occurrence of a trochanter tertius has been already referred to. Its presence is not confined to individuals of powerful physique, but may occur in those of slender build, so far suggesting that it is not to be regarded merely as an indication of excessive muscular development. The observations of Dixon (*Journ. Anat. and Physiol.*, vol. xxx. p. 502), who noted the occurrence of a separate epiphysis in three cases in connexion with it, seem to point to its possessing some morphological significance.

Occasionally the gluteal ridge may be replaced by a hollow, the fossa hypotrochanterica, or in some cases the two may co-exist.

The angle of the neck is more open in the child than in the adult, and tends to be less when the femoral length is short and the pelvic width great—conditions which particularly appertain to the female. There is no evidence to show that after growth is completed any alteration takes place in the angle with advancing years (Humphry).

The curvature of the shaft may undergo considerable variations, and the appearance of the posterior surface of the bone may be modified by an absence of the linea aspera, a condition resembling that seen in apes; or by an unusual elevation of the bone which supports the ridge (*femur à pilastre*), produced, as Manouvrier has suggested, by the excessive development of the muscles here attached.

Under the term "*platymeria*," Manouvrier describes an antero-posterior compression of the upper part of the shaft, frequently met with in the femora of prehistoric races.

Ossification.—The shaft begins to ossify early in the second month of fœtal life, and at birth displays enlargements at both ends, which are capped with cartilage. If the inferior cartilaginous end be sliced away, a small ossific nucleus for the inferior epiphysis will usually be seen. This, as a rule, makes its appearance towards the latter end of the ninth month

of fœtal life, and is at service from a medico-legal standpoint in determining the ag fœtus. According to Hartman, it is absent in about 12 per cent of children at ter may appear as early as the eighth month of fœtal life in about 7 per cent. The s extremity, entirely

laginous at birth, co the head, neck, an chanter major. A appears for the head the early part of th year. That for th chanter major beg ossify about the sec third year, whilst th is developed as an extension of the shaft, is, however, not confi the neck alone, but for lower circumference articular head, as n seen in bones up to t of twelve or sixteen that, the separate ep of the head begins t lap it so as to cover tirely when fusion i plete at the age of ei or twenty.

The epiphysis of th trochanter unites wi shaft and neck abou teen or nineteen, whi epiphysis for the trochanter minor, which usually makes its appearance about the or thirteenth year, is usually completely fused with the shaft about the age of ei The epiphysis for the lower end, although the first to ossify, is not completely un the shaft until from about the twentieth to the twenty-second year. It is worthy that the line of fusion of the shaft and inferior epiphysis passes through the ac tubercle, a point which can easily be determined in the living.

THE PATELLA.

The **patella**, the largest of the sesamoid bones, overlies the front of the joint in the tendon of the quadriceps extensor. Of compressed form and son triangular shape, its lower angle projects downwards and forms a peak, called the **apex** (apex patellæ), whilst its upper edge, or **base** (basis patellæ), broad, thick, and sloping forwards and a little downwards, is divided into two areas by a transverse line or groove; the anterior area so defined serves for the attachment of the common tendon of the quadriceps extensor muscle, whilst the posterior, of compressed triangular sh covered by synovial membrane. The *inner* and *outer borders*, of curved c receive the insertions of the vastus internus and externus muscles respective

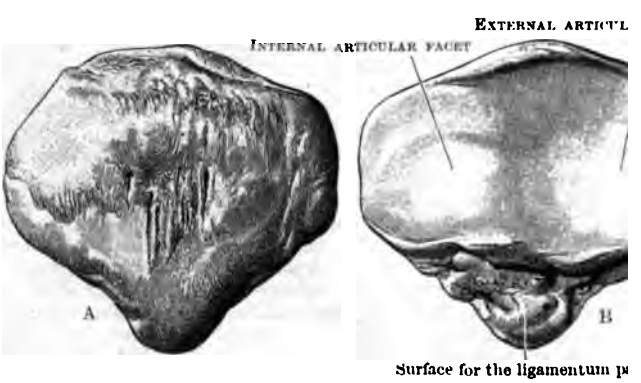

FIG. 174.—RIGHT PATELLA.

A. Anterior surface. B. Posterior surfac

attachment of the vastus internus being more extensive than that of the vastus externus. The *anterior surface* of the bone, slightly convex in both diameters, has a fibrous appearance, due to its longitudinal striation, and is pierced here and there by the openings of vascular canals. The *posterior* or *femoral articular surface* is divided into two unequal parts (of which the external is the wider) by a vertical elevation which glides in the furrow of the trochlear surface of the femur, and in extreme flexion passes to occupy the intercondylic notch. The outer of the two femoral surfaces is slightly concave in both its diameters; the inner, though slightly concave from above downwards, is usually plane, or somewhat convex transversely. Occasionally, in the macerated bone, indications of a third vertical area are to be noted along the inner edge of the internal aspect. This defines the part of the articular surface which rests on the border of the internal condyle in extreme flexion.

Below the femoral articular area the deep surface of the apex is rough and irregular; the greater part of this is covered by synovial membrane, the ligamentum patellæ being attached to its summit and margins, reaching some little distance round the borders on to the anterior aspect of this part of the bone.

Architecture.—The bone consists of a thick dense layer anteriorly, which thins towards the edges on either side and below; above, it corresponds to the area of insertion of the quadriceps. The femoral articular surface is composed of a layer of compact bone, thickest in correspondence with the vertical elevation. Sandwiched between these two layers is a varying thickness of spongy tissue of fairly close grain, the striation of which on cross section runs in parallel lines from back to front; on vertical section the tissue appears to be arranged in lines passing radially from the deep surface of the femoral area to the more extensive anterior dense plate.

Variations.—Cases of congenital absence of the patella have been recorded.

F. C. Kempson (*Journ. Anat. and Physiol.*, vol. xxxvi.) has recently drawn attention to the condition described as emargination of the patella. In specimens displaying this appearance the margin of the bones is concave from a point about half an inch to the outer side of the middle line, to a point half-way down the outer margin of the bone, here there is usually a pointed spine directed upwards and outwards. The condition appears to be associated with the insertion of the tendon of the vastus externus. G. Joachimstal (*Archiv u. Atlas der normalen und pathologischen Anatomie in typischen Röntgenbildern*, Bd. 8) figures a case in which on both sides the patella was double in an adult, the lower and much the smaller portion was embedded in the ligamentum patellæ.

Ossification.—The patella is laid down in cartilage about the third month of fœtal life. At birth it is cartilaginous, and the tendon of the quadriceps is continuous with the ligamentum patellæ over its anterior surface, and can easily be dissected off. About the third year an ossific centre appears in it and spreads more particularly over its deeper surface. Ossification is usually completed by the age of puberty.

THE TIBIA

The **tibia** is the inner bone of the leg. It is much stouter and stronger than its neighbour the fibula, with which it is united above and below. By its superior expanded extremity it supports the condyles of the femur, while inferiorly it shares in the formation of the ankle-joint, articulating with the upper surface and inner side of the astragalus.

FIG. 175.—UPPER SURFACE OF SUPERIOR EXTREMITY OF RIGHT TIBIA.

The **superior extremity** comprises the **inner** and **outer tuberosities**, the **spine**, and the **tubercle**. Each tuberosity is provided on its upper aspect with an articular surface (facies articularis superior), which supports the corresponding femoral condyle, as well as the

interposed semilunar cartilage. Of these two condylic surfaces the is the larger; of oval shape, its long axis is placed antero-posteriorly. Sli

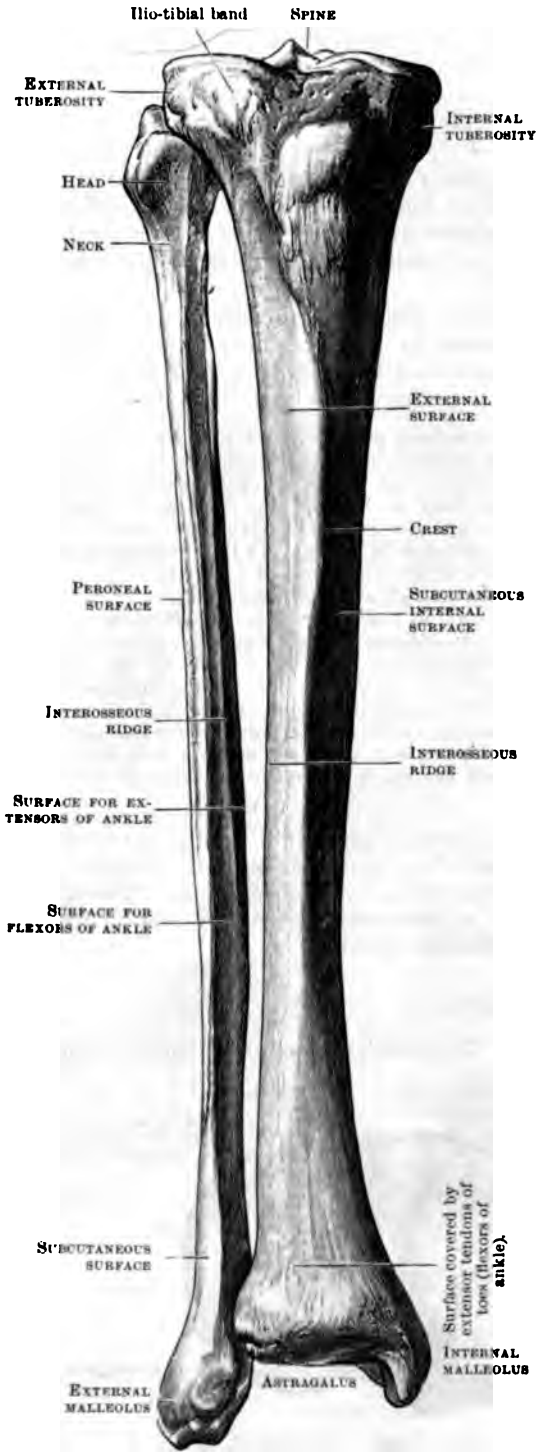

FIG. 176.—RIGHT TIBIA AND FIBULA AS SEEN FROM THE FRONT.

concave from before backward from side to side, its circumfe rises in the form of a sharp well-defined edge. The **outer cor surface** is smaller and rou Slightly concave from side to and gently convex from before wards, its circumference is wel fined in front, but is rounde behind, thus markedly incre the convexity of its posterior Between the two condylic sur the bone is raised in the cent form the **spine** (eminentia inte dyloidea), the summit of whi grooved and capped on either by **tubercles** which spring from are formed by the upward exte of the neighbouring condylic Of these tubercles the *inner* (t culum intercondyloideum me is the higher, and longer i antero-posterior direction, the (tuberculum intercondy eum laterale) being more po and not so elevated. In front behind the spine the articular are separated by two irre V-shaped surfaces, the **intercon fossæ**. The **anterior fossa** (fossa i condyloidea anterior), the large wider, furnishes areas for the at ment of the semilunar cartilag either side, and for the ant crucial ligament immediately in of the spine. The floor of this is pierced by many nutrient fora The **posterior intercondylic** (fossa intercondyloidea posteri concave from side to side, and s downwards and backwards. external semilunar cartilage i tached near its apex to a su which rises on to the back o spine; the internal semilunar lage is fixed to a groove which along its inner edge, and the terior crucial ligament derive attachment from the smooth post rounded surface.

The **external tuberosity** (con lateralis) is the smaller of the It overhangs the shaft to a gr extent than the internal, th this is obscured in the living articulation with the fibula. The facet for the fibula, often small and indis is placed postero-externally on the under surface of its most projecting

ıtero-externally the imprint caused by the attachment of the ilio-tibial band often quite distinct. The circumference of the **internal tuberosity** (condylus ɛdialis) is grooved postero-internally for the insertion of the tendon of the semi-ɛmbranosus.

In front of the tuberosities, and about an inch below the level of the condylic sur-ɛes, there is an oval elevation called the **tubercle of the tibia**, or the **anterior tuberosity** ıberositas tibiæ). The upper half of this is smooth and covered by a bursa, while ɛ lower part is rough and serves for the attachment of the ligamentum patellæ.

Considered in its entirety, the upper extremity of the tibia is broader trans-ɪrsely than antero-posteriorly, and is inclined backwards so as to overhang the aft posteriorly.

The **shaft** (corpus tibiæ) is irregularly three-sided. It is narrowest about the nction of its middle and lower thirds, and expands above and below to support ɛ extremities. Running down the front of the bone there is a gently-curved, ominent margin confluent above with the tubercle, but fading away inferiorly on ıe anterior surface of the lower third of the bone, where it may be traced in the rection of the anterior border of the internal malleolus. This is the **crest** or **shin** rista anterior), which is subcutaneous throughout its entire length. To the ıner side of this is a smooth, slightly convex surface, which reaches as high as the ıternal tuberosity above, and inferiorly becomes continuous with the inner surface f the internal malleolus. This is the *internal* or *subcutaneous surface* (facies ıedialis) of the shaft, which is covered only by skin and superficial fascia, except n its upper fourth, where the tendons of the sartorius, gracilis, and semitendinosus muscles overlie it, as they pass towards their insertions. This surface is limited posteriorly by the **internal border** (margo medialis) which passes from the inner and under surface of the internal tuberosity above to the hinder border of the internal malleolus below. This border is rounded and indefinite above and below, being usually best marked about its middle third. To the outer side of the tibial crest is the *external surface* of the bone (facies lateralis); it is limited behind by a straight vertical ridge, the **crista interossea**, to which the interosseous membrane, which occupies the interval between the tibia and the fibula, is attached. This ridge commences above, near the middle of the outer and under surface of the external tuberosity, and terminates below about two inches above the lower extremity by dividing into two lines, which separate and enclose between them the surface for articulation with the lower end of the fibula, and the area of attachment of the inferior interosseous ligament, which here unites the two bones. In its upper two-thirds the external surface provides an extensive origin for the tibialis anticus. Inferiorly, where the tibial crest is no longer well defined, the external surface turns forward on to the front of the shaft, and is limited inferiorly by the anterior margin of the inferior ırticular surface. Over this the tendon of the tibialis anticus, and the combined fleshy and tendinous parts of the extensor proprius hallucis and extensor communis digitorum muscles pass obliquely downwards. The *posterior surface* (facies ɔosterior) of the shaft lies between the interosseous ridge externally and the in-ɛrnal border on the inner side. Its contours are liable to considerable variation ıccording to the degree of lateral compression of the bone. It is usually full and ɔounded above, and flat below. Superiorly it is crossed by the **oblique** or **popliteal** ine (linea poplitea), which runs downwards and inwards, from the fibular facet ıbove, to the internal border on a level with the junction of the middle with the ıpper third of the shaft. To this line, as well as to the internal border for some listance below it, the soleus muscle is attached. Into the bulk of the triangular ırea above it the popliteus muscle is inserted. Arising from the middle of the ɔopliteal line there is a vertical ridge, which passes downwards and divides the ɔosterior aspect of the shaft into two surfaces—an external for the tibial origin of he tibialis posticus muscle, and an internal for the flexor longus digitorum muscle. The inferior third of this surface of the shaft is free from muscular attachments, ɔut is overlain by the tendons of the above muscles, together with that of the flexor ongus hallucis. A large nutrient canal, having a downward direction, opens on the ɔosterior surface of the shaft a little below the popliteal line and just external to he vertical ridge which springs from it.

The **inferior extremity** of the tibia displays an expanded quadrangular form. It is furnished with a saddle-shaped articular surface on its under surface (facies articularis inferior), which is concave from before backwards and slightly convex from side to side. This rests upon the superior articular surface of the body of the astragalus, and is bounded in front and behind by well-defined borders. The anterior border is the rounder and thicker, and is oftentimes channelled by a groove for the attachment of the anterior ligament of the joint; further, it is occasionally provided with a pressure facet caused by the locking of the bone against the neck of the astragalus in extreme flexion. Externally the edge of the articular area corresponds to the base of the triangle formed by the splitting of the interosseous ridge into two parts. Where these two lines join it, both in front and behind, the bone is elevated into the form of tubercles, in the hollow between which (incisura fibularis) the lower end of the fibula is lodged, being held in position by powerful ligaments. The cartilage-covered surface occasionally extends for some little distance above the base of the triangle. Internally there is a down-projecting process, called the **internal malleolus** (malleolus medialis), the inner aspect of which is subcutaneous and forms the projection of the inner ankle. Its external surface is furnished with a pyriform facet (facies articularis malleolaris), confluent above with the cartilage-covered area on the inferior extremity of the shaft; this articulates with a corresponding area on the inner surface of the body of the astragalus. Inferiorly the malleolus is pointed in front, but notched behind for the attachment of the internal lateral ligament of the ankle. Running obliquely along the posterior surface of the malleolus there is a broad groove (sulcus malleolaris) in which the tendons of the tibialis posticus and flexor longus digitorum muscles are lodged; whilst a little to the fibular side of this, and running downwards over the posterior surface of the lower extremity of the bone, there is another groove, often faintly marked, for the lodgment of the tendon of the flexor longus hallucis muscle. The proportionate length of the tibia to the body height is as 1 is to 4·32–4·80.

Arterial Foramina.—Nutrient canals are seen piercing the upper extremity of the bone around its circumference and above the tubercle. The floors of the intercondylic fossæ are also similarly pierced, and there is usually a canal of large size opening on the summit of the spine. Two or three foramina of fair size are seen running upwards into the substance of the bone a little below and to the inner side of the tubercle, while the principal vessel for the shaft passes downwards into the bone on its posterior surface, about the level of the junction of the upper and middle thirds. The inner surface of the internal malleolus, as well as the anterior and posterior borders of the inferior extremity, are likewise pitted by the orifices of small vascular channels.

Connexions.—Superiorly the tibia supports the condyles of the femur, and is connected in front with the patella by means of the patellar ligament. Articulating externally with the fibula above and below, it is united to that bone throughout nearly its entire length by the interosseous membrane. The crest and internal surface can be readily examined, as they are subcutaneous, except above where the internal surface is overlain by the thin tendinous aponeurosis of the muscles passing over the inner side of the knee. The form of the lower part of the knee in front is determined by the tuberosities on either side crossed mesially by the ligamentum patellæ. Inferiorly the internal malleolus forms the projection of the inner ankle, which is wider, not so low, less pointed, and placed in advance of the projection of the outer ankle. The front and back of the lower end of the bone are crossed by tendons, which mask to a certain extent its form.

Architecture.—The shaft of the bone is remarkable for the thickness and density of the osseous tissue which underlies the crest. The posterior wall is stout, but the internal and external walls are thinner. The several walls are thickest opposite the middle of the shaft, and thin out above and below where the shaft unites with the epiphyses. The medullary canal, narrow and circular in the middle of the bone, increases in all its diameters above and below, and reaches to within 2½ to 3 inches of either extremity. Superiorly the arrangement of the lamellæ of the spongy tissue resembles a series of arches springing from the dense outer walls. These form a platform on which the superior epiphysis rests, the spongy tissue of which displays a more or less vertical striation. This is much more compact under the condylic surfaces, the superficial aspect of which is formed by a thin layer of dense bone. The spine and tubercle are also formed of compact tissue, whilst the circumference of the tuberosities is covered by a thinner and less dense wall. In the lower end of the shaft the spongy tissue, of a loose and cellular character, is arranged in vertical fibres, blending inferiorly with the closer tissue of the inferior epiphysis, the articular surface of which is covered by a thin but dense layer.

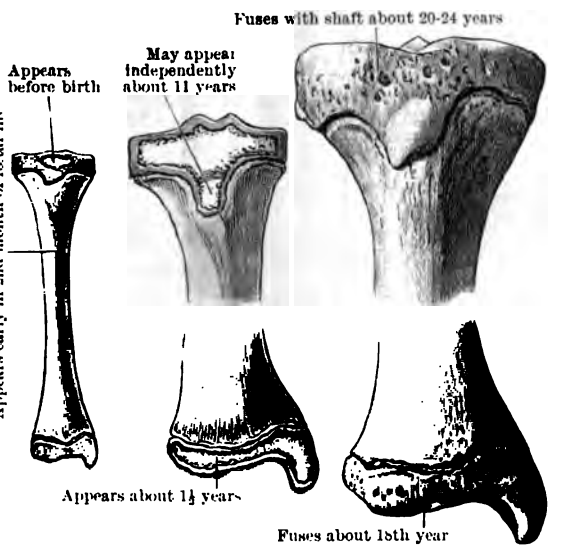
In the adult bone the nutrient canal for the shaft is embedded in the dense posterior wall for the space of two inches.

Variations.—The tibia is often unduly laterally compressed, leading to an increase in its

ero-posterior diameter as compared with its transverse width. This condition is more monly met with in the bones of prehistoric and savage races than in modern Europeans. tention was first directed to this particular form by Busk, who named the condition **tycnemia.** The general appearance of such tibiæ resembles that seen in the apes, and ends on an exceptional development of the tibialis posticus muscle, though, as Manouvrier s pointed out, in apes this is associated with the direct action of the muscle on the foot, as in ubing, whereas in man, as a consequence of the bipedal mode of progression, the muscle is ployed in an inverse sense, viz. by steadying the tibia on the foot, and thus providing a fixed e on which the femur can move. Such platycnemic tibiæ are occasionally met with in the re highly civilised races, and are, according to Manouvrier, associated with habits of great tivity among the inhabitants of rough and mountainous districts.

Another interesting condition is one in which the upper extremity is more strongly recurved an is usual. This retroversion of the head of the tibia was at one time supposed to represent intermediate condition in which the knee could not be fully extended so as to bring the axis the leg in line with the thigh; but such opinion has now been upset by the researches of lanouvrier, who claims that it is the outcome of a habit not uncommon amongst peasants and ountrymen, viz. that of walking habitually with the knees slightly bent.

Habitual posture also leaves its impress on the form of the tibia, and in races in which the e of the chair is unknown, the extreme degree of flexion of the knee and ankle necessitated by he adoption of the squatting position as an attitude of habitual rest is associated with an increase n the convexity of the external condylic surface, and the appearance, not infrequently, of a ressure facet on the anterior border of the lower extremity, which rests in that position on the eck of the astragalus. Cases of congenital absence of the tibia have been requently described, amongst the most recent being those recorded by Clutton, Joachimsthal, Bland Sutton, and Waitz.



Fuses with shaft about 20-24 years
Appears before birth
May appear independently about 11 years
Appears early in 2nd month of fœtal life
Appears about 1½ years
Fuses about 15th year
At birth.
About 12 years.
About 16 years.

FIG. 177.—OSSIFICATION OF THE TIBIA.

Ossification.—The shaft begins to ossify early in the second month of intrauterine life. At birth it is well formed, and capped above and below by pieces of cartilage, in the upper of which the centre for the superior epiphysis has already usually made its appearance. From this the tuberosities and tubercle are developed, though sometimes an independent centre for the latter appears about the eleventh or twelfth years, rapidly joining with the already well-developed mass of the rest of the epiphysis. Complete fusion between the superior epiphysis and the shaft does not take place until the twentieth or the twenty-fourth year. The centre for the lower articular surface and the internal malleolus makes its appearance about the end of the second year, and union with the shaft is usually complete by the age of eighteen. Lambertz notes the occasional presence of an accessory nucleus in the malleolus.

THE FIBULA.

The **fibula, or peroneal bone,** is a slender bone with two enlarged ends. It lies on the outer side of the tibia, with which it is firmly united by ligaments, and nearly equals that bone in length.

The first difficulty which the student has to overcome is to determine which is the upper and which the lower extremity of the bone. This can easily be done by recognising the fact that there is a deep pit on the inner aspect of the lower extremity immediately behind the triangular articular surface. Holding the bone vertically with the lower extremity downwards and so turned that the triangular articular area lies in front of the notch already spoken of, the subcutaneous non-articular aspect of the inferior extremity will point to the side to which the bone belongs.

The **superior extremity or head** of the fibula (capitulum fibulæ), of irregular rounded form, is bevelled on its inner surface so as to adapt it to the form of the under surface of the external tuberosity of the tibia. At the border, where this

surface becomes confluent with the outer aspect of the head, there is a p

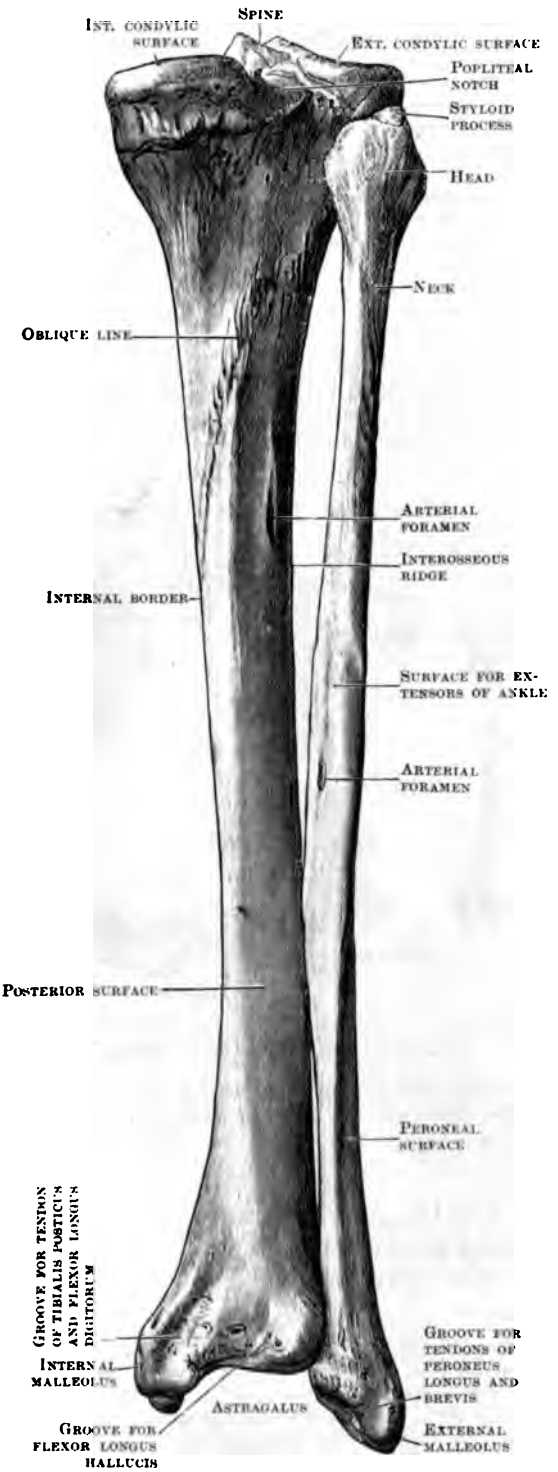


FIG. 178.—RIGHT TIBIA AND FIBULA AS SEEN FROM BEHIND.

upstanding eminence calle **styloid process** (apex c fibulæ); to this the short ex lateral ligament is attach well as a piece of the tendon biceps, which is inserted in fore-part. Immediately t inner side of this, and occu the summit of the internal s surface, there is an **articula** (facies articularis capituli), o able size and more or less tria shape. This serves for articu with the external tuberosity tibia. The long external l ligament, together with th mainder of the tendon of the muscle which surrounds it, tached to the outer and upp of the head in front of the s process. In front and behi head there are usually pron tubercles. The anterior of is associated with the ori the peroneus longus muscle posterior, whilst furnishin origin for the upper fibres soleus, serves to deepen the g behind the superior tibio-f articulation, in which the t and fleshy part of the po muscle play. The constricte tion of the shaft below the is often referred to as the around the outer side of th external popliteal nerve win

The **shaft** of the fibula (c fibulæ) presents many varie shape and form, being ridge channelled in such a way as g to increase the difficulties student in recognising the v surfaces described. The mo portant point is first to dete the position of the intero ridge. Holding the bone i position which it normally oc in the leg, it will be noticed the external surface of the extremity is limited in fron behind by two lines, which verging above, enclose be them a triangular subcuta area which lies immediately the outer ankle. From the su of the triangle so formed a defined ridge may be traced up the front of the shaft to reach the anterior of the head. This is the *anterior border*, and must not be mistaken for the

dge, which is now easy to find, for the next ridge which lies immediately to the anterior border, or towards the tibial side nterior aspect of the bone, is the line to which osseous membrane is attached. As a rule these are separated by a considerable interval in the lf of the bone, but tend to run much closer above; indeed it is not uncommon to find that esce to form a single crest. Let it therefore be t the interosseous line is that which lies im- r internal to the ridge which springs inferiorly malleolar subcutaneous triangular surface, not- ding the differences in width of the surface which the lines, or their occasional coalescence above. position of the interosseous ridge enables us at separate the flexor aspect of the bone from its surface, using these terms in relation to the nts of the ankle.

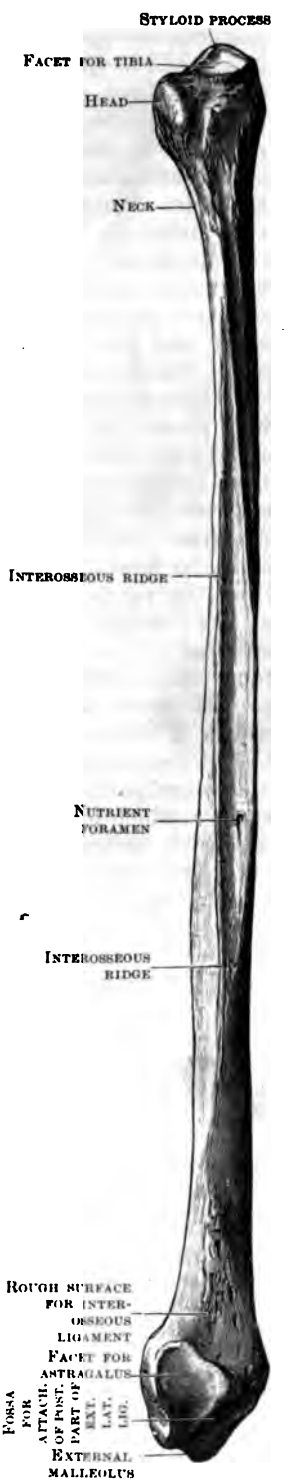

FIG. 179.—RIGHT FIBULA AS SEEN FROM THE INNER SIDE.

e of these terms is not, strictly speaking, correct, and ere used in a physiological and not in a morphological e anterior surface of the leg is the true extensor surface, nparable with the posterior surface of the forearm, the position having been brought about developmentally by in the rotation of the limbs. Flexion of the ankle, so in reality an extensor movement, and corresponds to at the wrist. (See Humphry, *Journ. Anat. and Physiol.*, . p. 15.)

ddition, there is the peroneal surface, which nds to the outer side of the shaft. Starting then nterosseous ridge, and passing forwards round r side of the shaft, the **flexor surface** is the first n; this is bounded externally by the anterior nd, as has been said, may be either of considerable : almost linear. From this arises the extensor is digitorum, together with the peroneus tertius extensor proprius hallucis muscles, which, though s of the toes, are also *flexors* of the ankle.

anterior border serves for the attachment of the scular septum, which separates the foregoing muscles from that which lies along the outer the shaft, viz. the peroneus longus and brevis

The surface from which these arise is limited by the *posterior border*, which is usually sharp defined below, where it is continuous with the mediately above the pit on the inner surface of r extremity, whilst it tends to be less distinct e rounded above where it runs into the base of oid process. In its upper third or fourth this s often rough and tubercular where it serves for in of the soleus. The **outer** or **peroneal surface** what twisted, being directed rather forwards ut tending to turn backwards below where it continuous with the groove which courses along of the external malleolus and which lodges the of the peroneus longus and brevis muscles. The er of the shaft, included between the posterior ehind and the interosseous ridge in front and ly, is the **extensor surface**, for here arise the muscles whose action in part is to extend the ankle. This surface is by a curved ridge often the *most prominent* and outstanding on the bone,

and hence frequently mistaken by the student for the interosseous ridge; it serve to define the area for the origin of the tibialis posticus, and arises below from th posterior border of the interosseous ridge at the junction of the middle and inferio thirds of the shaft, curves a little backwards, and passing upwards and obliquel forwards again joins the interosseous ridge once more in the region of the neck This is oftentimes called the internal border (crista medialis); and the surface s mapped off, the internal surface. The ridge itself serves for the attachmen of the aponeurosis which covers the tibialis posticus muscle. The remainder o the extensor aspect of the shaft, which, above, is directed backwards, is so twisted that inferiorly it is directed inwards. From this, in its upper part, the soleu muscle arises; whilst lower down, the flexor longus hallucis muscle derives an extensive origin. Both of these muscles, together with the tibialis posticus, act as *extensors* of the ankle. On this aspect of the bone, at or near the middle of the shaft, and just behind the prominent tibial ridge, is the opening of the nutrient canal, which has a downward direction.

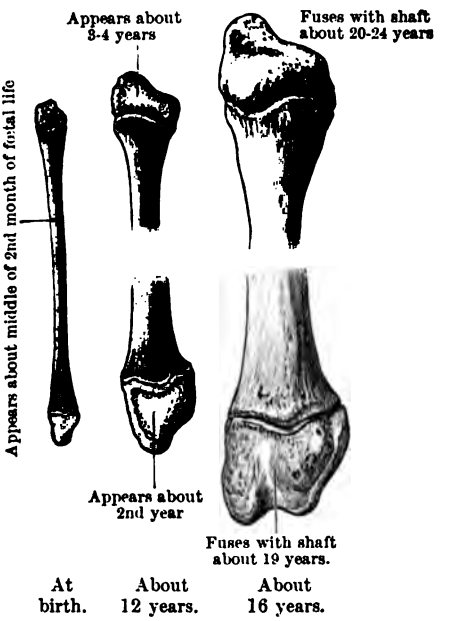
The **inferior extremity** of the fibula, or **external malleolus** (malleolus lateralis), is of pyramidal form. Its inner surface is furnished with a triangular articular area (facies articularis malleoli), plane from before backwards, and slightly convex from above downwards, which articulates with a corresponding surface on the outer side of the body of the astragalus. Behind this there is a deep pit, to which the posterior fasciculus of the external lateral ligament is attached. Above the articular facet there is a rough triangular area on the extensor surface of the shaft, from the summit of which the interosseous ridge arises; hereto are attached the strong fibres of the inferior interosseous ligament which binds together the opposed surfaces of the tibia and fibula. The external surface of the inferior extremity forms the elevation of the external malleolus which determines the shape of the projection of the outer ankle. Rounded from side to side and from above downwards, it terminates below in a pointed process, which reaches a lower level than the corresponding process of the tibia, from which it also differs in being narrower and more pointed and being placed in a plane nearer the heel. Superiorly, this surface, which is subcutaneous, is continuous with the triangular subcutaneous area so clearly defined by the convergence above of the lines which unite to form the anterior border. The anterior border and tip of the external malleolus furnish attachments to the anterior and middle bands of the external lateral ligament of the ankle. The posterior surface of the external malleolus, broad above, where it is confluent with the peroneal or external surface, is reduced in width below by the presence of the pit which lies to its inner side. This aspect of the bone is grooved (sulcus malleolaris) by the tendons of the peroneus longus and brevis muscles, which curve round the posterior and lower-pointed aspect of the malleolus. The proportionate length of the fibula to the body height is as 1 is to 4·37–4·82.

Arterial Foramina.—Numerous minute vascular canals are seen piercing the outer surface o the head, and one or two of larger size are seen on the inner surface immediately in front of th superior articular facet. The canal for the nutrient artery of the shaft, which has a downwar direction, is situated on the back of the bone about its middle. The outer surface of the extern malleolus displays the openings of many small canals, and one or two larger openings are to noted at the bottom of the pit behind the inferior articular surface.

Connexions.—The head and external malleolus, and part of the shaft immediately above latter, are subcutaneous. The remainder of the shaft is covered on all sides by the muscles wh surround it. Superiorly the bone plays no part in the formation of the knee-joint, but inferi assists materially in strengthening the ankle-joint by its union with the tibia and its articula with the astragalus. In position the bone is not parallel to the axis of the tibia, but obliqu it, its upper extremity lying posterior and external to a vertical line passing through the exte malleolus.

Architecture.—A medullary canal runs throughout the length of the shaft, reaching as h as the neck above, and extending as low as a point about 2½ inches above the inferior extrem of the external malleolus. The outer wall of the shaft is usually considerably thicker than inner. The head is formed of loose cellular bone, enclosed within a very thin dense envelope. T spongy tissue of the lower extremity is more compact, and acquires considerable density on surfaces underlying the articular area and the pit behind it. The canal for the nutrient artery the shaft opens into the medullary cavity about an inch below its external aperture.

ion.—The shaft begins to ossify about the middle of the second month of t the end of the third month there is but little difference in size between it and at birth the fibula is much ortion to the size of the tibia than Its extremities are cartilaginous, remity not being as long as the olar cartilage of the tibia. It is in that an ossific centre first appears of the second year, which increases ², and unites with the shaft about 's. The centre for the superior ins to ossify about the third or and union with the shaft is not il a period somewhat later than inferior epiphysis. The mode of the lower extremity is an exception rule that epiphyses which are the are the last to unite with the shaft.



Appears about 3-4 years
Fuses with shaft about 20-24 years

About 16 years.

FIG. 180.—OSSIFICATION OF FIBULA.

er stages of development it has been authority of Lebouco, Gegenbaur it the fibula as well as the tibia is in e femur. This is, however, denied by Proc. Anat. Soc.," *Journ. Anat. and* xvi. p. 22), who states that after the e fibula is not in contact with the it prior to that date it is impossible the tissue which is to form femur h forms fibula.

.—The fibula may be ridged and emarkable manner, as is the case in many bones of prehistoric races. This is ated with a greater or perhaps more active development of the muscles attached

or articular facet varies much in size. Bennett (*Dublin Journ. Med. Sc.*, Aug. case in which it was double, and also notes the occurrence of specimens in which nd in which the head of the bone did not reach as high as the tibial tuberosity. nces of partial or complete absence of the bone have been published. (Lefèbre, *l'étude de l'absence congénitale du péroné*, Lille, 1895.)

BONES OF THE FOOT.

s of the foot, twenty-six in number, are arranged in three groups: the in number; the metatarsal, five in number; the phalanges, fourteen

ig the foot with the hand, the student will be struck with the great pro- ze of the tarsus as compared with the carpus, and the reduction in size of the toes as compared with the fingers. The size of the metatarsal e nearly equals that of the metacarpus.

THE TARSUS.

is (ossa tarsi) consists of seven bones—the astragalus, os calcis, navi- hoid, three cuneiforms, and the cuboid. Of irregular form and varying y be described as roughly cubical, presenting for examination dorsal surfaces as well as anterior, posterior, internal, and external aspects.

THE ASTRAGALUS.

agalus (talus) is the bone through which the body weight is trans- the leg above to the foot below. Superiorly the tibia rests upon it, ner side it articulates with the internal and external malleolar processes nd fibula respectively; inferiorly it overlies the os calcis, and anteriorly with the navicular. For descriptive purposes the bone is divisible into the **body** (corpus tali) blended in front with the **neck** (collum tali), ·ts the **head** (caput tali).

The *upper surface* of the **body** is provided with a saddle-shaped **articular s** (trochlea tali), broader in front than behind, for articulation with the under s of the tibia. The inner edge of the trochlea is straight; whilst the outer b which is sharp in front and more rounded behind, is curved inwards poste

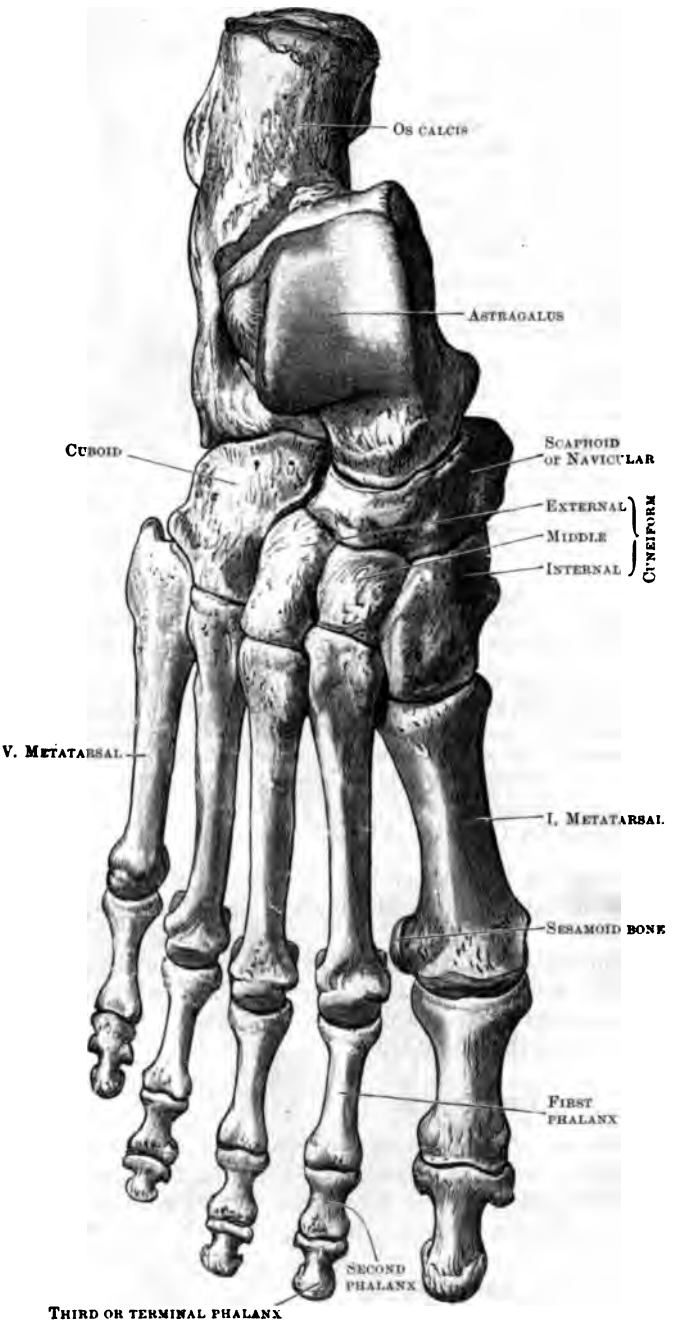

Fig. 181.—Bones of the Right Foot as seen from Above.

where it is bevel form a narrow, gated, triangular which is in contac the transverse c ferior tibio-fibular ment during flex the ankle (Fawcet *Med. Journ.*, Over the outer l the cartilage-co surface is conti externally with a tensive area of the of a quadrant. T concave from downwards, and a lates with the surface of the fi malleolus. The in angle of this ar prominent and what everted, and times referred to **external process** (p sus lateralis tali). inner aspect of the has a comma-sh facet, confluent the superior arti surface, over the edge of the troc this articulates the outer surface tibial malleolus. ferior to this fac bone is rough and by numerous openings, and just the tail of the c there is a circula pression for the at ment of the deep of the internal l ligament. On th *ferior surface* of body there is a concave facet, the **posterior calc facet** (facies cal articularis posterior), which is of more or less oval or oblong form and is obliquely from behind forwards and outwards; this rests upon a correspo surface on the upper aspect of the os calcis. In front of this, and crossin bone from within outwards and forwards, is a deep **furrow** (sulcus tali), the fl which is pierced by numerous large canals. It serves for the **attachment** c

ong interosseous ligament which unites the astragalus with the os calcis, and arates the facet already described from a smaller oval articular area having a htly convex surface, which lies immediately in front of it. This is called the **ddle calcanean facet** (facies articularis calcanea media), and articulates with the per surface of the stentaculum tali the os calcis. steriorly the body provided with two bercles, separated a groove; the ternal of these rocessus posterior li) is usually the rger, and is occaonally a separate sicle (os trigonum). o it is attached the sterior fasciculus the external teral ligament of e ankle-joint. The oove, which winds bliquely from above wnwards and inards over the posrior surface of the ne, lodges the ndon of the flexor ngus hallucis uscle.

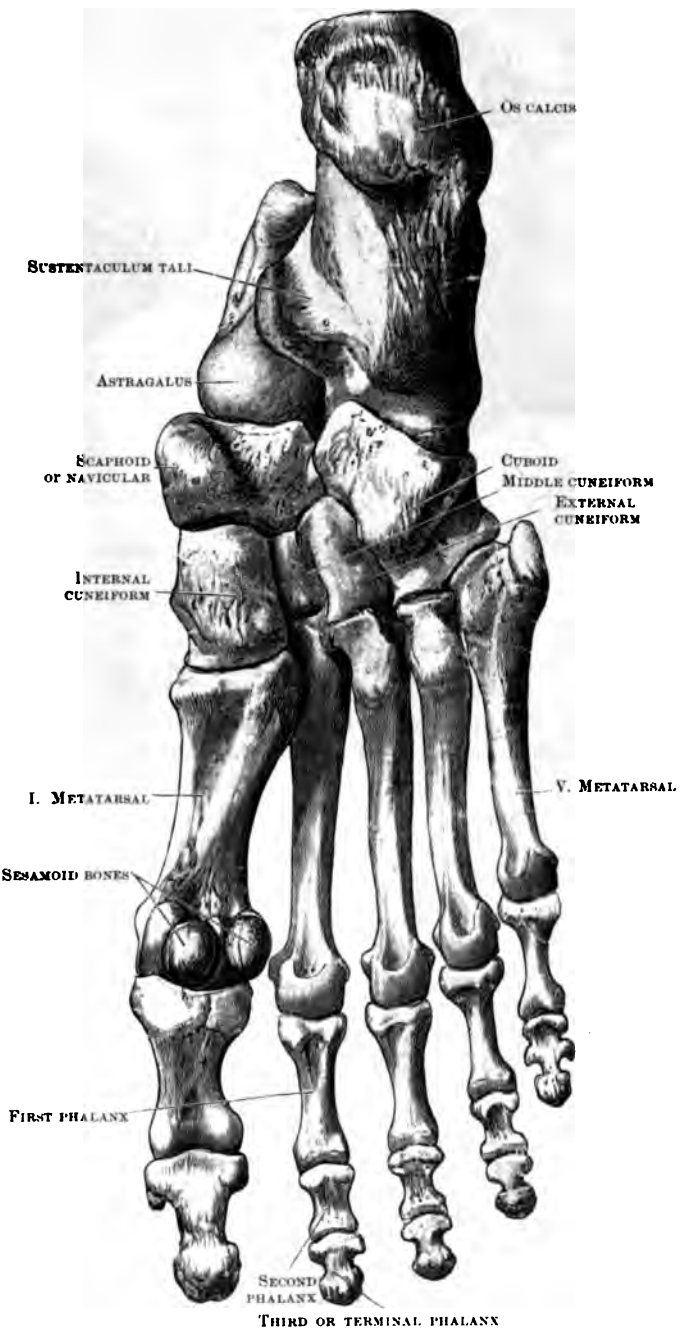

Fig. 182.—Bones of the Right Foot as seen from Below.

The head (caput li), of oval form, is irected forwards nd inwards. Its nterior surface is nvex from side to de and from above wnwards, and arculates with the avicular bone acies articularis avicularis). Inriorly this surface confluent with the iddle calcanean cet, but in well-arked specimens, when the bones e articulated, it ll be seen that a all area in front and external to, e middle calcanean cet rests upon an articular surface on the upper part of the fore portion of the calcis, and is called the **anterior calcanean facet** (facies articularis calcanea nterior). To the inner and under surface of the head there is a cartilage-covered rface which does not articulate with any bone, but rests on the upper surface the inferior calcaneo-navicular ligament, and is supported on the inner

side by the tendon of the tibialis posticus muscle (Fawcett, *Ed. Med. Jour* 1895, p. 987).

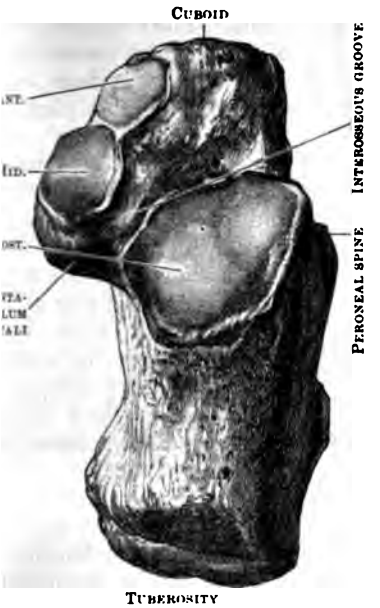
the internal malleolar facet, and externally forms a wide groove, which becom continuous inferiorly with the outer end of the interosseous groove.

iations.—The anterior is sometimes separated from the middle calcanean facet by a non- furrow. The posterior external tubercle, often largely developed, is occasionally (2·6) a separate ossicle forming what is known as the os trigonum (Bardeleben); or it may be o the body of the astragalus by a distinct synchondrosis. A smooth articular surface may ally be found on the outer side of the upper surface of the neck. This is a pressure facet nt on the frequent use of the ankle-joint in a condition of extreme flexion, and is caused pposition of the bone against the anterior edge of the lower end of the tibia.
a detailed study of the varieties of this bone, see R. B. S. Sewell (*Journ. Anat. and Physiol.*, viii.)

The Os Calcis.

e **os calcis** (calcaneus) is the largest of the tarsal bones. It supports the alus above and articulates with the cuboid in front. Inferiorly and behind, its ior extremity or tuberosity forms the heel on which so large a proportion of dy weight rests. The long axis of the bone inclines forwards and a little rds.

ıe *upper surface* of the os calcis is divisible into two parts—a posterior non-



185.—The Right Os Calcis as seen from above

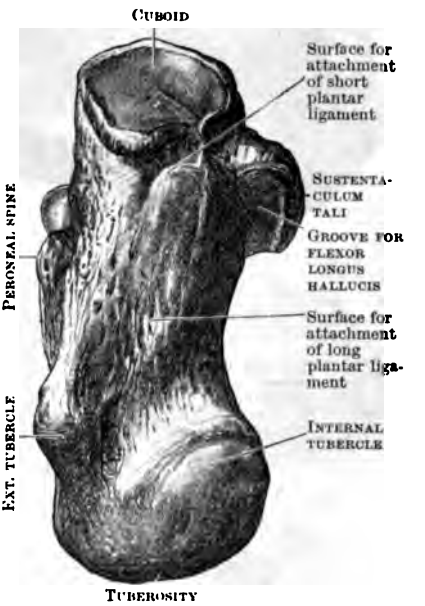


Fig. 186. -The Right Os Calcis as seen from below.

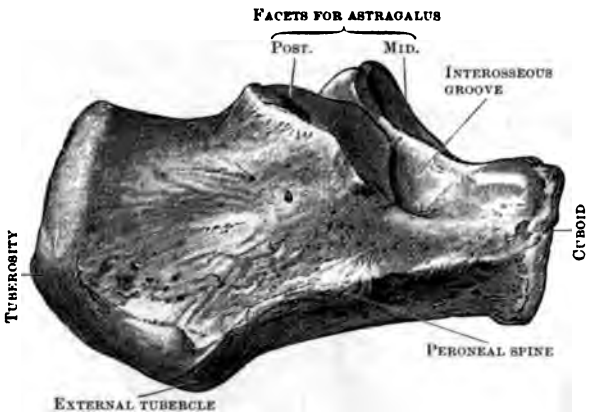
lar part and an anterior articular portion. The length of the former varies ing to the projection of the heel; rounded from side to side, it is slightly con- rom before backwards. In front of this there is a convex articular area of le shape (facies articularis posterior), sometimes nearly circular, at other times nd occasionally almost triangular. This is directed upwards and forwards, ticulates with the posterior calcanean facet on the under surface of the astra-

Anterior to this facet the bone is deeply excavated, forming a fossa from a **groove** (sulcus calcanei) leads backwards and inwards around the antero- al border of the articular surface. When the os calcis is placed in contact he astragalus, this groove coincides with the sulcus on the under surface of ter bone, and so forms a **canal** or tunnel (sinus tarsi) in which the strong sseous ligament which unites the two bones is lodged. To the front and inner f this groove there is an elongated articular facet directed obliquely from l forwards and outwards, and concave in the direction of its long axis. This uently divided into two smaller oval areas by an intermediate non-articular e. Of these facets the hinder (facies articularis media) articulates with the calcanean facet on the under surface of the astragalus, whilst the anterior articularis anterior) supports the under surface of the head of the astragalus articularis calcanei anterior). The outer side of the upper surface of the

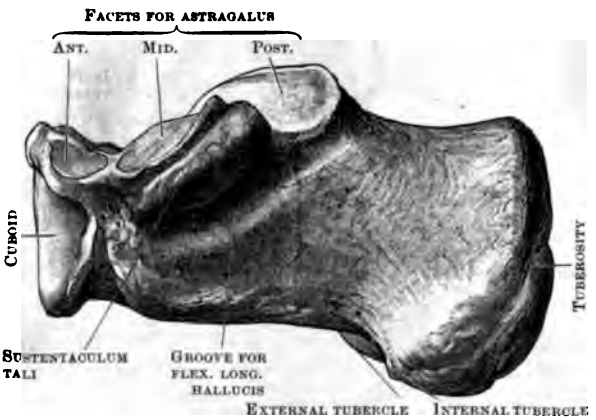
anterior extremity of the bone is rough, and hereto is attached the origin short extensor muscle of the toes.

The *inferior surface* of the bone is slightly concave from before backward convex from side to side. The under aspect of the tuberosity is provided wit **tubercles**, an **inner** (processus medialis tuberis calcanei) and an **outer** (pro lateralis tuberis calcanei), of which the former is the larger. From this the flexor of the toes and the abductor hallucis muscle arise, whilst from both tul spring the fibres of origin of the abductor minimi digiti muscle. On the for of the under surface there is an elevated elongated tubercle, which term somewhat abruptly just behind the anterior border of this aspect of the



A

A. As seen from the Outer Side.



B

B. As seen from the Inner Side.

FIG. 187.—THE RIGHT OS CALCIS.

giving rise at times to a From the former sprin fibres of the long planta ment, whilst the latter for the attachment of the fibres of the short plantar ment. The two heads of of the flexor accessorius n arise from the bone on side of the long plantar ment. The *internal surf* the os calcis is crosse liquely, from above down and forwards, by a broad of considerable depth; this pass many of the stru which enter the sole of th from the back of the leg. groove is overhung in fro above by a projecting br like process, called the **s taculum tali,** or **lesser p** The under surface of th tentaculum is channelled groove, in which is lodged th don of the flexor longus h muscle; whilst its inner b to which is attached a p the internal lateral ligam the ankle, is overlain by t of the flexor longus digit To the anterior border sustentaculum is attache inferior calcaneo-navicula ment, and placed on its surface is the articular already alluded to (facies a laris media). Posteriorly the internal surface of the bone is limited inferiorly projection of the internal tubercle, and above by the internal lipped edge tuberosity.

The *external surface*, broad behind and narrower in front, is of flattened Springing from it, just below the outer end of the sinus tarsi, is the **peroneal** (processus trochlearis), often indistinctly marked. To this the fibres of the ex annular ligament are attached; whilst in grooves, above and below it, pa tendons of the peroneus brevis and longus muscles respectively. To the and back part of this surface are attached the fibres of the middle fasciculus external lateral ligament of the ankle.

The *anterior extremity*, sometimes called the **greater process**, is furnished saddle-shaped surface on its anterior aspect for articulation with the cuboid.

ɔet is concave from above downwards, and slightly convex from side to side; its ges are sharply defined, except internally, and serve for the attachment of ɡaments.

The *posterior extremity*, called the **tuberosity** (tuber calcanei), forms the rojection of the heel. Of oval form and rounded surface, it rests upon the two ıbercles inferiorly. Its cutaneous aspect is divisible into three areas. Of these ne highest is smooth and crescentic, and is covered by a bursa; the intermediate s also fairly smooth, and is defined inferiorly by an irregular line, sometimes a efinite ridge, the edges of which are striated. Into this surface the tendo Achillis s inserted. The lowest surface is rough and striated, and is confluent below with he internal and external tubercles; this is overlain by the dense layer of tissue vhich forms the pad of the heel.

Variations.—The peroneal tubercle is occasionally unduly prominent, constituting the sub-alleolar apophysis of Hyrtl, and cases are recorded of the os calcis articulating with the navicular (Morestin, H., *Bull. de la Soc. Anat. de Paris*, 1894, ser. v. t. 8, n. 24, p. 798; and Petrini, *Atti del XI. Congr. Med. Internaz. Roma*, 1894, vol. ii., "Anat." p. 71). Pfitzner (*Morphologische Arbeiten*, vol. vi. p. 245) also records the separation of the sustentaculum tali to form an n sustentaculi. (See also P. P. Laidlaw, *Journ. Anat. and Physiol.*, vol. xxxviii. p. 133.)

The Navicular Bone.

The **navicular** or **scaphoid bone** (os naviculare pedis), of compressed pyriform hape, is placed on the inner side of the foot, between the head of the astragalus osteriorly and the three cuneiform bones anteriorly. The bone derives its name rom the oval or boat-haped hollow on its *osterior surface*, which ests upon the head of he astragalus. Its *nterior aspect* is furnished with a semilunar rticular area, which is ubdivided by two faint idges into three wedge-haped facets for articulation from within outwards with the internal, middle, and external uneiform bones. *Superiorly* the surface of the bone, convex from side to side, is rough for the ttachment of the ligaments on the dorsal aspect of the foot. *Inferiorly* the one is irregularly concave, and marked by the attachment of the plantar ligaments. The *external surface* is narrow from before backwards, and rounded from bove downwards. Usually devoid of any articular surface, it is occasionally provided ith a facet which rests upon a corresponding area on the cuboid. The *inner side* f the bone projects beyond the general line of the inner border of the foot, so as to orm a thick rounded **tubercle** (tuberositas oss. navicularis), the position of which an be easily determined in the living. To the inner and under surface of this rocess an extensive portion of the tendon of the tibialis posticus muscle is nserted.

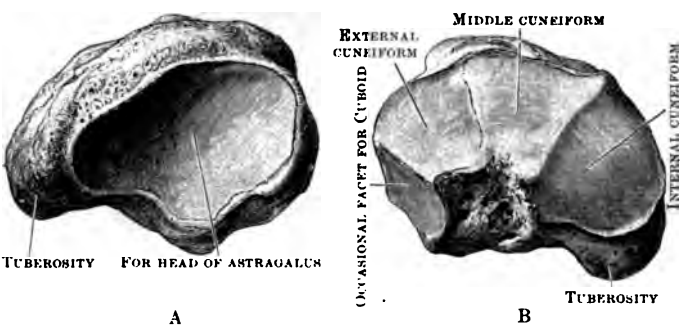


FIG. 188.—THE RIGHT NAVICULAR BONE.
A. As seen from Behind; B. As seen from the Front.

Variations.—Cases are recorded where the tubercle has formed an independent ossicle.

The Cuneiform Bones.

The **cuneiform bones**, three in number, are placed between the navicular osteriorly and the bases of the first, second, and third metatarsal bones anteriorly, or which reason they are frequently named the first, second, and third cuneiforms, r, from their position, internal, middle, and external. More or less wedge-shaped, s their name implies, the internal or first is the largest, whilst the middle or

second is the smallest of the group. Combined, they form a compact mas proximal surface of which, fairly regular in outline, rests on the anterior surf the navicular; whilst anteriorly they form a of support for the three inner metatarsal outline of which is irregular, owing to the of the second metatarsal bone being re between the inner and outer cuneiforms articulates with the distal extremity o shorter middle cuneiform.

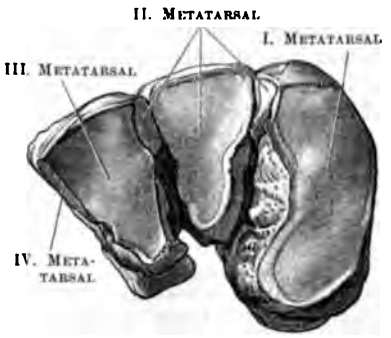

FIG. 189.—ANTERIOR VIEW OF THE THREE CUNEIFORM BONES OF THE RIGHT FOOT.

The **internal cuneiform bone** (os cunei primum), the largest of the three, lies on the border of the foot between the base of the tarsal bone of the great toe in front, and th and inner part of the navicular behind. *upper*, *lower*, and *internal* surfaces are conf and form a convexity from above down which is most pronounced inferiorly, where turned towards the plantar side of the foot. On the fore-part of the inner s of the bone there is usually a distinct oval impression, which indicates the s of insertion of a portion of the tendon of the tibialis anticus muscle. Else this surface is rough for ligamentous attachments. The *external surface* bone, quadrilateral in shape, is directed towards the middle cuneiform; but as it exceeds it in length, it also comes in contact with the inner side of the base of the second metatarsal bone. Running along the posterior and upper edges of this area is an ⌐-shaped articular surface, the fore and upper part of which is for the base of the s metatarsal bone, the remainder articulating with the inner side of the n cuneiform. The non-articular part of this aspect of the bone is rough f attachment of the strong interosseous ligaments which bind it to the n cuneiform and second metatarsal bones respectively. The *posterior* or *pro end* of the bone is provided with a form facet which fits on the inner ar area of the navicular. *Anterior* vertical diameter of the bone is mu creased, and the facet for the base metatarsal bone of the great toe i sequently much larger than that f navicular. The metatarsal facet is u of semilunar form, but not infreq is more reniform in shape, and n some cases display complete sepa into two oval portions.

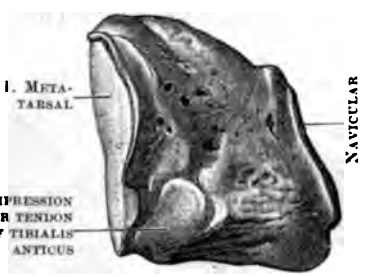

FIG. 190.—THE RIGHT INTERNAL CUNEIFORM (Inner Side).

FIG. 191.—THE RIGHT IN CUNEIFORM (Outer Sid

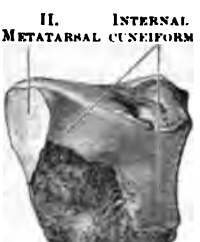

FIG. 192.—THE RIGHT MIDDLE CUNEIFORM (Inner Side).

FIG. 193.—THE RIGHT MIDDLE CUNEIFORM (Outer Side).

The **middle** or **second cuneifo** cuneiforme secundum) is of a typical wedge shape; shorter than the otl lies between them, articulating with the base of the second metatarsal in and the middle facet on the anterior surface of the navicular behind. Its *aspect*, which corresponds to the base of the wedge, conforms to the round the instep, and is slightly convex from side to side, affording attachments f dorsal ligaments. Its under surface is narrow and tubercular, forming th

of the wedge; with this the plantar ligaments are connected. The *inner surface*, quadrilateral in outline, is furnished with an Γ-shaped articular area along its posterior and superior borders in correspondence with the similar area on the outer side of the internal cuneiform. The rest of this aspect is rough for ligaments. The *outer side* displays a facet arranged along its posterior border, and usually somewhat constricted in the middle; this is for the external cuneiform. In front of this the bone is rough for the interosseous ligaments, which bind the two bones together. The proximal end is provided with a triangular facet slightly concave from above downwards; this rests on the central articular surface on the anterior aspect of the navicular. In front the bone articulates by means of a wedge-shaped facet with the base of the metatarsal bone of the second toe.

The **external** or **third cuneiform** (os cuneiforme tertium) intermediate in size between the first and second, is also of a typical wedge shape. Its *superior surface*, slightly convex from side to side, provides attachments for the dorsal ligaments. Its *inferior* or *plantar aspect* is narrow and tubercular, and serves for the attachment of the plantar ligaments. Its *inner side*, of quadrilateral form, displays two narrow articular strips, placed along its anterior and posterior borders respectively, each somewhat constricted in the middle. The anterior articulates with the outer side of the base of the second metatarsal bone, the posterior with the outer side of the middle cuneiform. The rough non-articular surface, which separates the two elongated facets, serves for the attachment of ligaments. The *outer aspect* of the bone is characterised by a large circular or oval facet, placed near its hinder border, for articulation with the cuboid; in front of this the anterior border is lipped above by a small semi-oval facet for articulation with the inner side of the base of the fourth metatarsal. The rest of the bone around and between these facets is rough for ligaments. *Proximally* the bone is furnished with a triangular facet for articulation with the outer wedge-shaped area on the front of the navicular, whilst *distally* it articulates with the base of the third metatarsal by a surface of corresponding shape.

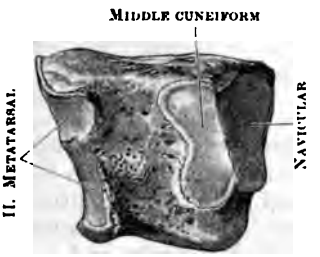

FIG. 194.—RIGHT EXTERNAL CUNEIFORM (Inner Side).

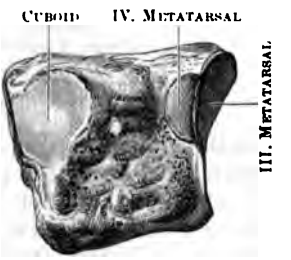

FIG. 195.—RIGHT EXTERNAL CUNEIFORM (Outer Side).

Variations.—Numerous cases of division of the internal cuneiform bone into dorsal and plantar parts have been recorded; the frequent division of its metatarsal articular facet is no doubt correlated with this anomalous condition. T. Dwight has described (*Anat. Anz.*, vol. xx. p. 465) in two instances the occurrence of an Os Intercuneiforme. The ossicle so named lies on the dorsum of the foot at the proximal end of the line of articulation between the internal and middle cuneiform bones.

THE CUBOID BONE.

The **cuboid** (os cuboideum) lies on the outer side of the foot, about its middle, articulating with the os calcis behind and the fourth and fifth metatarsal bones in front. Its *upper surface*, plane in an antero-posterior direction, is slightly rounded from side to side, and provides attachment for ligaments. Its *plantar aspect* is traversed obliquely from without inwards and forwards by a thick and prominent ridge, the outer extremity of which, at the point where it is confluent with the outer surface, forms a prominent **tubercle** (tuberositas oss. cuboidei), the anterior and external surface of which is smooth and faceted to allow of the play of a sesamoid bone which is frequently developed in the tendon of the peroneus longus muscle. In front of this ridge there is a groove (sulcus peronæi) in which the tendon of the peroneus longus muscle is lodged as it passes across the under surface of the bone. Behind the ridge the bone is rough, and serves for the attachment of the short plantar ligament, the superficial fibres of which pass forwards and are attached to the summit of the ridge. The *outer aspect* of the bone

is short and rounded, and is formed by the confluence of the superior
surfaces; it is more or less notched by the peroneal groove which turn
lower edge. The *internal surface* of the bone is the most extensive;
recognisable on account of the presence of a rounded or oval facet situa

corresponds to the dorsal roundness of the bone. The inferior external
sponds to the tubercle on the outer border of the bone, whilst the inferi
angle forms a pointed projection which is sometimes called the calcane
The posterior surface articulates with the os calcis by means of a sa
facet, which is convex from side to side, and concave from above downw

Variations.—Blandin has recorded a case of division of the cuboid.

The **tarsus as a whole** may be conveniently described as arranged in two c
inner, corresponding to the inner border of the foot, comprising the astragalus, n
three cuneiforms, and forming a base for the support of the three inner metatars
their phalanges. The outer column, formed by the os calcis and cuboid, suppor
and fifth metatarsal bones together with their phalanges. The superior surface of
portion of the tarsus determines the side-to-side roundness of the instep, whilst its
forms arches in both a transverse and longitudinal direction, in which the softer t
sole are lodged, and so protected from injury.

Architecture of the Bones of the Foot.—A longitudinal section through th
bones of the foot reveals the fact that the cancellous structure of each individual bone i
by the stress to which it is habitually subjected. In this connexion it is necessary t
arched arrangement of the bones of the foot, a subject which is also treated in the s
deals with the Joints. The summit of the arch is formed by the astragalus, on which r
Subjected as the astragalus is to a crushing strain, it is obvious that this load must b
throughout the arch, of which the os calcis is the posterior pillar, whilst the heads
tarsal bones constitute the anterior pillar. It is found, consequently, that the lamell
cellous tissue of the astragalus are arranged in two directions, which intercross a
below the superior articular surface. Of these fibres, some sweep backwards and
towards the posterior calcanean facet, beyond which they are carried in the substa
calcis in a curved and wavy manner in the direction of the heel, where they termi
others, curving downwards and forwards from the trochlea of the astragalus, pass
neck to reach the articular surface of the head, through which in like manner
regarded as passing onwards through the several bones which constitute the anterio
arch, thus accounting for the longitudinal striation as displayed in the structure
cular, cuneiform, and metatarsal bones. In the os calcis, in addition to the forego
ment, another set of curving fibres sweep from back to front of the bone beneath th
pact tissue which forms its under shell. These are obviously of advantage to prevei
of the bone when subjected to the crushing strain. In the sustentaculum tali a
arrangement of fibres is evident, and the under surface of the neck of the astragal
strengthened by lamellæ arranged vertically.

In the separate bones the investing envelope is thin, though under the artic
there is a greater density, due to the accession of lamellæ lying parallel to the arti

ıe **stoutest bony tissue in the astragalus** is met with in the region of the under surface of the ck, **whilst in the os calcis** the greatest density occurs along the floor of the sinus tarsi.

Numerical Variation in the Tarsus.—**Increase in the number** of the tarsal elements may ı due to the occurrence of division of either the internal cuneiform or the cuboid bone, or to ıe **occasional presence of an os trigonum.** Cases of separation of the tuberosity of the navicular ɔne **have been recorded, and instances of supernumerary ossicles** between the internal cuneiform ıd **second metatarsal bone have been noted.** Stieda mentions the occurrence of a small ossicle ı connexion with the articular surface on the fore and upper part of the os calcis, and Pfitzner ıotes the occurrence of an os sustentaculi. For further information on the variations of the keleton of the foot, see Pfitzner (*Morphologische Arbeiten*, vol. vi. p. 245).

The possibility of an injury having been the cause of the occurrence of some of these so-called ıupernumerary ossicles must not be overlooked. The use of the Röntgen rays has proved that ıccidents of this kind are much more frequent than was at first supposed.

The **reduction in the number** of the tarsus is due to the osseous union of adjacent bones. In many instances this is undoubtedly pathological, but cases have been noticed (Leboucq) of fusion of the cartilaginous elements of the os calcis and astragalus, and the os calcis and navicular in fœtuses of the third month.

Ossification.—Unlike the carpus, the tarsus is at birth partially ossified. At this period there is a well-marked osseous nucleus within the body and neck of the astragalus, and the os calcis is extensively ossified. In the latter the deposition of earthy matter appears as early as the sixth month of fœtal life, whilst in the astragalus the ossific centre makes its appearance in the later weeks of gestation. Shortly before or after birth the

A B

FIG. 197.—RADIOGRAPHS OF THE FŒTAL FOOT.

A. Between the seventh and eighth months. Here the ossific nuclei of the os calcis and astragalus are seen.
B. At birth. The centres of ossification for the os calcis and astragalus are well developed, the nucleus for the cuboid is quite distinct, and in this instance the external cuneiform is already commencing to ossify. Compare this figure with Fig. 155, in which the carpus is shown as still cartilaginous at birth.

cuboid begins to ossify, succeeded early in the first year by the external cuneiform, followed in order by the middle cuneiform, internal cuneiform, and navicular. The ossific centre of the latter appears at the third year or somewhat later. An epiphysis, which forms a cap over the extremity of the great tuberosity of the os calcis, appears from the seventh to the ninth year, and fusion is completed between the ages of sixteen and twenty.

THE METATARSUS.

The **metatarsal bones**, five in number, in their general configuration resemble ıe metacarpus. They are, however, slightly longer, their bases are proportionately

larger, their shafts more slender and laterally compressed, and their heads proportionately smaller. They are named numerically the first, second, third, fourth, and fifth metatarsal bones, in order from within outwards. The first can be readily recognised on account of its stoutness; it is also the shortest of the series. The second is the longest of the five, and the fifth can easily be distinguished by the projecting tubercle at its base.

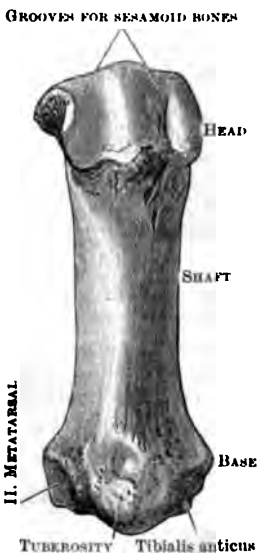

Fig. 198.—The First Metatarsal Bone of the Right Foot (Plantar Aspect).

The **first metatarsal** or metatarsal bone of the great toe, the shortest of the series, is remarkable for its stoutness. Its base, where the bone is provided with a reniform facet for articulation with the internal cuneiform, is wider from before backwards than from side to side. As a rule there are no facets on the lateral aspects of the base. The inferior angle projects backwards and outwards, and forms a prominent tubercle which is pitted for the insertion of the tendon of the peroneus longus muscle, whilst its internal margin is lipped by a surface for the attachment of part of the tendon of the tibialis anticus. The shaft, short, thick, and prismatic on section, tapers rapidly towards the head, the fore and under surfaces of which are articular. The former is convex from side to side, and from above downwards, and supports the proximal phalanx. It is confluent below with the inferior articular surface, which is divided by a median ridge into two shallow grooves, of which the inner is the wider. In these grooves are lodged the two sesamoid bones which underlie the metatarso-phalangeal joint. On either side of the head the bone is pitted for the strong lateral ligaments of the joint.

The **second metatarsal**, the longest of the series, has a base of wedge-shaped form, the proximal aspect of which articulates with the middle cuneiform. On its

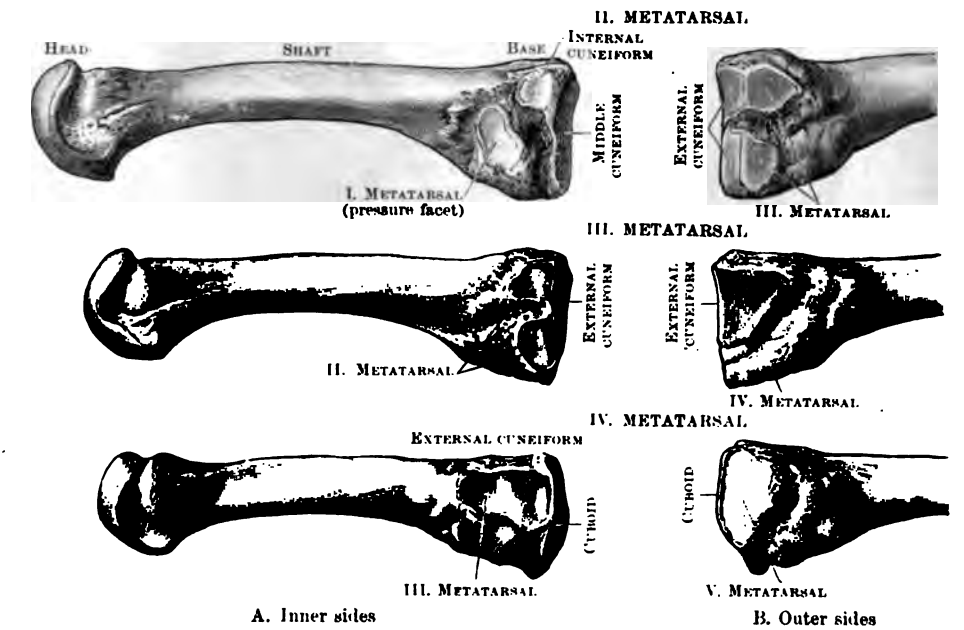

Fig. 199.—View of the Bases and Shafts of the Second, Third, and Fourth Metatarsal Bones of the Right Foot.

inner aspect, near its superior edge, there is a small circular facet for th internal cuneiform; below and in front of this there is sometimes a tubercle witl a "pressure" facet on it, where the bone comes in contact with the base of th first metatarsal. On the outer side of the base there is one, more usually two smal

ets, each divided into two parts, a posterior for articulation with the external neiform, and an anterior for the base of the third metatarsal. The shafts of this d the three succeeding bones are slender and laterally compressed. The heads e small and narrow, and display a pronounced side-to-side and vertical convexity.

The **third metatarsal bone** also possesses a base of wedge-shaped form, the roximal surface of which articulates with the external cuneiform. On its inner de it is provided with one, more usually two, small facets, for articulation with the ase of the second metatarsal. Externally the base has a larger facet for articulation with the base of the fourth metatarsal, more or less onical in outline, and having its lower edge sharply defined y a narrow groove which underlies it.

The **fourth metatarsal** has a base more cubical in shape. ts proximal aspect articulates with the cuboid, whilst internally an elongated oval facet, divided by a slight vertical idge, provides surfaces for articulation with the third metatarsal in front and the outer side of the internal cuneiform ehind. On the outer side there is a demi-oval facet, bearing a slightly saddle-shaped surface, for articulation with the inner ide of the base of the fifth metatarsal.

The **fifth metatarsal** can be readily recognised by the peculiar shape of its base, from the outer side of which there projects backwards and outwards a prominent tubercle (tuberositas oss. metacarpi V.) To the hinder extremity of this is attached the tendon of the peroneus brevis muscle. To its upper surface the tendon of the peroneus tertius is inserted, whilst its under surface provides an origin for the flexor brevis minimi digiti muscle. The inner surface of the base is provided with a demi-oval, slightly concave facet, for the outer side of the base of the fourth metatarsal, whilst proximally it articulates with the cuboid by means of a semicircular facet.

FIG. 200.—FIFTH RIGHT METATARSAL BONE (Dorsal Aspect).

Vascular Foramina.—The canals for the nutrient vessels open, as a rule, on the plantar aspects of the middle of the shafts. Those of the outer metatarsals are directed towards the bases of the bones, whilst that for the metatarsal of the great toe passes towards its head.

Architecture.—In structure and the arrangement of their lamellæ the metatarsal bones agree with the metacarpus.

Variations.—Several instances of separation of the tuberosity of the fifth metatarsal (os Vesalianum) have been recorded, whilst numerous examples of an os intermetatarsum between the bases of the first and second metatarsal bones have been recorded by Gruber and others. The tubercle on the base of the first metatarsal for the attachment of the peroneus longus tendon is occasionally met with as a separate ossicle.

Ossification.—In correspondence with the mode of ossification which maintains in the metacarpus, the primary centres for the metatarsus appear as early as the third month of fœtal life. In the case of the second, third, fourth, and fifth, these centres furnish the bases and shafts of the bones, the heads being developed from secondary centres which appear from two to four years after birth, fusion with the shaft being usually completed about the eighteenth year. In striking contrast to this is the mode of ossification of the first metatarsal. From its primary centre the head and shaft is developed; the secondary centre appears at its **base** about the second or third year, and unes with the shaft about eighteen. In this respect, therefore, the metatarsal bone of he great toe resembles in its mode of development the phalanges. Mayet, however *Bull. Soc. Anat. Paris*, 1895), describes the occurrence of two ossific centres in the roximal epiphysis. These fuse early, and he considers that the one represents the metatarsal element, whilst the other may be regarded as phalangeal in its origin.

THE PHALANGES.

The **phalanges** of the toes (phalanges digitorum pedis) differ from those of the fingers in the striking reduction of their size, and in the case of the bones of the first row, in the lateral compression of their shafts. Each toe is provided normally with three phalanges, except the great toe, which has only two. In their general configuration and in the arrangement of their articular facets they resemble the

digital phalanges, though, owing to the reduction in their size, the shafts, pa larly those of the second row, are often so compressed longitudinally as to r the bone to a mere nodule. The proximal end of ea the bones of the first row is proportionately large, a provided with a simple hollow in which the head o metatarsal bone rests; the distal ends are furnished condyloid surfaces. The proximal extremities of the s row are each provided with two small concavities, sep by a slight ridge for articulation with the condyles o first row. The joint between the second and thir displays the same arrangement—the third, termir ungual phalanx, being easily distinguished by the sp shaped surface at its extremity on which the bed of th is supported.

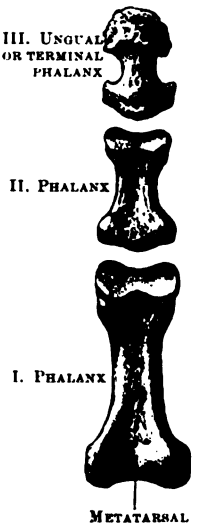

Fig. 201.—The Phalanges of the Toes (Dorsal Aspect).

The phalanges of the great toe, two in number, from the others in their size and length. Into the b the first phalanx are inserted the short muscles o great toe, whilst the second phalanx receives o plantar aspect the insertion of the flexor longus ha muscle, the tendon of the extensor longus hallucis inserted into the dorsal aspect.

Architecture.—In their general structure they resemb bones of the fingers.

Variations.—It is not uncommon to meet with fusion second and third phalanges, particularly in the fifth, less fre in the fourth, and occasionally in the second and third toes. The union of the pha elements has been observed in the fœtus as well as the adult (Pfitzner). The propor length of the phalanges varies much; in some cases the ungual phalanges are of fair s bones of the second row being mere nodules, whilst in other instances the reduction in siz terminal phalanges is most marked.

Ossification.—Each phalanx is developed from two centres—one primary f shaft and distal extremity, the other for the epiphysis on the proximal end. The primary centres for the ungual phalanges are the first to appear, commencing to ossify from the eleventh to the twelfth week of fœtal life. The centre for the ungual phalanx of the great toe makes its appearance before that of its corresponding metatarsal bone. The primary centres for the phalanges of the first row appear from the fourteenth to the sixteenth week. The primary centres for the middle phalanges of the second and third toes begin to ossify about the sixth month, those for the fourth and fifth toes not till later—the shaft of the middle phalanx of the fourth toe being frequently cartilaginous at birth, the normal condition in the case of the fifth toe (Lambertz). The proximal epiphyses do not begin to ossify until about the fourth year, and are usually fused with the diaphyses about the age of sixteen or ei Union between the shafts and epiphyses of the first row precedes that of the seco third rows.

Fig. 202.

B.[1] A little later. The centres for the terminal phalange four inner toes are seen, as well as the centres for phalanges of the great and second toe.

C. About the fourth month. The centres for all the phalanges as well as those of the first row are well oss

D. About the fifth month. In this the centre for the phalanx of the second toe has already made its appear

[1] This specimen displays the occurrence of anomalous centres w tarsus the significance of which is not apparent. The appearance i to any defect in the plate but recurred in repeated skiographs.

Sesamoid Bones.

As in the hand, small independent nodules of bone, called **sesamoid bones**, are met h in the ligaments and tendons of the foot. The most constant of these are found in nexion with the metatarso-phalangeal articulation of the great toe, where they lie in oves on the under surface of the head of the metatarsal bone in connexion with the dons of the short muscles of the great toe. Small osseous nodules occupying a responding position are occasionally met with in the other toes, and instances have en recorded of like ossicles occurring on the plantar aspect of the interphalangeal joint the great toe.

An osseous nodule is not infrequently met with in the tendon of the peroneus longus it turns round the outer border of the foot to lie in the groove on the under surface of e cuboid.

MORPHOLOGY OF LIMBS.

Development and Morphology of the Appendicular Skeleton.

The paired limbs first appear in the human embryo about the third week as small buds on ther side of the cephalic and caudal ends of the trunk. That these outgrowths are derived from large number of trunk segments is assumed on the ground that they are supplied by a corre-onding number of segmental nerves, and the circumstance that they are more particularly sociated with the ventral offsets of these nerves would point to the conclusion that they belong ther to the ventral than the dorsal surface of the body.

At first the surfaces of these limb buds are so disposed as to be directed ventrally and dorsally, e ventral aspect corresponding to the future flexor surface of the limb, the dorsal to the ex-nsor side. At the same time, the borders are directed headwards (pre-axial), and tailwards ost-axial). As the limbs grow, they soon display evidence of division into segments correspond-g to the hand and foot, forearm and leg, upper arm and thigh. Coincident with this (about the ond month) the cartilaginous framework of the limb is being differentiated. The disposition these cartilages furnishes a clue to their homologies. In the fore limb the radius and thumb e along the pre-axial borders, and correspond to the tibia and great toe, which are similarly dis-ed in the hind limb; whilst the ulna and fifth finger are homologous with the fibula and fifth e, which are in like manner arranged in relation to the posterior (post-axial) border of their spective limbs. Up to this time the limbs are directed obliquely ventralwards from the head wards the tail-end of the embryo. During the third month, however, a change in their posi-n takes place, owing to their axes being rotated in opposite directions. The fore limb is rned outwards and forwards to the extent of 90°, whilst the lower hind limb is twisted inwards d backwards to a corresponding degree. This gives rise to a change in the disposition of the nts of the flexor and extensor surfaces. The flexor surface of the elbow is now directed for-rds, whilst the corresponding aspect of the knee is turned backwards, and in consequence the nal or extensor aspect of the fore limb is posterior, whilst the dorsal or extensor aspect of the nd limb has become anterior. Correspondingly, the pre-axial border of the fore limb with the umb now lies external, whilst the pre-axial border of the hind limb with the great toe has come internal. A knowledge of these changes is necessary to account for the homologies of the rious structures within the limb. In the axial mesoderm of each member, differentiation to cartilaginous segments begins about the second month; each of these cartilages becomes in-sted by a perichondrial layer which stretches from segment to segment, and ultimately forms e ligaments surrounding the joints, which are subsequently developed between the segments. ondrification first begins in the basal part of the limb, and extends towards the digits. In the per arm and thigh the humerus and femur are homodynamous. In the forearm and leg the e-axial radius corresponds with the pre-axial tibia, and the post-axial ulna with the post-axial bula. The homodynamy of the carpal and tarsal elements may be tabularly expressed, and mpared with the more generalised types from which they are evolved.

Type.	Hand.	Foot.
Radiale (Tibiale)	= Scaphoid (body)	= Astragalus.
Intermedium	= Semilunar	= Absent, or Os trigonum (?)
Ulnare (Fibulare)	= Cuneiform	= Os Calcis.
Centrale	= Absent, or Tubercle on Scaphoid	= Navicular.
Carpale (Tarsale), i.	= Trapezium	= Internal Cuneiform.
Carpale (Tarsale), ii.	= Trapezoid	= Middle Cuneiform.
Carpale (Tarsale), iii.	= Os Magnum	= External Cuneiform.
Carpale (Tarsale), iv. } Carpale (Tarsale), v. }	= Uncifform	= Cuboid.

The pisiform is omitted from the above table, since it is now generally regarded as being a estige of an additional digit placed post-axial to the little finger (digitus post-minimus). Its omologue in the foot is by some considered as fused with the os calcis. Similarly, on the pre-xial border of the hand and foot, vestiges of a suppressed digit (prepollex and prehallux) may

occasionally be met with. The frequent occurrence of an increase in the number of digits seems to indicate that phylogenetically the number of digits was greater than at present, and included a prepollex or prehallux, and a digitus post-minimus. The correspondence of the metacarpus with the metatarsus and the phalanges of the fingers with those of the toes is so obvious that it is sufficient merely to mention it.

The differences in size, form, and disposition of the skeletal elements of the hand and foot is easily accounted for by a reference to the functions they subserve.

In the hand strength is sacrificed to mobility, thus leading to a reduction in the size of the carpal elements, and a marked increase in the length of the digital phalanges. The freedom of movement of the thumb, and its opposability to the other digits, greatly enhances the value of the hand as a grasping organ. In the foot, where stability is the main requirement, the tarsus is of much greater proportionate size, whilst the phalanges are correspondingly reduced. Since the foot no longer serves as a grasping organ, the great toe is not free and opposable like the thumb.

Limb Girdles.—The free limbs are linked to the axial skeleton by a chain of bones which constitute their girdles. The fundamental form of these limb girdles consists each of a pair of carved cartilages placed at right angles to the axis of the trunk on either side, and embedded within its musculature. Each cartilage has an articular surface externally, about the middle, for the reception of the cartilage of the first segment of the free limb. In this way each pectoral and pelvic cartilage is divided into an upper or dorsal half and a lower or ventral half. The dorsal halves constitute the scapula and ilium of the pectoral and pelvic girdles respectively. With regard to the ventral halves there is more difficulty in establishing their homologies. The original condition is best displayed in the pelvic girdle; here the ventral segment divides into two branches—one anterior, which represents the pubis, the other posterior, which ultimately forms the ischium. Ventrally, the extremities of these cartilages unite to enclose the obturator foramen. In the pectoral girdle the disposition of the ventral cartilages is not so clear, consisting primitively of an anterior branch or precoracoid, and a posterior portion or coracoid; these, in higher forms, have undergone great modifications in adaptation to the requirements of the free limbs. The posterior or coracoid element, the homologue of the ischial cartilage in the pelvic girdle, is but feebly represented in man by the coracoid process and the coraco-clavicular ligament. With regard to the homologue of the pubic element in the pectoral girdle, there is much difference of opinion; in reptiles and amphibia it corresponds most closely to the precoracoid, but it is doubtful what represents it in mammals. According to Goette and Hoffman, the clavicle is a primordial bone, and not, as suggested by Gegenbaur, of secondary or dermic origin. If this be so, it corresponds to the ventral anterior segment of the pectoral girdle, and is therefore homologous with the ventral anterior (pubic) segment of the pelvic girdle. On the other hand, if Gegenbaur's view be accepted, the clavicle has no representative in the pelvic girdle. It must, however, be borne in mind that during its ossification it is intimately associated with cartilage, and that that cartilage may represent the precoracoid bar; nor must too great stress be laid upon the fact that the clavicle begins to ossify before it is performed in cartilage, since that may be merely a modification in its histogenetic development.

According to another view (Sabatier), the subcoracoid centre (see Ossification of Scapula) is derived from the posterior ventral segment, and corresponds to the ischium, whilst the coracoid process is the remains of the anterior ventral segment (precoracoid), and is homodynamous with the pubis.

In no part of the skeleton does function react so much on structure as in the arrangement of the constituent parts of the pectoral or pelvic girdles. In man, owing to the assumption of the erect position and the pipedal mode of progression, the pelvic girdle acquires those characteristic which are essentially human, viz. its great relative breadth and the expansion of its iliac portions, which serve as a support to the abdominal viscera, and also furnish an extensive origin to the powerful muscles which control the movements of the hip-joint. The stability of the pelvic girdle is insured by the nature of its union with the axial skeleton, as well as by the osseous fusion of its several parts, and their union in front at the symphysis pubis.

In man, since the erection of the figure no longer necessitates the use of the fore limb as a means of support, the shoulder girdle has become modified along lines which enhance its mobility and determine its utility in association with a prehensile limb. Some of its parts remain independent (clavicle and scapula), and are united by diarthrodial joints, whilst others have become much reduced in size or suppressed (coracoid-precoracoid, see *ante*). The dorsal part of the girdle (scapula) is not directly united with the axial skeleton as is the ilium, but is only indirectly joined to it through the medium of the clavicle, which is linked in front with the presternum. The same underlying principles determine the differences in mobility and strength between the shoulder, elbow, and wrist, and the hip, knee, and ankle joints of the fore and hind limbs respectively, whilst the utility of the hand is further enhanced by the movements of pronation and supination which occur between the bones of the forearm. In the leg such movements are absent, as they would interfere with the stability of the limb.

THE ARTICULATIONS OR JOINTS.

ARTHROLOGY.

By David Hepburn.

Arthrology is that branch of human anatomy which treats of the articulations or joints.

An articulation or joint constitutes a mode of union or connexion subsisting between any two separate segments or parts of the skeleton, whether osseous or cartilaginous, and having for its primary object either the preservation of a more or less rigid continuity of the parts joined together, or else to permit of a variable degree of mobility, subject to the restraints of the uniting media.

Classification of Joints.—In attempting to frame a classification of the numerous joints in the body, several considerations must be taken into account, viz. the manner and sequence of their appearance in the embryo; the nature of the uniting media in the adult, and also the degree and kind of movement permitted in those joints where movement is possible.

In this way we obtain two main subdivisions of joints:—

(1) Those in which the uniting medium is coextensive with the opposed surfaces of the bones entering into the articulation, and in which a direct union of these surfaces is thereby effected.

(2) Those in which the uniting medium has undergone more or less of interruption in its structural continuity, and in which a cavity of greater or less extent is thus formed in the interior of the joint.

To the first group belong all the immovable joints, many of which are likewise of temporary duration; to the second group belong all joints which possess as their outstanding features mobility and permanence.

SYNARTHROSES.

The general characteristics of this group are partly positive and partly negative. Thus there is uninterrupted union between the opposed surfaces of the bones joined together at the plane of the articulation, *i.e.* there is no trace of a joint cavity, and further, there is an entire absence of movement. Developmentally, these joints result from the approximation of ossific processes which have commenced from separate centres of ossification, and therefore the nature of the uniting medium varies according as the bones thus joined together have originally ossified in membrane or in cartilage. In the former case union is effected by an interposed fibrous membrane continuous with and corresponding to the periosteum. To such articulations the term **suture** (Fig. 203) is applied. In the latter case the uniting medium is a plate of hyaline cartilage. Such articulations are called **synchondroses** (Fig. 204). In all the synchondroses, and in many of the sutures, the uniting medium tends to disappear in the progress of

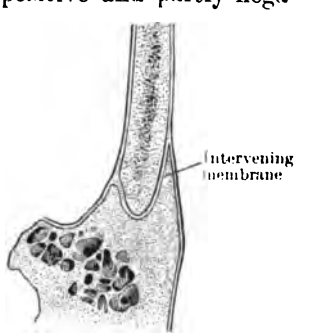

Fig. 203.—Vertical Section through a Suture.

ossification, and thus the plane of articulation becomes obliterated, so that structural continuity between the osseous segments takes place. The pr

FIG. 204. — SECTION THROUGH THE OCCIPITO-SPHENOID SYNCHONDROSIS.

features common to all synarthroses are—(*a*) conti and direct union of the opposing surfaces; (*b*) nc cavity; (*c*) no movement.

Suture.—This form of synarthrosis is only fou connexion with the bones of the skull. In a number of cases the bones which articulate by s present irregular interlocking margins, between there is the interposed fibrous membrane to which ence has already been made. When these interlo margins present well-defined projections they are s form true sutures—**sutura vera**; on the other hand, the opposed surfaces present ill-defined projectio even flat areas, they are described as false sutu **sutura notha.** In each of these subdivisions the part characters of the articulating margins are utilised in framing additional descr terms. Thus true sutures may possess interlocking margins whose projectio tooth-like (sutura dentata), *e.g.* in the interparietal suture; saw-like (sutura se (Fig. 205) *e.g.* in the interfrontal suture; ridge-like, or comparable to the parallel ridges on the welt of a boot (sutura limbosa). Similarly false sutures may articulate by margins which are scale-like (sutura squamosa), *e.g.* in the squamoso-parietal suture; or by rough opposed surfaces (sutura harmonia), *e.g.* in the suture between the palate plates of the superior maxillary bones. There is one variety of synarthrosis which, in the adult, can scarcely be called a suture, although the differences are of minor importance, viz. **schindylesis,** which is an articulation between the edge of a plate-like bone, such as the rostrum of the sphenoid, and the cleft in another, such as the vomer.

FIG. 205.—
SERRAT

Synchondrosis.—Illustrations of this group can only be found in the young growing individual, because as age advances and growth ceases, the process of ossification affects the hyaline cartilage which stitutes the uniting medium, and the plane of articulation disappears. Unde heading we may include the planes of junction between all epiphyses an shafts or diaphyses to which they severally belong. The occipito-sphenoid 204) and the petro-jugular articulations in the base of the skull provide well-marked examples.

MOVABLE JOINTS.

The leading features of this group are capability of **movement and perma** In very few instances do such joints ever become obliterated under norma ditions. Determining their permanence, and regulating the amount of pc movement, there is always more or less of interruption in the continuity structures which bind the osseous elements together. That is, there is always evidence of a joint cavity, although as a matter of course such interruptio never be so extensive as to entirely disassociate the articulating elements. T fore in all movable joints a new class of structures is found, viz. the **ligamen** means of which continuity is maintained even when all the other uniting have given place to a joint cavity. The further subdivision of this group is fo upon the amount of movement permissible, and the extent to which the joint takes the place of the original continuous uniting medium. Thus we obta partly movable or **amphiarthroses**, and the freely movable or **diarthroses.**

An **amphiarthrosis** (Fig. 208) presents the following characteristics partial movement; (*b*) union by ligaments and by an interposed plate or d fibro-cartilage, in the interior of which there is, (*c*) an incomplete or partial cavity which may be lined by a rudimentary synovial membrane whose funct is to secrete a lubricating fluid, the **synovia** or joint-oil; (*d*) a plate of h

artilage coating each of the opposing surfaces of the bones concerned. All the oints belonging to this group occur in the mesial plane of the body. It includes he symphysis pubis, the joints between the bodies of the vertebræ, and the joint etween the manubrium sterni and the gladiolus.

A diarthrosis (Fig. 206) is the most elaborate as well as the most complete form f articulation. It is characterised by (*a*) capability of movement which is more or ess free in its range; (*b*) a reduction of the uniting structures to a series of retaining ligaments; (*c*) a joint cavity which is only limited by the surrounding ligaments; (*d*) the constant presence of **synovial membrane**; (*e*) hyaline encrusting cartilage which clothes the opposed surfaces of the articulating bones. The majority of the joints in the adult belongs to this group. This series of joints has been subdivided into a number of minor sections, in order to emphasise the occurrence of certain well-marked structural features, or because of the particular nature of the movement by which they are characterised. Although in all diarthroses there is a certain amount of *gliding* movement between the opposed surfaces of the bones which enter into their formation, yet, when this gliding movement becomes their prominent feature, as in most of the joints of the carpus and tarsus, they are termed **arthrodia**. But bones may be articulated together so as to permit of movement in one, two, or more fixed axes of movement, or in modifications of these axes. Thus in **uniaxial joints** the axis of movement may lie in the longitudinal axis of the joint, in which case the **rotatory form** of joint results, as in the superior and inferior radio-ulnar articulations; or it may correspond with the transverse axis of the articulation, as in the elbow-joint and knee-joint, when the **ginglymus** or **hinge variety** results. If movement takes place about two principal axes situated at right angles to each other, as in the radio-carpal joint, the terms **biaxial** or **condyloid** are applied. Movements occurring about three principal axes placed at right angles to each other, or in modifications of these positions, constitute **multiaxial joints**, in which the associated structural peculiarities provide the alternative terms of **enarthrodial** or **ball-and-socket joints**.

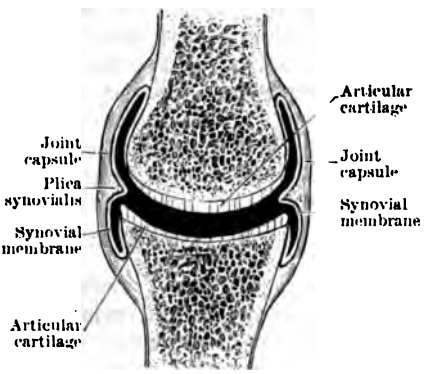

FIG. 206.—DIAGRAM OF A DIARTHRODIAL JOINT.

STRUCTURES WHICH ENTER INTO THE FORMATION OF JOINTS.

The structures which enter into the formation of joints vary with the nature of the articulation. In every instance there are two or more skeletal elements, whether bones or cartilages, and in addition there are the uniting media, which are either simple or elaborate according to the provision made for rendering the joint more or less rigid or capable of movement. We have already seen that the uniting medium in **synarthrodial joints** is a remnant of the common matrix, whether fibro-vascular membrane or hyaline cartilage, in which ossification has extended from separate centres. Among the **amphiarthroses** there is still extensive union between the opposing surfaces of the articulating bones, but the character of the uniting medium has advanced from the primitive embryonic tissue to fibrous and fibro-cartilaginous material, as well as hyaline cartilage. These, with very few exceptions, are permanent, non-ossifying substances, such as may be seen between the opposing, osseous surfaces of two vertebral bodies. The joint cavity, more or less rudimentary, is confined to the centre of the fibro-cartilaginous plate, and may result from the softening or imperfect cleavage of the central tissue. It may also present rudiments of a synovial membrane.

In the **diarthrodial group** the extensive cavity has produced great interruption in the continuity of the uniting structures which originally existed between the bones forming such a joint. Ligaments have therefore additional importance in this group, for not only do they constitute the uniting media which bind the articulating bones together, but to a large extent they form the peripheral

boundary of the joint cavity, although not equally developed in all positi Thus every diarthrodial joint possesses a fibrous or ligamentous envelope **capsule** which is attached to the adjacent ends of the articulating bones. special purposes, particular parts of the capsule may undergo enlargement thickening, and so constitute strong ligamentous bands, although still forming c tinuous constituents of the capsule.

Within the capsule a series of intracapsular structures are present. Thus capsule itself is always lined by a **synovial membrane**,[1] which is continued from inner surface of the capsule to the surface of the intracapsular portion of e articulating bone. The part of the bone included within the capsule consists o "non-articular" portion covered by synovial membrane, and an "articular" port covered by encrusting hyaline cartilage. The latter provides the surface wh comes into apposition with the corresponding area of another bone. In its gene disposition the synovial membrane may be likened to a cylindrical tube open each end. This membrane is richly supplied by a close network of vessels a nerves.

Certain diarthroses present additional intracapsular structures which may distinguished as interarticular ligaments and interarticular fibro-cartilages.

Interarticular ligaments extend between and are attached to non-articular ar of the intracapsular portions of the articulating bones. They usually occupy long axis of the joint, and occasionally they widen sufficiently to form partiti which divide the joint-cavity into two compartments, *e.g.* the costo-central, a certain of the chondro-sternal joints.

Interarticular fibro-cartilages or **menisci** (Fig. 207) are more or less compl partitions situated between and separating opposing articular surfaces, and wl complete they divide the joint cavity into two distinct compartments. By periphery, a meniscus is rather to be associa with the joint capsule than with the arti lating bones, although its attachments n extend to non-articular areas on the latter

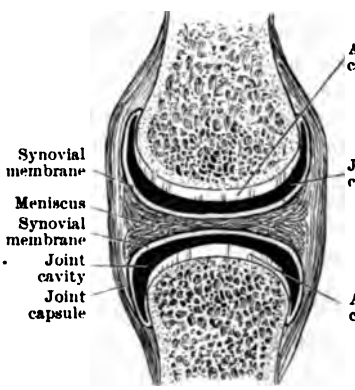

FIG. 207.—DIAGRAM OF A DIARTHRODIAL JOINT WITH AN INTERARTICULAR MENISCUS DIVIDING THE JOINT-CAVITY INTO TWO COMPARTMENTS.

Both interarticular ligaments and men have their free surfaces covered by syno membrane.

Adipose tissue forming pads of varying is usually found in certain localities wit the joint, between the synovial membrane the surfaces which it covers. These pads soft and pliable, and act as packing mate filling up gaps or intervals in the jo During movement they adapt themselve the changing conditions of the articulatio

In addition to merely binding together or more articulating bones, ligaments perf very important functions in connexion v the different movements taking place at a joint. They do not appreciably lengt under strains, and thus ligaments may act as inhibitory structures, and by bec ing tense may restrain or check movement in certain directions.

Synovial membranes, in the form of closed sacs termed **synovial bursæ**, are frequently f in other situations besides the interior of joints. Such bursæ are developed for the purpo reducing the friction, (*a*) between the integument and certain prominent subcutaneous bony jections, as, for instance, the point of the elbow, or the front surface of the patella (subcutan synovial bursæ); (*b*) between a tendon and some surface, bony or cartilaginous, over whi plays (subtendinous synovial bursæ); (*c*) between a tendon or a group of tendons and the of osteo-fascial tunnels, in which they play (thecal synovial bursæ). Subtendinous syn bursæ are often placed in the neighbourhood of joints, and in such cases it not infrequ

[1] The term "synovial membrane" has been so long in use that one hesitates to discard it, even althoug structure so described is not in many cases capable of being *removed* from the objects of which it forms a A more precise description in these cases would be "synovial surface." There is still considerable c whether the "synovial fluid" is a true secretion or merely a diluted friction product.

appens that there is a direct continuity between the bursa and the synovial membrane which nes the cavity of the joint through an aperture in the joint capsule.

THE DIFFERENT KINDS OF MOVEMENT AT JOINTS.

Reference has already been made to the existence of fixed axes of movement as a basis for the classification of certain forms of diarthrodial joints. Hence it is evident that the movements which are possible at any particular joint depend to a large extent upon the shape of its articular surfaces as well as upon the nature of its various ligaments. Therefore the technical terms descriptive of movements either indicate the directions in which they occur, or else the character of the completed movement.

In the great majority of articulations between short bones, the amount of movement is so restricted, and the displacement of the opposing articular surfaces so slight, that the term **gliding** sufficiently expresses its character.

A **gliding** movement of an extensive kind, for example that of the patella upon the femur, in which the movement largely resembles that of the tyre of a wheel revolving in contact with the ground so that different parts are successively adapted to each other, is called **co-aptation**.

Articulations between long bones, on the other hand, are usually associated with a much freer range of movement, with a corresponding variety in its character. **Rotation** is a movement about an axis which is longitudinal. Sometimes it is the only form of movement which a joint possesses; at other times it is merely one of a series of movements capable of execution at the same joint. **Flexion** or bending is a movement in which the formation of an angle between two parts of the body is an essential feature. As it is possible to perform this movement in relation to two axes, viz. a transverse and an antero-posterior axis, it is necessary to introduce qualifying terms. Thus, when two anterior or ventral surfaces are approximated, as at the hip-, elbow-, or wrist-joints, the movement is called **ventral, anterior,** or **palmar flexion**; but if posterior or dorsal surfaces be approximated by the process of bending, then the flexion becomes **posterior** or **dorsi-flexion**, as at the knee- or wrist-joints. Further, at the wrist-joint, the formation of an angle between the ulnar border of the hand and the corresponding aspect of the forearm, produces **ulnar flexion**, and similarly the bending of the hand towards the radial border of the forearm is **radial flexion**.

Extension or straightening consists in obliterating the angle which resulted from flexion. In the case of certain joints, therefore, such as the elbow, wrist, and knee, the segments of the limb occupy a straight line as regards each other when extended.

At the ankle-joint the natural attitude of the foot to the leg is flexion at a right angle. The diminution of this angle by approximating the dorsum of the foot towards the front of the leg constitutes *flexion*; while any effort at placing the foot and leg in a straight line, *i.e.* obliteration of the angle, as in pointing the toes towards the ground and raising the heel, constitutes *extension*.

Abduction is a term which either expresses movement of an entire limb, in a direction away from the mesial plane of the body, or of a digit, away from the plane of the middle finger in the hand, or the plane of the second toe in the case of the foot.

Adduction is the reverse of abduction, and signifies movement towards the mesial plane of the body, or towards the planes indicated for the digits of the hand and foot.

Circumduction is a movement peculiarly characteristic of multiaxial or ball-and-socket joints. It consists in combining such angular movements as flexion, extension, abduction, and adduction, so as to continue the one into the other, whereby the joint forms the apex of a cone of movement, and the free end of the limb travels through a circle which describes the base of this cone.

THE DEVELOPMENT OF JOINTS.

Just as the question of structure determines to a large extent the presence or absence of movement in joints, so in tracing their development it will be found that the

manner of their appearance forecasts their ultimate destination as immovable or mo able articulations.

All joints arise in mesodermic tissue which has undergone more or less differentiatio

When this differentiation has produced a continuous membranous layer, in whic ossific centres representing separate skeletal segments make their appearance, we get th primitive form of suture. The plane of the articulation merely indicates the limit o the ossific process extending from different directions. If, again, the differentiation o the mesoblast has resulted in the formation of a continuous cartilaginous layer, in whic ossification commences at separate centres, the plane of the articulation is marke out by the unossified cartilage—in other words, the articulation is a synchondrosis. Ult mately this disappears through the extension of the process of ossification.

To some extent sutures also disappear, although their complete obliteration is no usual even in aged people. Developmentally, therefore, synarthroses or immovabl joints do not present any special structural element, and, speaking generally, they hav only a temporary existence.

The development of all movable joints is in marked contrast to that of synar throses. Not only are they permanent arrangements so far as concerns normal conditions but they never arise merely as planes which indicate the temporary phase of an ossifi process. From the outset they present distinct skeletal units, from which the specia structures of the joint are derived.

The primitive movable joint is first recognised as a mass of undifferentiated meso dermic cells situated between two masses, which have differentiated into primitive cartilage

The cell-mass which constitutes the joint-unit presents the appearance of a thick cellular disc, the proximal and distal surfaces of which are in accurate apposition with th primitive cartilages, while its circumference is defined from the surrounding mesoderm b a somewhat closer aggregation of the cells of which the disc is composed. From thi cellular disc or joint-unit all the structures characteristic of amphiarthrodial and dia throdial joints are ultimately developed.

Thus by the transformation of the circumferential cells into fibrous tissue the inves ing ligaments are produced. Within the substance of the disc itself a transverse cleft more or less well-defined and complete, makes its appearance. In this manner the disc i divided into proximal and distal segments, separated from each other by an interv which is the primitive joint cavity. This cleft, however, never extends so far as to inte rupt the continuity of the circumferential part of the disc which develops into the fibro tissue of the investing ligaments. From the proximal and distal segments of th articular disc the various structures, distinctive of movable joints, are developed.

Thus, in amphiarthrodial joints the cellular articular disc or primitive joint-unit giv origin to the following structures:—From its circumference, investing ligaments; fro its interior, the fibro-cartilaginous plate or disc in which an imperfect joint cavity wi corresponding imperfect synovial may be found.

In the case of a diarthrodial joint the changes take place on a more extended scal The joint cavity becomes a prominent feature, in relation to which the surroundi fibrous structures form an investing capsule, lined by a synovial membrane.

When a single cleft arises, but does not extend completely across the longitudinal a of the articular disc, the undivided portion develops into fibrous interarticular ligamen On the other hand, when two transverse clefts are formed, that portion of the cellul disc which remains between them becomes transformed into a fibro-cartilaginous int articular disc or meniscus, which in its turn may either be complete or incomplete, a thus we may obtain two distinct synovial joint cavities belonging to one articulation.[1]

In considering the development of the synovial membrane, and the surfaces on whi it is found in the interior of a joint, it is necessary to keep clearly in mind that a synov membrane is a special structure, whose function it is to produce a lubricating fluid synovia, and that, therefore, its position is determined by the essential necessity proximity to a direct blood-supply. In other words, this condition is provided by parts of the interior of a joint cavity except the articular encrusting cartilage. Con quently synovial membrane is only absent from the free surface of articular cartila although it forms a thicker layer upon the inner surface of the joint capsule than up the free surfaces of interarticular ligaments and menisci.

[1] From a series of observations upon the development of diarthrodial joints, the writer considers th there is evidence to show that the "cellular articular disc" is directly responsible for the production the epiphyses which adjoin the completed joint cavity, and that, among such amphiarthroses as ex between the bodies of vertebræ, not only the intervertebral disc, but the proximal and distal epiphy which ultimately unite with the vertebral bodies have a common origin in the joint-unit.

It is not necessary to suppose that the synovial membrane has disappeared from these ticular cartilages as the result of friction, because, notwithstanding constant friction, ch parts as the interior of capsular ligaments or the semilunar cartilages of the knee-int have not been denuded of their synovial covering.

MORPHOLOGY OF LIGAMENTS.

From what has been said in connexion with the development of joints, it will be evident at ligaments are essentially products derived from the cellular articular disc.

Nevertheless, in relation to the fully-formed joint, many structures are described as ligaments hich do not take origin in the manner just indicated. Some of these ligamentous structures emain fairly distinct from the capsular ligaments with which they are immediately associated; thers become thoroughly incorporated with the capsular ligaments and cannot be separated herefrom, while yet others may be found situated within the capsule of a joint, and thus play he part of interarticular ligaments.

Instances of each of these forms of adventitious ligaments may be readily given. For example, we may instance the expansion of the tendon of the semimembranosus muscle to the posterior ligament of the knee-joint, and the offshoots from the tendon of the tibialis posticus muscle to the plantar aspects of various tarsal bones, as illustrations of structures which play an important part as ligaments, but are not indelibly incorporated with the joint capsule.

Of structures which have become indelibly incorporated with the primitive capsule, we may instance the broad tendinous expansions of the quadriceps extensor muscle around the knee-joint.

The internal lateral ligament of the same joint is regarded as a detached portion of the tendon belonging to that part of the adductor magnus muscle which takes origin from the ischium, while the external lateral ligament of the knee is considered by some to be the primitive femoral origin of the peroneus longus muscle. Another illustration of the same condition is found in the coraco-humeral ligament, which is regarded by some as representing a detached portion of the pectoralis minor muscle.

Two illustrations may be given of structures playing the part of ligaments within the capsule of a joint, although in the first instance they are not developed as ligaments. It is questionable if the ligamentum teres of the hip-joint is an interarticular ligament in the true sense of the term; it has been regarded as the isolated and displaced tendon of the ambiens muscle found in birds. In the shoulder-joint, many observers look upon the superior gleno-humeral ligament as representative of the ligamentum teres.

Such structures as the stylohyoid ligament and the internal lateral ligament of the temporo-mandibular joint, although described as ligaments, are in reality skeletal parts which have not attained their complete ossific development.

Again, certain portions of the deep or muscular fascia of the body which become specialised into restraining and supporting bands (*e.g.* the ilio-tibial band of the fascia lata; the stylo-mandibular ligament; the anterior and posterior annular ligaments of the wrist-joint; the anterior, inner, and outer annular ligaments of the ankle-joint), although called ligaments, have no direct developmental association with articular ligaments.

Lastly, the ligament of Poupart and the ligament of Gimbernat, being special developments in connexion with an expanded tendon or aponeurosis, are still further removed from association with an articulation.

LIGAMENTS OF THE VERTEBRAL COLUMN AND SKULL.

All vertebræ, with the exception of those which deviate from the common vertebral type, present two sets of articulations whose various parts are arranged upon a uniform pattern. Thus every pair of typical vertebræ presents an articulation between the centra, termed **intercentral**, and a pair of articulations between the neural arches, called **interneural**. With the latter there are associated various important accessory ligaments which bind together laminæ, spinous processes, and transverse processes.

Intercentral Articulations.—These are amphiarthrodial joints. Singly, they present only a slight degree of mobility, but when this amount of movement is added to that of the whole series, the range of movement of the spine becomes considerable. The articular surfaces are the flattened surfaces of adjacent vertebral bodies. They are bound together by the following structures:—

Intervertebral Discs (fibro-cartilagines intervertebrales, Fig. 208).—Each disc accommodates itself to the space it occupies between the two vertebral bodies, to both of which it is firmly adherent. The discs, from different parts of the spinal column, vary in vertical thickness, being thinnest from the third to the seventh dorsal vertebra, and thickest in the lumbar region. In the cervical and lumbar regions each disc is thicker in front than behind, thereby assisting in the production of the

anterior convexity which characterises the spinal column in these two regions. In the dorsal region the discs are thinnest on their anterior aspects in correspondence with the anterior concavity of this section of the spine.

Each disc consists of a circumferential portion (annulus fibrosus), formed for

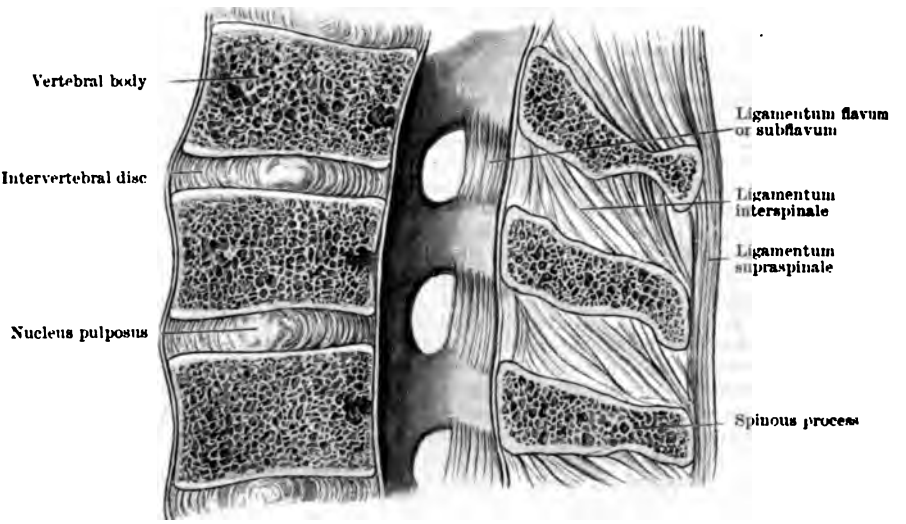

FIG. 208.—MESIAL SECTION THROUGH A PORTION OF THE LUMBAR PART OF THE SPINE.

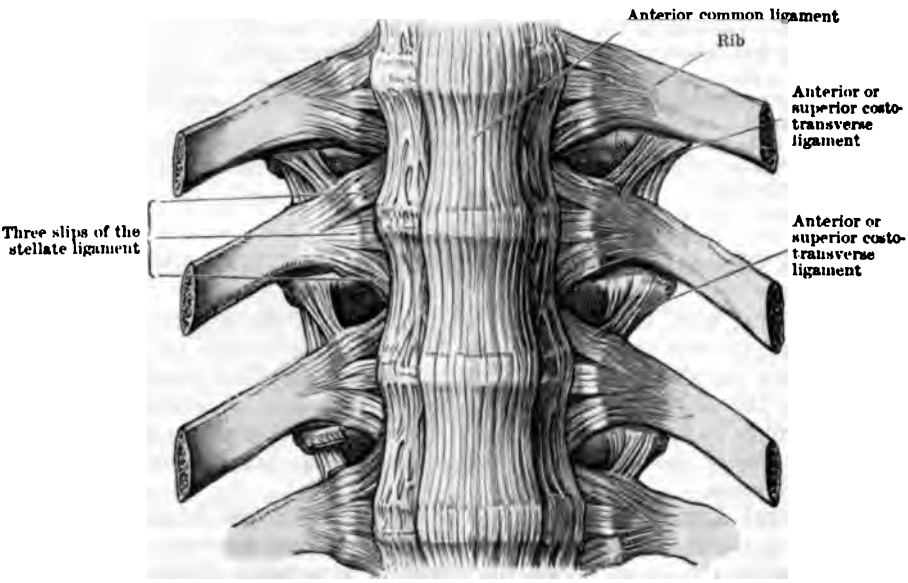
the most part of oblique parallel fibres running from one vertebra to the other. Horizontal fibres are also found. The axial or central part of the disc is elastic, soft, and pulpy (nucleus pulposus).[1]

The upper and lower surfaces of the disc are closely adherent to the adjoining



Anterior common ligament

Anterior or superior costo-transverse ligament

FIG. 209.—ANTERIOR COMMON LIGAMENT OF THE VERTEBRAL COLUMN, AND THE COSTO-VERTEBRAL JOINTS AS SEEN FROM THE FRONT.

epiphyseal plates of the vertebral bodies, and as ossification advances, the distinction between epiphyseal plates and vertebral body disappears.

As a rule the transverse diameter of the disc corresponds to that of the vertebral bodies which it joins together; but in the cervical region, where the lowe

[1] This pulpy substance does not present a joint cavity, but in certain cases it is more or less divided by fissures which occupy a transverse horizontal direction.

argin of the superimposed vertebra is overlapped on each side by the one which ars it, the disc does not extend to the extreme lateral margin, and in this position small diarthrosis may be seen at each lateral margin of the disc.

The **anterior common ligament** (lig. longitudinale anterius, Fig. 209) consists f a wide stratum of longitudinal fibres which extends from the front of the axis ertebra to the front of the upper segment of the sacrum, and becomes gradually ider from above downwards. It lies in front of the intervertebral discs, to which t is firmly attached as it passes from one vertebra to the other. Its fibres vary in ength. Some are attached to contiguous margins of two adjoining vertebræ; others pass in front of one vertebra to be attached to the next below, and yet others find their lower attachment three or four vertebræ below the one from which they started. None of the fibres are attached to the transverse depression on the front of a vertebral body.

The **posterior common ligament** (lig. longitudinale posterius, Fig. 210) is found within the spinal canal upon the posterior aspect of the vertebral bodies. It consists of longitudinal fibres, and it extends from the back of the sacrum to the axis vertebra, superior to which it is continued to the skull as the posterior occipito-axial ligament. Opposite each intervertebral disc it is attached to the entire width of the adjacent margins of the two vertebral bodies, its fibres being continued over the posterior surface of the disc. In the lumbar and dorsal regions the width of the ligament is considerably reduced opposite the back of each vertebral body, and thus it forms a series of dentate projections along both of its margins; but in the cervical region the width of the ligament is more uniform.

One or two large thin-walled veins escape from the body of each vertebra under cover of this ligament.

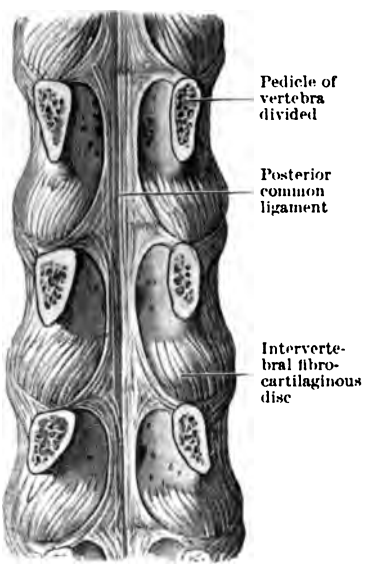

FIG. 210.—POSTERIOR COMMON LIGAMENT OF THE VERTEBRAL COLUMN.

Interneural Articulations.—The neural arch of each typical vertebra carries two pairs of articular processes, by means of which it articulates with adjacent neural arches. The articulations between these processes are true diarthroses of the arthrodial variety.

The distinctive characters of these articular surfaces, as regards their shape and direction in the different groups of vertebræ, have been referred to in the section on osteology.

All these articulations are provided with complete but very thin-walled **capsules** (capsulæ articulares), which are thinnest and loosest in the cervical region, where also the movements are freest. Each capsule is lined by a **synovial membrane.**

Associated with these interneural joints are certain ligaments which are accessory to the articulations, although they are quite distinct from the capsule.

The laminæ of adjoining vertebræ are bound together by the **ligamenta subflava** (ligamenta flava vel subflava, Fig. 211), which consist of yellow elastic fibres. The ligamenta subflava close the spinal canal in the intervals between the laminæ. Each ligament is attached superiorly to the anterior aspect of one lamina at a short distance above its lower border, and inferiorly it is attached to the posterior aspect of the subjacent lamina.

In the dorsal region, where the imbrication of adjoining laminæ is a prominent feature, these ligaments are not so distinctly visible from behind as they are in the regions where imbrication of the laminæ is not so marked.

Laterally they extend as far as the articular capsules, while mesially the margins of the ligaments of opposite sides meet under cover of the root of the spinous process.

Contiguous pairs of spinous processes are also attached to each other by **interspinous ligaments** (ligamenta interspinalia, Fig. 208). These are strongest in the

lumbar, and weakest in the dorsal region. Each consists of layers of ob interlacing fibres which spring from near the tips of the two adjacent spin radiate to their op margins. In the a posterior directio extend from the l the tip of the s process.

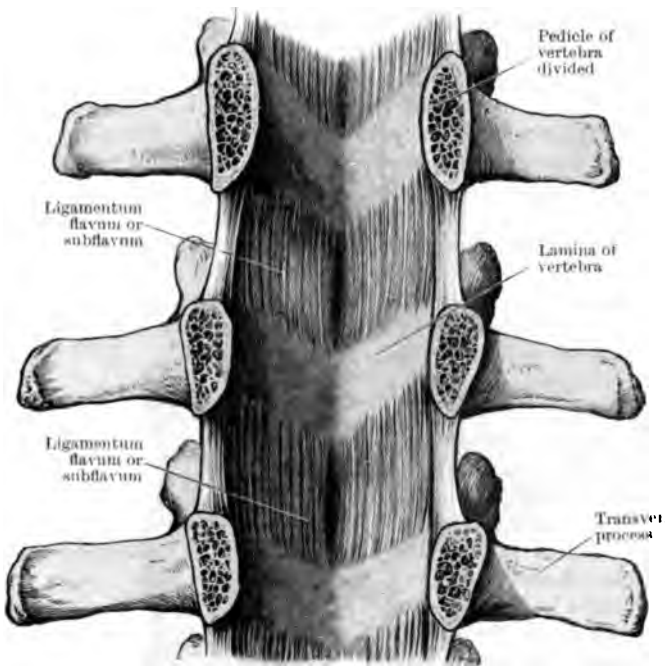

FIG. 211.—LIGAMENTA SUBFLAVA AS SEEN FROM THE FRONT AFTER REMOVAL OF THE BODIES OF THE VERTEBRÆ BY SAWING THROUGH THE PEDICLES.

The **supraspinou ments** (ligg. s spinalia, Fig. 208)(of longitudinal ba fibres of varying le They extend from to spine, being atta their tips, and are si superficial to, alt in continuity wit interspinous ligam

In the cervical this series of liga is extensively dev where they project wards from the s processes betwee muscles of the tw of the neck in the of an elastic pa called the **ligam nuchæ**.

The antero-posterior extent of the ligamentum nuchæ increases as it appr the occiput, where it is attached to the occipital crest from the external oc protuberance to the posterior border of the foramen magnum. Its posterior m is free, and extends from the external occipital protuberance to the spine vertebra prominens.

Between the transverse processes there are **intertransverse ligaments** (ligg. transversaria), which consist of vertical fibres extending from the postero-in aspect of one transverse process to the superior margin of that next below. ligaments are generally absent from the cervical and upper dorsal regions.

Sacro-coccygeal Joint.—The last piece of the sacrum is joined to the piece of the coccyx by an intervertebral disc, and the junction is rei more secure by the presence of certain strong ligaments. An **anterior lig** (lig. sacro-coccygeum anterius), continuous with the anterior common ligam placed in front. A **posterior ligament** (lig. sacro-coccygeum posterius), stretches downwards from the sharp border of the lower opening of the canal, strengthens the joint behind. A **lateral ligament** (lig. sacro-cocc laterale) supports the joint on each side, whilst strong bands pass betwe cornua of the two bones and constitute the **interarticular ligaments**.

Inter-coccygeal Joints.—So long as they remain separate, the different of the coccyx are joined by intervertebral discs and by anterior and posterio ments.

Movements of the Vertebral Column.—Although the amount of movement peri between any two vertebræ is extremely limited, yet the total range of movement cap being attained by the entire vertebral column is very considerable.

Flexion may occur both forwards and backwards at the intercentral articulations, bu freely in the lumbar and cervical regions than in the dorsal region, where the limited am intervertebral disc and the imbrication of the laminæ and spines restrict the movement. ward flexion is most pronounced in the cervical region, and forward flexion in the lumbar Between the articular surfaces of the interneural articulations a variety of movements a mitted, dependent upon the directions of these surfaces. Thus **lateral flexion** is permi

the lumbar, but not in the cervical or dorsal regions. Again, in the lumbar region rotation does not occur, owing to the shape of the articular processes, while it is possible in the dorsal region. In the cervical region the shape and position of the articular surfaces prevent the occurrence both of lateral flexion and of rotation as isolated movements, but a combination of these two movements may take place, whereby rotatory movement in an oblique median axis results. Finally, in the lumbar region, by combining the four forms of flexion, viz. forward, backward, and lateral, a certain amount of circumduction is possible.

Articulation of Atlas with Axis.

Between these two vertebræ three diarthroses occur. Two of them are situated laterally in relation to the articular processes, and are called arthrodial diarthroses, because of the flattened nature of the articulating surfaces. The third articulation is mesial in position. It is found between the smooth anterior surface of the odontoid process of the axis and the articular facet on the posterior aspect of the anterior arch of the atlas. This joint is a rotatory diarthrosis.

Ligaments.—Each of the joints is furnished with a **capsular ligament** whereby

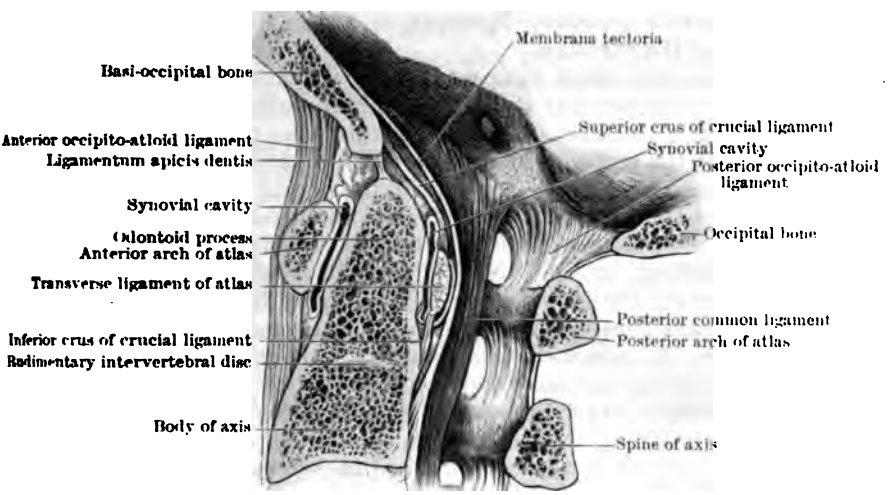

Fig. 212.—Mesial Section through the Occipito-atloid and Atlo-axoid Joints.

the joint cavity is circumscribed. In the case of the lateral articulations, each capsular ligament presents a distinct band, named the **accessory ligament**, which is situated within the neural canal (Fig. 213), and passes downwards and inwards from the lateral mass of the atlas to the superior aspect of the body of the axis.

The following additional ligaments constitute the leading bonds of union:—

The **anterior atlo-axoid ligament** (Fig. 212) is a membranous structure which is thin laterally, but strong mesially where it is thickened by a prolongation of the anterior common ligament. It extends from the anterior arch of the atlas to the front of the body of the axis.

The **posterior atlo-axoid ligament** (Fig. 212) occupies the position which is elsewhere taken by the ligamenta subflava. It extends from the posterior arch of the atlas to the upper border of the neural arch of the axis.

The **transverse ligament of the atlas** (lig. transversum atlantis, Figs. 212 and 213) is a strong band, placed transversely, which arches backwards behind the neck of the odontoid process of the axis. By its extremities it is attached to the tubercle on the inner aspect of each lateral mass of the atlas. A thin plate of fibro-cartilage is developed in its central part.

Synovial membrane lines each of the three capsular ligaments, and in addition a synovial sac is developed between the odontoid process and the transverse ligament. This is more extensive than the synovial cavity between the odontoid process and the atlas.

Articulation of Spine with Cranium.

There are two articulations between the atlas and the occiput. Each i diarthrosis in which movement takes place in relation to two axes, viz. transverse and the antero-posterior. The condyle of the occiput being biconv fits into the biconcave superior articular surface of the atlas, while the long axes the two joints are directed horizontally forwards and inwards.

Ligaments.—Each articulation is provided with a **capsular ligament** which thin but complete. It is attached to the rough non-articular surfaces surroundi the articular areas on the atlas and occiput.

The following supplementary ligaments are the chief structures which bind t atlas to the occiput:—

The **anterior occipito-atloid ligament** (membrana atlanto-occipitalis anteri Fig. 212) is a strong although thin membrane, attached inferiorly to the anteri arch of the atlas, and superiorly to the anterior half of the circumference of t foramen magnum. Laterally it is in continuity with the capsular ligaments, wh in the mesial plane, where it extends from the anterior tubercle of the atlas to t basi-occiput, it presents a specially well-defined thickened band which might regarded as a separate accessory ligament or as the beginning of the anter common ligament of the vertebræ.

The **posterior occipito-atloid ligament** (membrana atlanto-occipitalis posteri Fig. 212) is another distinct but still thin membrane which is attached superio to the posterior half of the circumference of the foramen magnum, and inferiorly the upper border of the posterior arch of the atlas. Laterally it also is continuc with the capsular ligaments. On each side of the mesial plane its inferior borc is arched in relation to the vertebral groove, and is therefore to some extent fr in order to permit the passage of the posterior primary division of the first cervi nerve and the vertebral artery. Not infrequently this arched border becon ossified, thus converting the groove in the bone into a foramen.

Synovial membrane lines each of the capsular ligaments. There is no dir articulation between the axis and the occiput, but union between them is effect by means of the following accessory ligaments:—

The **posterior occipito-axoid ligament** (membrana tectoria, Fig. 213) is situat within the neural canal, and is usually regarded as the upward continuation of t posterior common ligament of the vertebral bodies. It extends from the poster

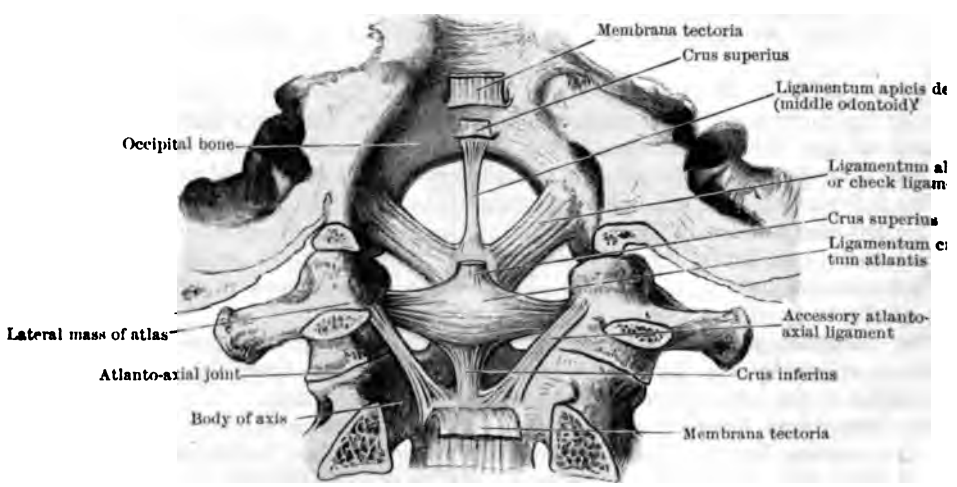

Fig. 213.—Dissection from behind of the Ligaments connecting the Occipital Bone, the Atl and the Axis with each other.

surface of the body of the axis to the basilar groove on the upper surface of basi-occipital bone, spreading laterally on the circumference of the foran magnum. Some of its deepest fibres are attached to the atlas immediately ab the atlo-axoid articulation.

Subjacent to the preceding ligament there is the **ligamentum cruciatum atlantis** Fig. 213), a structure which is very closely associated with the lig. transversum tlantis. It consists of a *crus transversum*, formed by the superficial fibres of he transverse ligament of the atlas; a *crus inferius*, consisting of mesial longiudinal fibres which are attached below to the posterior surface of the body of the axis, and above to the crus transversum and a *crus superius*, also mesial and ongitudinal, whose fibres extend from the crus transversum upwards to the posterior surface of the basi-occiput, immediately subjacent to the posterior occipito-axoid ligament.

The **check ligaments** or **lateral odontoid ligaments** (ligamenta alaria, Fig. 213) are two very powerful, short, and somewhat rounded bands. They are attached mesially to the sides of the summit of the odontoid process, and laterally to the tubercle on the inner aspect of the condylar portions of the occipital bone, viz. the ex-occipital bones.

The **middle odontoid ligament** (ligamentum apicis dentis, Fig. 213) consists of fibres running vertically upwards from the apex of the odontoid process to the mesial part of the anterior margin of the foramen magnum. This ligament to some extent represents an intervertebral disc, in the centre of which remains of the notochord may be regarded as present.

Even in advanced life a small lenticular mass of cartilage, completely surrounded by bone, persists in the plane of fusion between the odontoid process and the body of the axis.

Movements at these Joints.—At the joints between occiput and atlas the movements are very simple, and consist essentially of movements whereby the head is elevated and depressed upon the vertebral column (nodding movements). In addition a certain amount of oblique movement is possible, during which great stability is attained by resting the front and hinder parts of opposite condyles upon corresponding parts of the atlas.

The head and the atlas rotate together upon the axis, the pivot of rotation being the odontoid process, and the amount of rotation is limited by the check ligaments. No rotation can occur between the occiput and atlas, and stability between atlas and axis is best attained after a slight amount of rotation, similar to the oblique movement between occiput and atlas.

TEMPORO-MANDIBULAR JOINT.

This joint is an arthrodial **diarthrosis**. It occurs between the articular part of the glenoid fossa of the temporal bone and the condylar head of the mandible. These two articular surfaces are markedly dissimilar both in size and shape. In its general outline the articular surface of the head of the mandible is cylindrical, having its long axis directed from within outwards and forwards. On the other hand, the articular part of the glenoid fossa in front of the Glaserian fissure is concavo-convex from behind forwards. Its articular surface includes the eminentia articularis, the eminence at the base of the anterior root of the zygoma. The articular surfaces of the bones are clothed by hyaline encrusting cartilage, whilst the joint cavity is divided into an upper and lower part by a meniscus of fibro-cartilage.

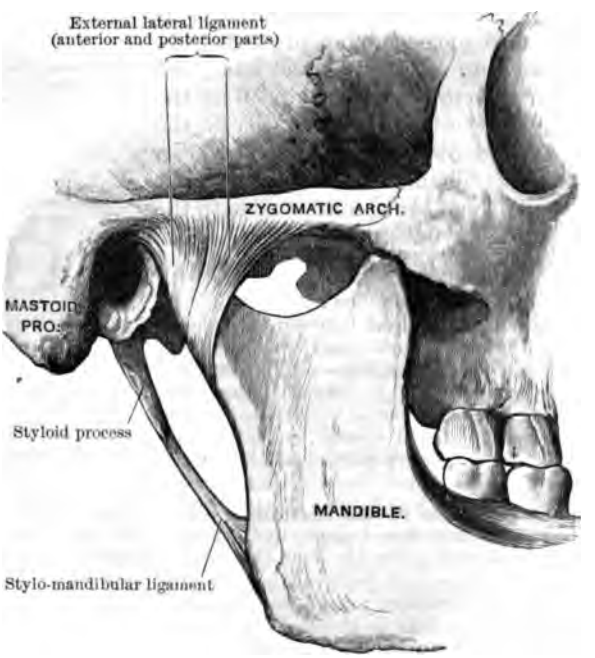

FIG. 214.—TEMPORO-MANDIBULAR JOINT.

Ligaments.—The joint is invested by a **capsular ligament** which is quite com-

plete, but is very thin on the inner side. The outer wall of the capsul **external lateral ligament** (lig. temporo-mandibulare, Fig. 214)—is divisibl anterior and posterior portions which are attached superiorly to the root t and lower border of the zygom inferiorly to the outer side and po border of the neck of the mandible. direction of its fibres is downward backwards.

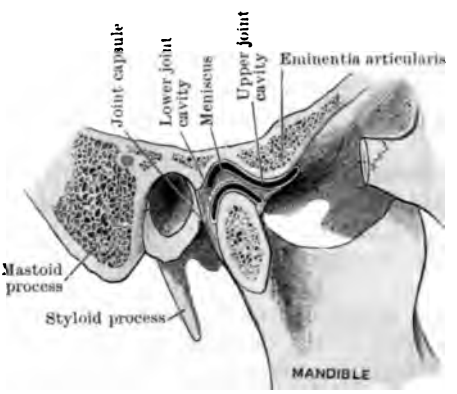

FIG. 215.—SECTION THROUGH THE TEMPORO-MANDIBULAR JOINT.

Within the capsule there is an articular disc or meniscus of fibro-car the **discus articularis** (Fig. 205), wh moulded upon the condyle of the ma below, and on the articular surface temporal bone above. It thus compe for the incongruity between the art surfaces of the two bones. The attached circumferentially to the ca It is widest in the transverse dir thicker behind than in front, and th towards the centre, where it may b forated. Its anterior margin is intimately associated with the insertion external pterygoid muscle.

A **synovial membrane** lines each of the compartments into which the cavity is divided by the meniscus. As a rule these membranes are separate each other, but they become continuous when the disc is perforated. The synovial membrane is larger and more loosely disposed than the lower.

Situated on the mesial aspect of the joint, but at a short distance from i quite distinct from the capsule, there is an accessory band called the in **lateral ligament** (lig. spheno-mandibulare, Fig. 216). Superiorly it is attached to the spinous process of the great wing of the sphenoid bone, and inferiorly to the lower as well as the hinder border or lingula of the inferior dental foramen. It is not an articular ligament in the true sense, for instead of being connected with the joint, it is developed in the tissue surrounding part of Meckel's cartilage.

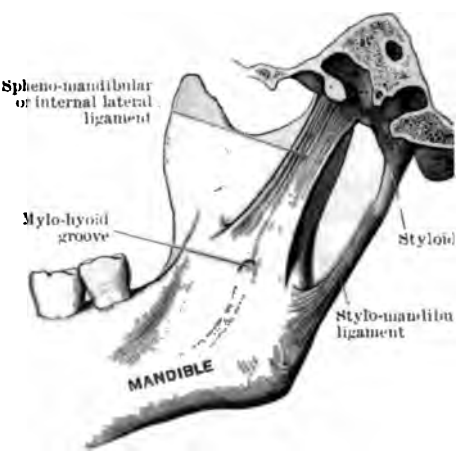

FIG. 216.—INTERNAL LATERAL LIGAMENT OF TEMPORO-MAXILLARY JOINT.

Portions of the following structures are found in the interval between the spheno-mandibular ligament and the ascending ramus of the mandible—viz. the external pterygoid muscle; internal maxillary vessels; inferior dental vessels and nerve; middle meningeal vessels; auriculo-temporal nerve; a deep portion of the parotid gland.

Movements of the Mandible.—The nature of the movements which the lower j perform is determined partly by the character of the articular surfaces of the temporo-man joint, and partly by the fact that, while the two joints always act simultaneously, th also, to some extent, perform the same movement alternately.

When movement takes place through the long or transverse horizontal axis of eacl the mandible may be elevated, as in clenching the teeth, or it may be depressed, as in In the latter movement the condyle leaves the glenoid fossa, and, along with the meni moves forwards until they rest upon the articular eminence. Meantime the chin descri arc of a circle, of which the centre or point of least movement corresponds to the positior inferior dental foramen, and thus the structures which enter at that foramen are pr against stretching. Coincidently with the forward movement of the condyle, it glid revolving manner upon the inferior aspect of the meniscus.

At any stage in the movement of depressing the chin the mandible may be protru that the inferior incisor teeth are projected in front of the upper set, a movement which from the condyles of the jaw being drawn forwards upon the articular eminences. A

elation of the condyle to the articular eminence occurs during the exaggerated depression of he mandible which results from yawning, in which position the articulation is liable to be lislocated. When the two joints perform the same movement alternately, a certain amount of ateral motion results, from the fact that the long axis of each joint presents a slight obliquity o the transverse axis of the skull, and consequently a grinding or oblique movement in the horizontal plane is produced. Excessive depression, with the risk of dislocation, is resisted by the fibres of the external lateral ligament which becomes tense.

In all movements of the mandible the meniscus conforms closely to the position of the condyle, and they move forwards and backwards together, but at the same time the meniscus does not restrict the movements of the condyle. Thus while the meniscus, along with the condyle, is gliding upon the temporal aspect of the joint, the condyle itself revolves upon the inferior surface of the meniscus.

Cranial Ligaments not directly associated with Articulations.

The **stylo-mandibular ligament** (lig. stylo-mandibulare, Figs. 214 and 216) is a specialised portion of the deep cervical fascia which extends from the anterior aspect of the tip of the styloid process of the temporal bone to the posterior border of the angle of the mandible, between the insertions of the masseter and internal pterygoid muscles.

The **pterygo-spinous ligament** (lig. pterygo-spinosum) is a membrane extending from the upper part of the posterior free margin of the external pterygoid plate, backwards and slightly outwards, to the spinous process of the sphenoid. An interval is left between its upper border and the floor of the skull for the outward passage of those branches of the inferior maxillary nerve which supply the external pterygoid, temporal, and masseter muscles. This ligament has a tendency to ossify either wholly or partially.

The **stylo-hyoid ligament** (lig. stylo-hyoideum) may be regarded as the downward continuation of the styloid process of the temporal bone. Inferiorly it is attached to the lesser cornu of the hyoid bone. It is not infrequently ossified, in which case it constitutes the epihyal bone found in many animals.

THE JOINTS OF THE THORAX.

Costo-vertebral articulations (articulationes costo-vertebrales). The typical rib articulates with the vertebral column both by its head and by its tubercle. Thus, two sets of articulations, with their associated ligaments, exist between the ribs and the vertebræ, but each set is constructed upon a common plan, with the exception of certain joints situated at the upper and lower ends of the series, where the ribs themselves deviate from the typical form.

Costo-Central Joints.

The articulations of the heads of the ribs with the centra or bodies of the vertebræ (articulationes capitulorum, Fig. 209) are all diarthroses, which, from their somewhat hinge-like action, may be classed as ginglymoid.

The head of every typical rib is wedge-shaped, and presents two articular facets, an upper and a lower, separated from each other by an antero-posterior ridge which abuts against an intervertebral disc, while the articular facets articulate with similar surfaces on the contiguous margins of the two vertebræ adjoining the disc. These surfaces form a wedge-shaped depression or cup, the bottom of which is more elastic than the sides, and thus an arrangement is provided which tends to reduce the shock of blows upon the walls of the chest.

Each of these articulations is provided with a **capsular ligament** which surrounds and encloses the joint, and is attached to contiguous non-articular margins on the head of the rib and the two vertebral bodies. On its anterior or ventral aspect the capsule presents three radiating fasciculi which collectively form the **stellate or anterior costo-vertebral ligament** (lig. capituli costæ radiatum, Fig. 209). These fasciculi radiate from a centre on the front of the head of the rib, so that the middle fasciculus becomes attached to the intervertebral disc while

the upper and lower fasciculi proceed to the adjacent margins of the two vertebræ between which the disc is situated, and with which the rib articulates. To a slight extent these radiating fasciculi pass under cover of the lateral margin of the anterior common ligament of the vertebral bodies. In those joints in which the head of the rib does not articulate with an intervertebral disc the central fasciculus of the stellate ligament is wanting, but the other two retain the same general arrangement.

The **interarticular ligament** (lig. capituli costæ interarticulare) consists of short transverse fibres within the capsule. These are attached, on the one hand, to the ridge which intervenes between the two facets on the head of the rib, and on the other to the lateral aspect of the intervertebral disc. This ligament is not a meniscus, but merely an interarticular ligament, of width sufficient to divide the joint cavity into an upper and a lower compartment. It is absent from those joints which do not articulate with an intervertebral disc, *i.e.* from those ribs which only articulate with the body of one vertebra.

The interarticular ligament is supposed to represent the outer end of a ligament which, under the name of the **lig. conjugale costarum**, connects the heads of the ribs of certain mammals across the posterior aspect of the intervertebral disc, and, in the human subject, until the seventh month of fœtal life, connects the posterior aspects of the necks of a pair of ribs with each other across the mesial plane.

Synovial membrane lines each joint cavity, and therefore, in all cases where the joint is divided into two compartments, each one has its own synovial lining.

Costo-Transverse Joints.

The tubercle of each *typical* rib articulates with the transverse process of the lower of the two dorsal vertebræ with which the head of the rib is associated (articulatio costo-transversaria). Near the tip of the transverse process there is an articular facet, on its anterior aspect, for articulation with the corresponding facet on the mesial articular part of the rib tubercle. The joint so formed is an arthrodial diarthrosis.

The joint cavity is surrounded by a comparatively feeble **capsular ligament**, which is attached immediately beyond the margins of the articular facets, and in which no special bands can be distinguished.

A simple **synovial membrane** lines the capsular ligament in all cases where the latter is present.

The following accessory ligaments, in connexion with this joint, strengthen and support the articulation:—

The **anterior** or **superior costo-transverse ligament** (ligamentum costo-transversarium anterius, Fig. 209) consists of strong bands of fibres which are attached to the upper border of the neck of the rib, extending from the head outwards to the non-articular part of the tubercle. All these fibres may be traced upwards. Those situated nearest to the head of the rib proceed obliquely upwards and outwards, to be attached to the transverse process immediately above, but with extensions to the adjoining rib and its costo-transverse capsular ligament. Others proceed almost vertically upwards to the adjoining transverse process, while those which ascend from the upper surface of the tubercle pass obliquely upwards and inwards to reach the postero-inferior aspect of the adjoining transverse process.

The **posterior costo-transverse ligament** (ligamentum costo-transversarium posterius) is a band of transverse fibres applied to the postero-external aspect of the capsule. By one end these fibres are attached to the tip of the transverse process behind its articular facet, and by the other to the external rough surface of the tubercle of the rib.

The **middle costo-transverse ligament** (lig. colli costæ) consists of short fibres which stretch from the posterior aspect of the neck of the rib, backwards and inwards, to the front of the transverse process, but, in addition, a proportion of the fibres passes to the posterior aspect of the inferior articular process of the upper of the two vertebræ with which the head of the rib articulates.

The following exceptions to the general plan of rib-articulation indicated above ust be noted:—

1. There is no articulation between the eleventh and twelfth ribs and the transverse processes of the corresponding vertebræ.
2. The superior costo-transverse ligament is wanting from the first rib, and is either rudimentary or wanting in the case of the twelfth rib.
3. The middle costo-transverse ligament is rudimentary in the eleventh and twelfth ribs.

The **ligamentum lumbo-costale** extends from the upper surface of the base of the ransverse process of the first lumbar vertebra to the under surface of the neck of he twelfth rib, as well as to the under surface of the transverse process of the welfth dorsal vertebra.

Articulations between the Ribs and their Cartilages.

Each rib possesses an unossified portion, termed its costal cartilage. As age dvances, this cartilage may undergo a certain amount of superficial ossification, ut it never becomes entirely transformed. The line of demarcation between one and cartilage is clear and abrupt, and usually the bone forms an oval cup, in hich the end of the cartilage is retained by means of the continuity which exists between the periosteum and the perichondrium. There is no articulation in the proper sense between the rib and its cartilage, although a synovial cavity has occasionally been found between the first rib and its cartilage.

Interchondral Joints.

These articulations are arthrodial diarthroses, and they are found between adjoining margins of certain of the costal cartilages, viz. from the fifth to the eighth or ninth. The cartilages which thus articulate develop flattened, somewhat conical, prolongations of their substance, and thereby the intercostal spaces are interrupted where these flat articular facets abut against each other. Each joint is closed by a surrounding **capsular ligament**, the superficial and deep aspects of which are specially strengthened by **external** and **internal interchondral ligaments**. These bands extend obliquely between adjacent cartilages.

A **synovial membrane** lines each joint capsule.

Costo-sternal Joints.

The upper seven pairs of costal cartilages, as a rule, extend to the lateral margins of the sternum (articulationes sternocostales). Of these, the first pair is implanted directly upon the manubrium sterni. The ossific process ends abruptly in connexion with the rib, and also ceases as suddenly in connexion with the sternum, and hence the cartilage does not normally present an articulation at either end.

From the second to the seventh pairs of ribs inclusive, the costo-sternal joints are constructed upon the type of arthrodial diarthroses, although, in the case of the sixth and seventh cartilages, the joint cavity is always small, and is frequently obliterated.

The sternal end of each of these costal cartilages presents a slight antero-posterior ridge which fits into a shallow V-shaped depression upon the lateral margin of the sternum. With the exception of the sixth cartilage, the others articulate opposite the lines of union between the primary segments of the sternum, whereas the sixth articulates upon the side of the lowest segment of the meso-sternum.

Each joint is enclosed by a **capsular ligament**, composed of fibrous tissue, attached to the adjacent borders of the articulating elements. Specially strong fibres distinguish the superficial and deep aspects of the capsule.

The **anterior costo-sternal ligament** (lig. costo-sternalium radiatum, Fig. 217) is composed of strong fibres which radiate from the anterior surface of the costal cartilage, near its sternal end, to the front of the sternum. The ligaments of opposite sides interlace with each other, and so cover the front of the sternum with a felted membrane—the **membrana sterni**.

The **posterior costo-sternal ligament**—also a part of the capsule—has attachments similar to the foregoing, but the arrangement of its fibres is not so powerful.

The **ligamentum costo-xiphoidea** passes from the front of the upper part of the xiphoid cartilage, obliquely upwards and outwards to the front of the seventh, and sometimes to the front of the sixth costal cartilage.

Within the capsules of these joints **interarticular ligaments** (ligg. sterno-costalia interarticularia, Fig. 217) may be found. Their disposition is somewhat uncertain, for

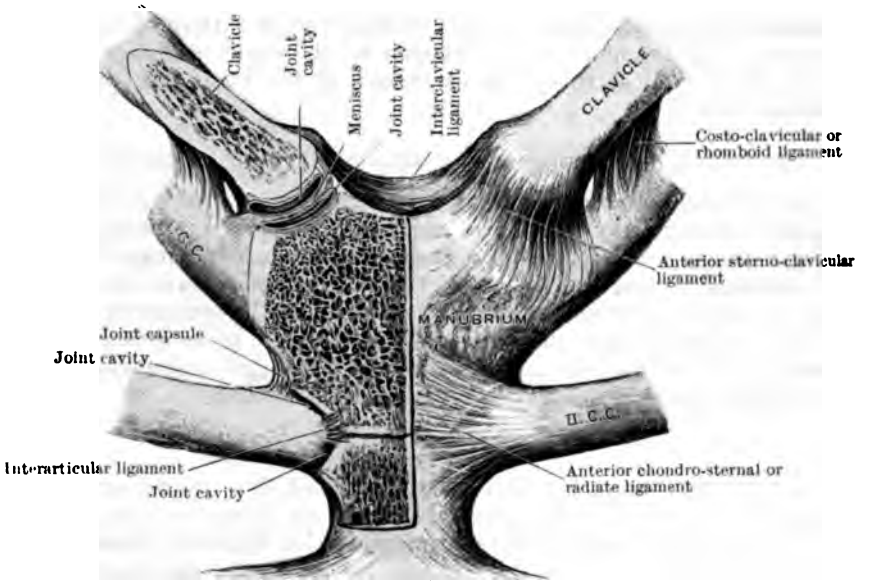

FIG. 217.—STERNO-CLAVICULAR AND COSTO-STERNAL JOINTS.

whereas, in the case of the second pair of cartilages, they invariably divide the joint cavity into two distinct compartments—an upper and a lower—such an arrangement is very uncertain in the other joints, and they occasionally, especially in the cases of the sixth and seventh cartilages, entirely obliterate the joint cavity. These ligaments extend horizontally between the ends of the costal cartilages and the side of the sternum.

Synovial membrane is found wherever a joint cavity is developed, and therefore there may be one or two synovial membranes, according to the presence or absence of a proper interarticular ligament. When the joint cavity is obliterated by the fibrous structure which represents the interarticular ligament, a synovial membrane is also absent.

STERNAL ARTICULATIONS.

Primarily the sternum consists of an elongated plate of hyaline cartilage, which becomes subdivided into segments by the process of ossification.

The four segments of which the **gladiolus** is originally composed unite with each other after the manner of typical synchondroses.

Similarly the ensiform cartilage and the gladiolus ultimately become united. It is not usual to find the manubrio-gladiolar joint obliterated by the ossification of the two bony segments. Even in advanced life it remains open, and the joint partakes of the nature of an amphiarthrosis (Fig. 217), although a joint cavity is not found under any circumstances in the plate of fibro-cartilage which intervenes between the manubrium and the gladiolus.

The **membrana sterni**, to which reference has already been made, assists in strengthening the union between the different segments of the sternum.

Movements of the Ribs and Sternum.—These movements may be considered either independently of, or as associated with, respiration.

In the former condition the ribs move in connexion with flexion and extension of the vertebral column, being more or less depressed and approximated in the former, and elevated

lled apart in the latter case. Considered in connexion with respiration, it is necessary to serve that, to all intents and purposes, the vertebral column and the sternum are rigid structures. ext we must remember that the heads of all the ribs occupy fixed positions, and similarly e anterior ends of seven pairs of cartilages are fixed to the lateral margins of the sternum. he ribs thus form arches, presenting a large amount of obliquity from behind forwards. Therefore, during inspiration, when the rib is elevated, the arch becomes more horizontal, and the ansverse diameter of the chest is increased. At the same time, the anterior ends of the sternal ibs tend to thrust the sternum forwards and upwards; but the nature of the attachment of the irst pair of ribs to the sternum, as well as the attachment of the diaphragm to the ensiform artilage, prevents this movement from becoming excessive, and hence the sternum becomes a line of resistance to the forward thrust of the ribs. As a consequence, the ribs rotate upon themselves about an oblique axis which passes downwards, outwards, and backwards through the capitular joint and the neck of the rib anterior to the costo-transverse joint.

In this way increase, both of the antero-posterior and transverse diameters of the thorax, is provided for, although the amount of increase is not equally pronounced in all planes. Thus at the level of the first rib very little eversion is possible, because the axis of rotation is nearly transverse, and therefore any increase in the transverse or antero-posterior thoracic diameters at this level may be disregarded, although a certain amount of elevation of the manubrium sterni and anterior end of the first rib is evident.

Below the level of the sixth rib elevation and rotation of the rib during inspiration are usually said to be complicated by a certain amount of backward movement, due to the character of the costo-transverse joint, until, in the case of the last two ribs, which are destitute of costo-transverse joints, a movement backwards is almost entirely substituted for elevation. It is probable, however, that the movements of the asternal ribs exactly correspond to those of the sternal series, and that by the contraction of the costal digitations of the diaphragm the anterior ends of the asternal ribs are provided with fixed positions comparable to those supplied by the sternum to the ribs of the sternal series.

We may therefore say that during inspiration the ribs move upwards and outwards between their fixed ends, while as a whole the rib rotates, and its anterior end is thrust slightly forwards.

During expiration these movements are simply reversed.

THE ARTICULATIONS OF THE SUPERIOR EXTREMITY.

The bony arch formed by the clavicle and scapula articulates directly with the axial skeleton only at one point, viz. the sterno-clavicular joint.

ARTICULATIONS OF THE CLAVICLE.

The Sterno-clavicular Joint.

The sterno-clavicular joint (articulatio sterno-clavicularis) is an example of an arthrodial diarthrosis. The articular surfaces concerned in its formation present the following appearances:—

1. The sternal end of the clavicle is somewhat triangular in outline, having its most prominent angle directed downwards and backwards. The anterior and posterior sides of the triangle are slightly roughened for the attachment of ligaments, while the base or inferior side is smooth and rounded, owing to the prolongation of the articular surface to the inferior aspect of the bone. In the antero-posterior direction the articular surface tends to be concave, while vertically it is slightly convex.

2. An articular facet, situated on the superior lateral angle of the manubrium sterni, but in a plane slightly behind the supra-sternal notch, articulates with the clavicle. This facet is considerably smaller than the clavicular facet with which it articulates.

3. The superior surface of the first costal cartilage close to the sternum also participates to a small extent in the articulation.

It should be noted that the articular surfaces of the clavicle and sternum are covered mainly by **fibro-cartilage**.

A **capsular ligament** is well marked on all sides except inferiorly, where it is very thin.

The **anterior sterno-clavicular ligament** (Fig. 217) forms part of the capsule, and consists of short fibres which extend obliquely downwards and inwards from the anterior aspect of the sternal end of the clavicle to the adjoining anterior surface of the sternum and the anterior border of the first costal cartilage.

The **posterior sterno-clavicular ligament** also forms part of the capsule, and

consists of similarly disposed, but not so strong, oblique fibres situated on t posterior aspect of the articulation.

A **fibro-cartilaginous meniscus** (discus articularis, Fig. 217) divides the joi cavity into two compartments. It is nearly circular in shape, and adapts itself the articular surfaces between which it lies. It is thickest at the circumference a thinnest at the centre, where it occasionally presents a perforation, there permitting the two synovial cavities to intercommunicate. By its circumference is in contact with, and adherent to, the surrounding capsule, but its upper margin attached to the apex of the articular surface of the clavicle, while by its low margin it is fixed to the sternal end of the first costal cartilage.

Two **accessory ligaments** are associated with this joint, viz. the interclavicul and the rhomboid.

The **interclavicular ligament** (Fig. 217) is a structure of considerable strengt forming a broad band of fibrous tissue which is attached to the superior rounded ang or apex of the sternal end of the clavicle as well as to the adjacent margins of t articular surface. Its fibres pass across the interclavicular notch to become attach to corresponding parts of the opposite clavicle, but in their course they dip down in the suprasternal notch, in which many of them are fixed to the sternum. In th way their presence neither bridges nor obliterates the notch between the t clavicles, and the ligament really becomes a superior sterno-clavicular ligament f each joint.

The **rhomboid ligament** (lig. costo-claviculare, Fig. 217) consists of short, stro fibres which are attached inferiorly to the upper surface of the first costal cartila They pass obliquely upwards and outwards to a rough impression situated on t lower aspect of the sternal end of the clavicle, and are distinct from the capsul ligament. Occasionally a bursa is found in the interior of this ligament.

As a rule there are two **synovial membranes** lining the two joint cavities (F 217), separated from each other by the interarticular meniscus. Sometimes, howev the two membranes establish continuity through a perforation in the meniscus.

The Acromio-clavicular or Scapulo-clavicular Joint.

The acromio-clavicular joint (articulatio acromio-clavicularis) is anoth instance of an arthrodial diarthrosis. It is situated between the acromial end the clavicle and the inner aspect of the acromion process of the scapula. Ea articular surface is an oval, flattened facet, covered by **fibro-cartilage.**

The **ligaments** which surround this small joint form a complete **capsu** (capsula articularis), of which the upper and lower parts are specially strong, a are therefore named the **superior** and **inferior acromio-clavicular ligaments** (Fig. 21 These consist of short fibres passing between the adjacent rough margins of t two bones in the positions indicated by their names.

A **meniscus** (discus articularis), which is nearly always incomplete, and m occasionally be wanting, is usually found within the joint cavity, where it l obliquely, with its upper margin farther from the mesial plane than its lo margin, and having its borders attached to the surrounding capsule. Frequen the meniscus is wedge-shaped, with its base directed upwards and its apex free.

A **synovial membrane** is found forming either a single or a double sac, accordin the condition of the meniscus. Complete division of the joint cavity, however, is ra

Ligamentum Coraco-claviculare.—Accessory to this articulation there is strong **coraco-clavicular ligament** which binds the acromial end of the clavicle the coracoid process of the scapula. It is readily divisible into two parts, viz. conoid and trapezoid ligaments.

The **conoid ligament** (Fig. 219) is situated internal to and slightly behind trapezoid. It is narrow and pointed at its inferior end, by which it is attacl to the upper aspect of the coracoid process, in close proximity to the suprascapu notch. Its upper end widens out in the manner expressed by its name, and attached to the conoid tubercle of the clavicle.

The **trapezoid ligament** (Fig. 219) is attached inferiorly to the upper surface of posterior half of the coracoid process, external and anterior to the attachment

ıe **conoid ligament.** Superiorly it is attached to the trapezoid ridge on the under ırface of the acromial end of the clavicle. Its outer and inner borders are free. ts anterior surface is principally directed upwards, and its posterior surface, to a imilar extent, looks downwards.

A synovial bursa usually occupies the re-entrant angle between these two ligaments.

Movements at the Clavicular Joints.—The movements of the inner end of the clavicle at the **sterno-clavicular joint** are limited in their range, owing to the tension of the ligaments. When the shoulder is raised or depressed the outer end of the clavicle moves upwards and downwards, whilst its sternal end glides upon the surface of the interarticular meniscus within the joint; when, on the other hand, the shoulder is carried forwards or backwards, the inner end of the clavicle along with the interarticular meniscus moves upon the sternal facet. In addition to these movements of elevation, depression, forward movement and backward movement of the clavicle, there is also allowed at the sterno-clavicular joint a certain amount of circumduction of the clavicle.

The part which is played by certain of the ligaments in restraining movement requires careful consideration. The **rhomboid ligament** checks excessive elevation of the shoulder, and restrains within certain limits both backward and forward movement of the clavicle. When the clavicle is depressed, as in cases where a heavy weight, such as a bucket of water, is carried in the hand, it receives support by resting upon the first rib, and the tendency for the inner end of the bone to start up out of its sternal socket is obviated by the tension of the **interarticular meniscus**, the **interclavicular ligament**, and the **anterior** and **posterior sterno-clavicular ligaments.**

The **interarticular meniscus** not only acts as a cushion which lessens the shock of blows received upon the shoulder, but it also acts as a most important bond of union, and prevents the inner end of the clavicle from being driven upwards upon the top of the sternum when force is applied to its outer end.

The movements at the **acromio-clavicular joint** are of such a kind as to allow the inferior angle, and to some extent the base of the scapula, to remain more or less closely applied to the chest-wall during the various movements of the shoulder. The strong connexion between the coracoid process and the acromial end of the clavicle, by means of the conoid and trapezoid ligaments, renders it necessary that the scapula should follow the clavicle in its various excursions. The presence of the acromio-clavicular joint, however, enables the scapula to change its position somewhat with reference to the clavicle as the shoulder is moved. Thus, when the shoulder is raised and depressed, a marked difference takes place in the angle between the two bones; again, when the shoulder is thrown forwards or backwards, these movements can be performed without altering in a material degree the direction of the glenoid cavity of the scapula, or in other words, the socket of the shoulder-joint.

The **conoid** and **trapezoid ligaments** set a limit upon the movements of the scapula at the acromio-clavicular joint. They both, but more particularly the trapezoid ligament, prevent the acromion process of the scapula from being carried inward below the outer end of the clavicle when blows fall upon the outer aspect of the shoulder.

Ligaments of the Scapula.

These ligaments are not directly connected with any articulation. The **coraco-acromial ligament** (lig. coraco-acromiale, Fig. 219) completes the arch between the coracoid and acromion processes of the scapula, and thus provides a secondary socket for the greater protection and security of the shoulder-joint. It is a flat triangular structure stretched tightly between its lines of attachment. By its base it is fixed to a varying amount of the postero-external border of the coracoid process, and by its narrower apical end to the tip of the acromion process, immediately external to the acromio-clavicular joint. Its surfaces look upwards and downwards, and its free borders outwards and inwards. It is thinnest in the centre, where it is sometimes perforated by a prolongation of the tendon of the pectoralis minor muscle.

The **suprascapular ligament** (lig. transversum scapulæ superius) is a distinct but short flat band which bridges the notch of the same name. It may be continuous with the conoid ligament, and it is frequently ossified. As a rule the foramen completed by this ligament transmits the suprascapular nerve, while the corresponding vessels travel above the ligament to reach the supraspinous fossa.

A small duplicate of this ligament may often be found bridging the foramen on its ventral aspect, subjacent to which small branches of the suprascapular artery return from the supraspinous to the subscapular fossa.

The **spino-glenoid ligament** (lig. transversum scapulæ inferius) consists of another set of bridging fibres which are situated on the posterior aspect of the

neck of the scapula. By one end they are attached to the external border of tl scapular spine, and by the other to the adjacent part of the posterior aspect the head of the scapula. The suprascapular nerve and vessels pass subjacent this ligament.

THE SHOULDER-JOINT.

The shoulder-joint (articulatio humeri) is one of the largest as well as the mo important of the joints of the upper limb. It is an example of the enarthrodia *i.e.* ball-and-socket variety of a diarthrosis, and, at the cost of a certain amount security, it has obtained an extended range of movement.

The bones which enter into its formation are the glenoid fossa of the scapu and the head of the humerus.

The glenoid fossa is a shallow pyriform articular surface, having its narrow en directed upwards and slightly forwards. The upper half of the anterior margin the fossa is characterised by a shallow notch which accommodates the narrow pa of the subscapularis muscle as it runs outwards to its insertion. At the apex of th fossa there is a flat area for the attachment of the long tendon of the biceps flex cubiti muscle. The head of the humerus is hemispherical and articular, whil external to its articular margin, there is a slight constriction (the anatomical true neck of the humerus), which is most strongly marked in relation to th greater and lesser tuberosities of the humerus.

Under ordinary conditions the two articular surfaces are maintained i apposition by muscular action, aided by atmospheric pressure, and thus, when th muscles are removed, the bones fall asunder to the full extent of the restrainin ligaments. Only a small part of the humeral head is in contact with the glenoi fossa at any particular moment, because the former is much larger than the latte but, by reason of the shallow character of this fossa, all parts of the two articula surfaces may successively be brought into contact with each other.

In the position of rest, as the limb hangs parallel to the vertical axis of th trunk, the inferior aspect of the neck of the humerus is brought into close relatio with the lower part of the glenoid fossa.

The **glenoid ligament** (labrum glenoidale, Fig. 219) deepens the glenoid foss and thus extends the articular surface. It is situated within the joint capsule, an to some slight e tent increases t security of the ar culation. It co sists of a stro ring of dense fibro tissue attached the free margin the glenoid fos Many of its fib are short, and p obliquely from t inner to the ou aspect of the rid so that its attach base is broader th its free edge, a therefore in crossa tion it appears son what triangul The long tendon the biceps, whi arises from the apex of the glenoid fossa, becomes to a considerable extent i corporated with this ligament.

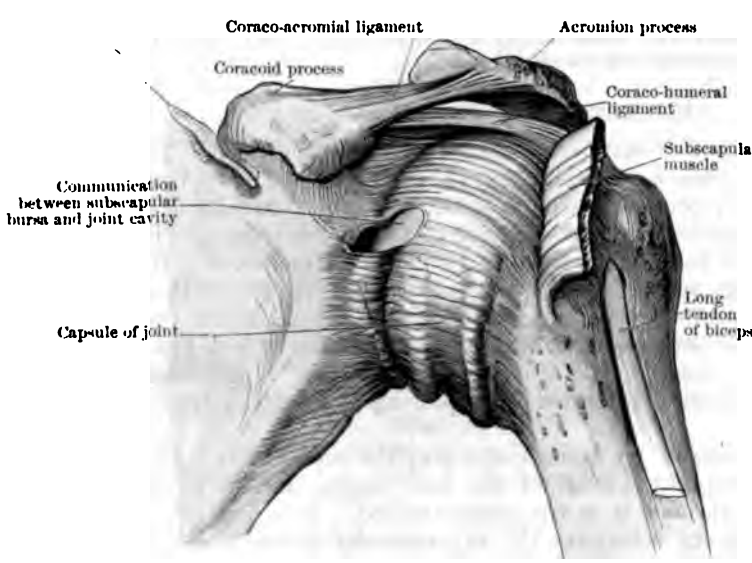

FIG. 218.—CAPSULE OF THE SHOULDER-JOINT AND CORACO-ACROMIAL LIGAMENT.

The **capsular ligament** (capsula articularis, Fig. 218) presents the general sha which is characteristic of the corresponding ligament in other ball-and-socket join

viz. a hollow cylinder. By its upper end the capsule is attached to the circumference of the glenoid fossa, external to the glenoid ligament, and also, to a considerable extent, to the glenoid ligament itself.

By its lower end it is attached to the neck of the humerus, and therefore beyond the articular area of the head. The capsule is strongest on its superior aspect, while inferiorly, where the neck of the bone is least defined, it extends downwards for a short distance upon the humeral shaft. Its fibres for the most part run longitudinally, but a certain number of them pursue a circular direction.

A prolongation of the capsule, the **transverse humeral ligament** presenting both longitudinal and transverse fibres, bridges that part of the bicipital groove which is situated between the tuberosities of the humerus. At this point an interruption in the capsule, beneath the transverse humeral ligament, permits the long tendon of the biceps to escape from its interior. In addition to the opening just referred to, there is another very constant deficiency in the upper and anterior part of the capsule, where the narrowing tendon of the subscapularis muscle is brought into contact with a bursa formed by a protrusion of the synovial membrane. This defect in the capsule has its long axis in the direction of the longitudinal fibres. Occasionally there is a similar but smaller opening under cover of the tendon of the infraspinatus muscle. Through the two latter openings the joint cavity communicates with bursæ situated between the capsule and the muscles referred to.

The tendons of the subscapularis, supraspinatus, and infraspinatus muscles fuse with, and so strengthen, the capsule as they approach their respective insertions.

On the superior aspect of the articulation the capsule is augmented by an accessory structure, the **ligamentum coraco-humerale** (Fig. 218). By its inner end, which is situated immediately above the glenoid fossa, but subjacent to the coraco-acromial ligament, it is attached to the external border of the root of the coracoid process, while its outer end is attached to the humeral neck close to the great tuberosity. This ligament forms a flattened band, having its hinder and lower border fused with the capsule, but its anterior and upper margin presents a free edge, slightly raised above the level of the capsule. This structure is believed to represent that portion of the pectoralis minor to which reference has already been made in connexion with the coraco-acromial ligament (p. 275).

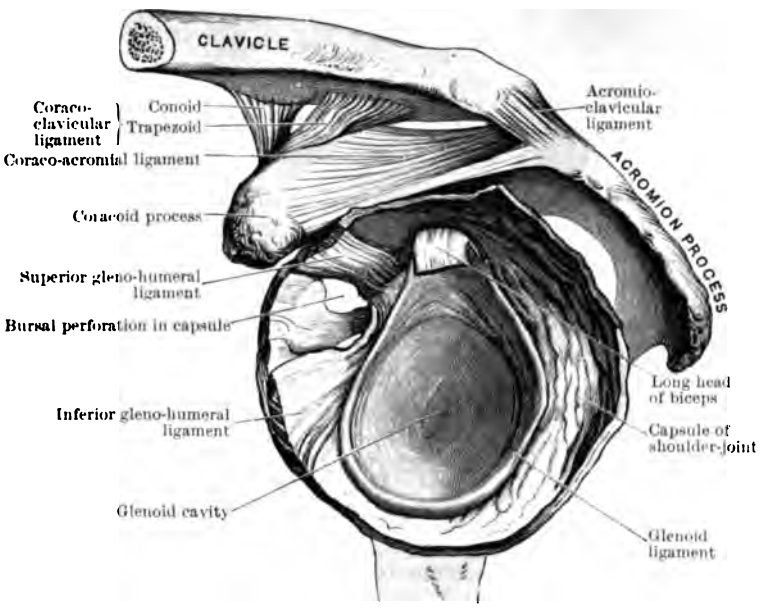

FIG. 219. CAPSULAR LIGAMENT OF SHOULDER-JOINT CUT ACROSS AND HUMERUS REMOVED.

The **coraco-glenoid ligament** is another accessory structure which is not always present. It springs from the coracoid process along with the former ligament, and extends to the upper and hinder margin of the head of the scapula.

Gleno-humeral Ligaments (Fig. 219).—If the capsule be opened from behind, and the head of the humerus be removed, it will be seen that the longitudinal fibres of the anterior part of the capsule are specially developed in the form of thick flattened bands which extend from the anterior border of the glenoid fossa to the *anterior aspect of the neck* of the humerus. These gleno-humeral

ligaments are three in number, and occupy the following positions: the **superior** is placed *above* the aperture in the front of the capsule; the **middle** and **inferior** on the antero-inferior aspect of the capsule, and *below* the aperture mentioned.

The superior gleno-humeral ligament, which some believe to represent the ligamentum teres of the hip-joint, springs, along with the middle gleno-humeral band, from the upper part of the anterior glenoid margin. The inferior band is the strongest of the three, and springs from the lower part of the anterior glenoid margin.

Intra-capsular Structures.—1. The glenoid ligament, already described. 2. The long tendon of the biceps passes outwards from its attachment to the apex of the glenoid fossa and the adjoining part of the glenoid ligament, above the head and neck of the humerus, to escape from the interior of the capsule by the opening between the tuberosities of the humerus, subjacent to the transverse humeral ligament.

Synovial membrane (Fig. 220) lines the capsule of the joint, and extends from the margin of the glenoid fossa to the humeral attachments of the capsule, where it is reflected towards the margin of the articular cartilage. It is therefore important to note that the inferior aspect of the humeral neck has the most extensive clothing of synovial membrane. Further, the synovial membrane envelops the intra-capsular part of the tendon of the biceps, and although this tubular sheath is prolonged upon the tendon into the upper part of the bicipital groove, yet the closed character of the synovial cavity is maintained. Thus, while the tendon is within the capsule, it is not within the synovial cavity. The synovial membrane is continuous with those bursæ which communicate with the joint cavity through openings in the ligamentous capsule.

FIG. 220.—VERTICAL SECTION THROUGH THE SHOULDER-JOINT.

Bursæ (*a*) *Communicating with the Joint Cavity.*—Practically there is only one bursa which is constant in its position, viz. the **subscapular**, between the capsule and the tendon of the subscapularis muscle. It varies considerably in its dimensions, but its lining membrane is always continuous with that which lines the capsule (Figs. 217 and 218), and therefore it may be regarded merely as a prolongation of the articular synovial membrane. Occasionally a similar but smaller bursa occurs between the capsule and the tendon of the infraspinatus muscle.

(*b*) *Not communicating with the Joint Cavity.*—The **sub-deltoid** or **sub-acromial bursa** is situated between the muscles on the superior aspect of the shoulder-joint on the one hand and the deltoid muscle on the other. It is an extensive bursa, and is prolonged subjacent to the acromion process and the coraco-acromial ligament. It does not communicate with the shoulder joint, but it greatly facilitates the movements of the upper end of the humerus against the under surface of the coraco-acromial arch.

Movements at the Shoulder-Joint.—A ball-and-socket joint permits of a great variety of movements, practically in all directions; but if these movements be analysed, it will be seen that they resolve themselves into movements about **three** primary axes at right angles to each other or about axes which are the possible combinations of the primary ones.

Thus, about a transverse axis, the limb may move forwards (**flexion**) or backwards (**extension**). About an antero-posterior axis it may move outwards, *i.e.* away from the mesial plane of the trunk (**abduction**), or inwards, *i.e.* towards, and to some extent up to, the mesial plane (**adduction**).

About a vertical axis, the humerus may **rotate** upon its axis in an inward or outward direction to the extent of a quarter of a circle.

these axes all pass through the shoulder-joint, and since each may present varying
f obliquity, it follows that very elaborate combinations are possible until the movement
duction is evolved. In this movement the head of the humerus acts as the apex of a
ovement with the distal end of the humerus, describing the base of the cone.
ange of the shoulder-joint movements is still further increased from the mobility of
ula as a whole, and from its association with the movements of the clavicle already

aments.—Taken as a whole, the ligaments form a complete **capsule** (capsula
uris), which is not defective at any point, although it is not of equal thick-
roughout, and certain bands of fibres stand out distinctly because of their
strength.

anterior ligament *(Fig. 221) consists of* a layer whose fibres run in several

directions—obliquely, transversely, and vertically—and of these the vertical fibres are of most importance. It is attached above to the upper margins of the coronoid and supracapitellar fossæ; below, to the margins of the coronoid process and to the orbicular ligament of the superior radio-ulnar joint, but some loosely arranged fibres reach as far as the neck of the radius. The lateral portions of this ligament, which are situated in front of the capitellum and the inner margin of the trochlea respectively, are much thinner and weaker than the central part. Fibres of origin of the brachialis anticus muscle are attached to the front of this ligament.

The **posterior ligament** is an extremely thin, almost redundant layer. Superiorly it is attached, in relation to the margin of the olecranon fossa, at a varying distance from the trochlear articular surface, and inferiorly to the summit and sides of the lip of the olecranon process. Externally some of its fibres pass from the posterior aspect of the capitellum to the posterior border of the lesser sigmoid cavity of the ulna. This ligament derives material support from, and participates in the movements of, the triceps extensor cubiti muscle, since they are closely adherent to each other in the region of the olecranon process.

The **internal lateral ligament** (lig. collaterale ulnare, Figs. 221 and 222) is a fan-

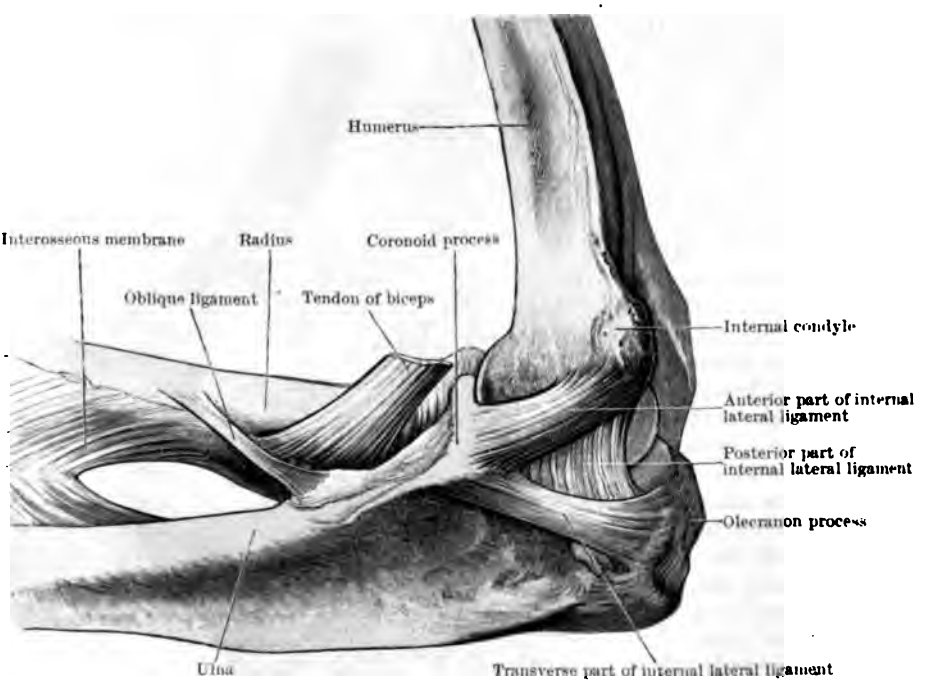

FIG. 222.—ELBOW-JOINT (inner aspect).

shaped structure of unequal thickness, but its margins, which are its strongest bands, are continuous with the adjoining parts of the anterior and posterior ligaments. By its upper end it is attached to the anterior, inferior, and posterior aspects of the internal condyle of the humerus. By its broad lower end it is attached to the inner margin of the greater sigmoid cavity, so that the *anterior band* is associated principally with the inner margin of the coronoid process, and the *posterior band* with the inner margin of the olecranon process, while the intermediate weaker portion sends its fibres downwards to join a *transverse band*, sometimes very strong, which bridges the notch between the adjoining inner margins of the coronoid and olecranon processes.

The **external lateral ligament** (lig. collaterale radiale, Fig. 221) is a strong flattened band attached superiorly to the lower and posterior aspects of the external condyle of the humerus. It completes the continuity of the capsule on the outer side, and blends inferiorly with the orbicular ligament, on the surface of which its fibres may be traced both to the anterior and posterior ends of the lesser sigmoid

ch. **Both of the lateral ligaments are intimately associated with the muscles** ich **take origin from the inner and outer condyles of the humerus.**

Synovial Pads of Fat (Fig. 223).—Internal to the capsule, there are several pads fat situated be- en it and the sy- ial membrane. all pads are so ced as to lie im- diately in front he coronoid and pra-capitellar ss, but a larger e projects to- rds the olecra- n fossa.

Synovial mem- ane (Fig. 223) es the entire psule and clothes e pads of fat ove referred to, s well as those rtions of bone closed within the psule which are ot covered by rticular cartilage. By its disposition the elbow and the uperior radio-

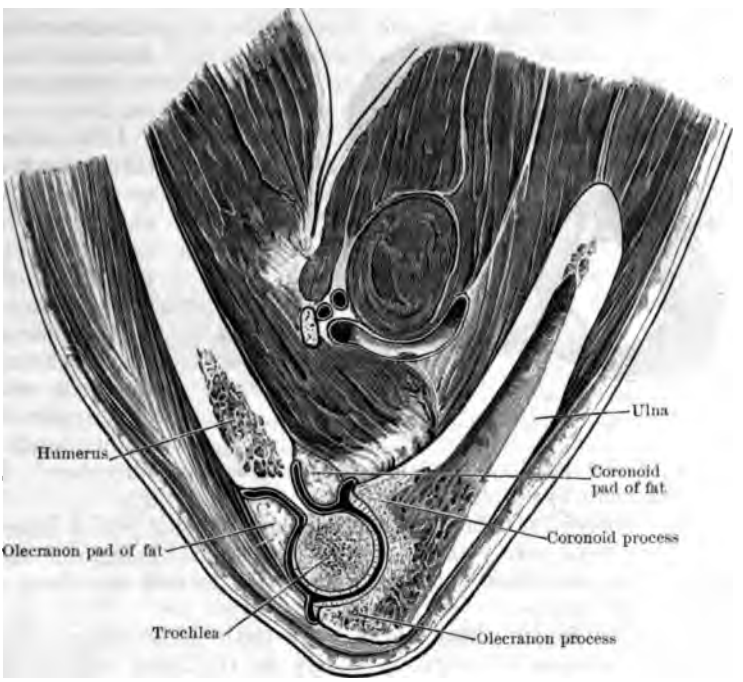

FIG. 223.—VERTICAL SECTION THROUGH THE TROCHLEAR PART OF THE ELBOW-JOINT.

ulnar joints possess a common joint cavity. It should be specially noted that the upper part of the neck of the radius is surrounded by this synovial membrane.

Movements at the Elbow-Joint.—The movements of the radius and ulna upon the humerus have already been referred to as those characterising a uniaxial joint constructed on the plan of a hinge. In this case the axis of the joint is obliquely transverse, so that in the extended osition the humerus and ulna form an obtuse angle open towards the radius, whereas in the exed position the hand is carried inwards in the direction of the mouth. Extreme flexion is hecked by the soft parts in front of the arm and of the fore-arm coming into contact, and xtreme extension by the restraining effect of the ligaments and muscles. In each case the ovement is checked before either coronoid or olecranon processes come into contact with the umerus. The anterior and posterior bands of the internal lateral ligament are important factors n these results. Lateral movement of the ulna is not a characteristic movement, although it ay occur to a slight extent, owing to a want of complete adaptation between the trochlear rface of the humerus and the sigmoid cavity of the ulna. This incongruence is noteworthy nce the inner lip of the trochlea is prominent in front, and the outer lip is prominent behind. onsequently, this latter part is associated with a surface on the outer side of the olecranon hich is only utilised in complete extension.

The capitellum and the opposing surface upon the head of the radius are always in varying egrees of contact. The head of the radius participates in the movements of flexion and exten- on, and is most closely and completely in contact with the humerus during the position of semi- exion and semi-pronation. In complete extension a very considerable part of the capitellum is covered by the radius.

THE RADIO-ULNAR JOINTS.

These articulations, which are two in number, are situated at the proximal and stal ends of the radius and ulna. They provide an adaptation whereby the radius otates around a longitudinal axis in the movements of pronation and supination, nd hence this form of uniaxial diarthrosis is termed lateral ginglymus.

Superior Radio-ulnar Joint (articulatio radio-ulnaris proximalis).—In this oint the articular surfaces which enter into its formation are the lesser sigmoid avity of the ulna and the lateral aspect of the head of the radius. In each case he articular cartilage is continuous with an articular surface entering into the ormation of the elbow-joint, *consequently the joint* cavity is continuous with that

of the elbow-joint, and therefore, in a sense, it lies within the cover of the capsule of the elbow-joint; but its special feature is the—

Orbicular ligament (lig. annulare radii, Figs. 221 and 224), which has formerly been mentioned as the inferior line of attachment of the external lateral ligament and the ligaments of the front and back of the elbow-joint.

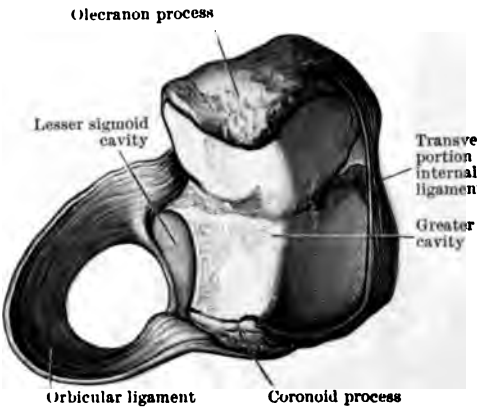

FIG. 224.—ORBICULAR LIGAMENT OF THE RADIUS.

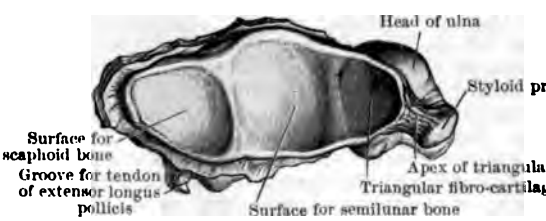
It is a strong, well-defined structure, attached by its extremities to the anterior and posterior margins of the lesser sigmoid cavity, and thus it forms nearly four-fifths of an osseo-tendinous circle or ring. This circle is somewhat wider at the upper than at the lower margin of the orbicular ligament, which, by encircling the upper part of the neck of the radius, tends to prevent displacement of the head of that bone in a downward direction. The lower margin of this ligament is not directly attached to the radius.

The **synovial membrane** is continuous with that which lines the elbow-joint. It closes the joint cavity at the inferior unattached margin of the orbicular ligament, where it is somewhat loosely arranged in its reflexion from the ligament to the neck of the radius.

Inferior Radio-ulnar Joint (articulatio radio-ulnaris distalis).—This joint is situated between the sigmoid cavity on the inner side of the lower end of the radius and the lateral aspect of the head of the ulna. In addition, it includes the inferior surface of the head of the ulna, which articulates with the superior surface of a triangular plate of fibro-cartilage, by means of which the joint is excluded from the radio-carpal articulation

The **triangular interarticular fibro-cartilage** (discus articularis, Figs. 225 and 227), besides presenting articular surfaces to two separate joints, is an important ligament concerned in binding together the lower ends of the radius and ulna. It is attached by its apex to the depression at the outer side of the root of the styloid process of the ulna, and by its base to the sharp line of demarcation between the sigmoid cavity and the carpal articular surface of the radius.



Head of ulna
Styloid process of ulna
Surface for scaphoid bone
Groove for tendon of extensor longus pollicis
Apex of triangular fibro-cartilage
Triangular fibro-cartilage
Surface for semilunar bone

FIG. 225.—CARPAL ARTICULAR SURFACE OF THE RADIUS, AND TRIANGULAR FIBRO-CARTILAGE OF THE WRIST.

The **ligamentous capsule** is very imperfect, and consists of scattered fibres, termed the **anterior and posterior radio-ulnar** ligaments (Fig. 226). These ligaments pass transversely between adjoining non-articular surfaces on the radius and ulna, and are of sufficient length to permit of the movements of the radius in pronation and supination.

The **synovial membrane** completes the closure of the joint cavity. It forms a loose bulging projection (recessus sacciformis), passing upwards between the lower ends of the shafts of the radius and ulna, and it also clothes the upper surface of the triangular fibro-cartilage (Fig. 227). The cavity of this joint is quite distinct from that of the radio-carpal articulation, except when the triangular fibro-cartilage presents a perforation.

Between the foregoing articulations there are two **accessory ligaments**, viz. the interosseous membrane and the oblique ligament, which connect together the shafts of the radius and ulna.

The interosseous membrane (Fig. 222) of the fore-arm (membrana interossea interrachii) is a strong fibrous membrane which stretches across the interval between the radius and ulna, and is firmly attached to the interosseous border of each. Below it extends downwards to the lower limit of the space between the bones, whilst above it does not reach higher than a point about one inch below the tuberosity of the radius. A gap, called the *hiatus interosseus*, is thus left above its upper margin, and through this the posterior interosseous vessels pass backwards between the bones to reach the dorsal aspect of the fore-arm. This gap is bounded above by the oblique ligament. The fibres which compose the interosseous membrane run for the most part downwards and inwards from the radius to the ulna, although on its dorsal aspect several bands may be observed stretching in an opposite direction. The interosseous membrane augments the surface available for the origin of the muscles of the fore-arm; it braces the radius and ulna together; and when shocks are communicated from the hand to the radius, owing to the direction of its fibres, the interosseous membrane transmits these, to some slight extent, to the ulna.

The oblique ligament (Fig. 222) is a slender tendinous band of very varying strength which springs from the outer part of the coronoid process of the ulna, and stretches obliquely downwards and outwards to the radius where it is attached immediately below the bicipital tuberosity.

Movements of the Radius on the Ulna.—The axis about which the radius moves is a longitudinal one, having one end passing through the centre of the head of the radius and the other through the styloid process of the ulna and the line of the ring-finger. In this axis the head of the radius is so secured that it can only rotate upon the lesser sigmoid cavity of the ulna within the orbicular ligament, and consequently the radial head remains upon the same plane as the ulna; but the lower end of the radius being merely restrained by the triangular fibro-cartilage, is able to describe nearly a half-circle, of which the apex of this ligament is the centre. In this movement the radius carries the hand from a position in which the palm is directed forwards, and in which the radius and ulna lie parallel to each other (**supination**), to one in which the palm is directed backwards, and the radius lies diagonally across the front of the ulna (**pronation**).

The ulna is unable to rotate upon a long axis, but while the radius is travelling through the arc of a circle from without inwards in front of the ulna, it will usually be seen that the ulna appears to move through the arc of a smaller circle in the reverse direction, viz. from within outwards. If the humerus be prevented from moving at the shoulder-joint, a very large proportion, if not the entire amount, of this apparent movement of the ulna will disappear. At the same time some observers maintain that it really occurs at the elbow-joint, associated with lateral movement during slight degrees of flexion and extension at that joint.

THE RADIO-CARPAL JOINT.

This joint (articulatio radiocarpea) is a bi-axial diarthrosis, frequently called a condyloid joint.

The articular elements which enter into its formation are: on its *proximal side*, the inferior surface of the lower end of the radius, together with the inferior surface of the triangular fibro-cartilage; on its *distal side*, the superior articular surfaces of the scaphoid, semilunar, and cuneiform bones. The articular surface of the radius is concave both in its antero-posterior and transverse diameters, in order to adapt itself to the opposing surfaces of the scaphoid and semilunar, which are convex in the two axes named. In the ordinary straight position of the hand the triangular fibro-cartilage is in contact with the semilunar bone, and the upper articular surface of the cuneiform bone is in contact with the capsule of the joint. When, however, the hand is bent towards the ulna, the cuneiform bone is carried outwards as well as the semilunar and scaphoid, and the triangular fibro-cartilage comes into contact with the cuneiform. The articular surface of the radius is subdivided by an antero-posterior, slightly elevated ridge, into an outer triangular facet which usually articulates with the scaphoid, and an inner quadrilateral facet for articulation with a portion of the semilunar bone.

In the intervals between the scaphoid, semilunar, and cuneiform bones, the continuity of the articular surfaces is usually maintained by the presence of interosseous ligaments which are situated upon the same level as the articular cartilage.

Ligaments.—A capsular ligament completely surrounds the joint. It is somewhat loosely arranged, and permits of subdivision into the following portions:—

The external lateral ligament (Fig. 226) is a well-defined band which is attached

by one end to the tip of the styloid process of the radius, and by the otl rough area at the base of the tubercle of the scaphoid bone, *i.e.* externa radial articular surface.

The **internal lateral ligament** (Fig. 226) is also a distinct rounded st having one end attached to the tip of the styloid process of the ulna, and the the rough non-a border of the cu bone, some of it being prolonged pisiform bone.

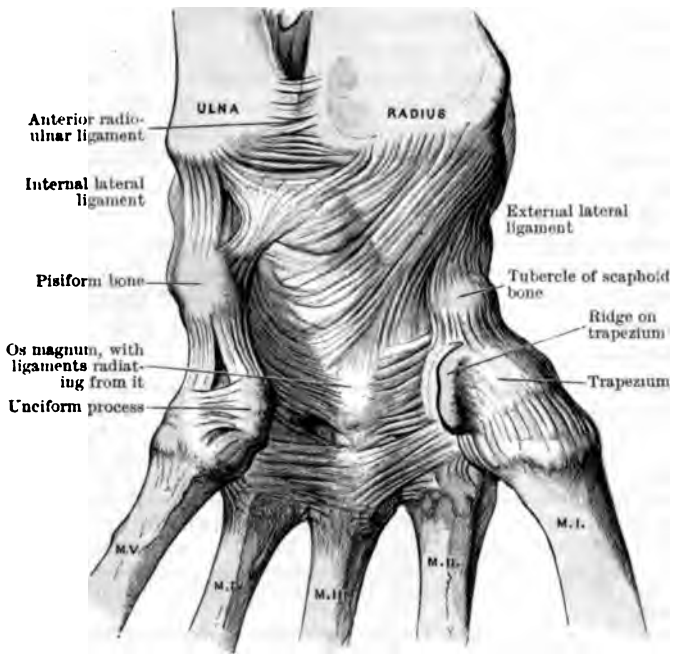


FIG. 226.—LIGAMENTS ON ANTERIOR ASPECT OF RADIO-CARPAL, CARPAL, AND CARPO-METACARPAL JOINTS.

The **anterior l** (Fig. 226) is a superiorly to the margin of the lo of the radius, as slightly to the the styloid proces ulna. Some tra fibres may be se the greater numl obliquely downwa inwards to the non-articular sur the scaphoid, sen and cuneiform while some of th even be continue as the os ma Those fibres fr ulna run oblique wards. On its aspect this ligar closely adherent to the anterior border of the triangular fibro-cartilage inferior radio-ulnar articulation.

The **posterior ligament** extends from the posterior margin of the low of the radius, obliquely downwards and inwards, to the dorsal non-a areas on the proximal row of the carpal bones. The slip to the latter as forming the fibrous sheath through which the tendon of the extensor carpi muscle travels to its insertion. The principal bundle of fibres is connect the cuneiform bone.

The **synovial membrane** (Fig. 227) is simple, and is confined to the artic except in those cases in which the triangular fibro-cartilage is perforated, or i one of the interosseous ligaments between the carpal bones of the first row is

Movements at the Radio-carpal Joint.—The radio-carpal joint affords an excellent of a biaxial articulation, in which a long transverse axis of movement is situated more c right angles to a short axis placed in the antero-posterior direction. The nature of th ments which are possible about these two axes is essentially the same in both cases, viz. and **extension**. The movements about the longer transverse axis are anterior or palmar extension, and its continuation into dorsi-flexion. About the shorter antero-posterior ax movements which result from combined action by certain flexor and extensor muscles, the radial or ulnar borders of the hand may be approximated towards the corresponding of the fore-arm. Lateral movement may also be possible to a slight extent. The range ment in connexion with either of the principal axes is largely a matter of individual pec for, with the exception of the lateral ligaments, there is no serious obstacle to the cultiv greater mobility at the radio-carpal joint.

CARPAL JOINTS.

The articulations subsisting between the individual carpal bones (articul intercarpeæ) are all diarthroses, and although the total amount of mo throughout the series is considerable, yet the extent of movement which is p

between the two rows or between any two carpal bones is extremely limited. For this reason, as well as because of the nature of the movement, these articulations are called gliding joints (arthrodia).

It is advisable to consider, *first*, the articulations between individual bones of the proximal row; *second*, the articulations between the separate bones of the distal row; *third*, the articulation of the proximal and distal rows with each other; *fourth*, the pisiform articulation.

The proximal row of carpal articulations (Fig. 226) comprises the joints between the scaphoid, semilunar, and cuneiform bones. On their adjacent lateral aspects these bones are partly articular and partly non-articular.

Three sets of simple but strong, although short ligamentous bands bind these three carpal bones together, and form an investment for three sides of their intercarpal joints. These are—(1) the **anterior** or **palmar ligaments**, two in number, which consist of transverse fibres passing between the adjacent rough palmar surfaces of the bones; (2) the **posterior** or **dorsal ligaments**, also two in number, and composed of similar short transverse fibres passing between the adjacent dorsal surfaces; (3) the **interosseous ligaments** (Fig. 227), again two in number, and transverse in direction, situated on a level with the superior articular surfaces, and extending from the palmar to the dorsal aspect of the bones, while attached to non-articular areas of the opposing surfaces. The radio-carpal joint is entirely shut off from the intercarpal joints, and also from the joint between the two rows of carpal bones, except in rare cases, when an interosseous ligament is wanting.

The **distal row of carpal articulations** (Fig. 226) includes the joints between the trapezium, trapezoid, os magnum, and unciform bones. Articular facets occur on the opposing lateral faces of the individual bones.

Associated with this row there are again simple bands of considerable strength, and presenting an arrangement similar to that seen in the proximal row. As in the former case, they invest the intercarpal articulations, except on the superior aspect, where they communicate with the transverse carpal joint, and on the inferior aspect, where they communicate with the carpo-metacarpal joint cavity.

The **anterior** or **palmar ligaments** are three in number. They extend in a transverse direction between contiguous portions of the rough palmar surfaces of the bones. The **posterior** or **dorsal ligaments**, also three in number, are similarly disposed on the dorsal aspect. The **interosseous ligaments** (Fig. 227) are two or three in number. That which joins os magnum to unciform is the strongest; that between the trapezoid and os magnum is situated towards the dorsal parts of their opposing surfaces; the third, situated between contiguous non-articular surfaces of the trapezium and trapezoid, is always the feeblest, and is frequently absent.

The **transverse carpal articulation** (Fig. 227) is situated between the proximal and distal rows of the carpus. The bones of the proximal row present the following characters on their inferior or distal aspect. The outer part of the articular surface is deeply concave, both in the antero-posterior and in the transverse directions, but the inner part of the same surface is concavo-convex, more especially in the transverse direction.

Superiorly, the articular surfaces of the distal row of carpal bones present an irregular outline. That part pertaining to the trapezium and trapezoid is concave in the antero-posterior and transverse directions, and lies at a considerably lower level than the portion belonging to the os magnum and unciform, which is, moreover, markedly convex in the antero-posterior and transverse directions, with the exception of the innermost part of the unciform, where it is concavo-convex in both of these directions.

This articulation is invested by a complete short **capsule** (Fig. 226) which binds the two rows of the carpus together, and sends prolongations to the investing capsules of the proximal and distal articulations. The ligament as a whole is very strong, and individual bands are not readily defined, although certain special bands may be described. The **palmar ligaments** radiate from the os magnum to the scaphoid, unciform, and pisiform. The interval between the os magnum and semilunar is occupied by oblique fibres, some of which pass from scaphoid to cuneiform, while these are joined by others, prolonged obliquely downwards and inwards, from the

radial end of the anterior radio-carpal ligament. By these different banc palmar aspect of the joint is completely closed.

The **dorsal ligaments** are more feeble than the palmar. They form a thin, lc arranged stratum, in which the only noteworthy bands are one which joi scaphoid to os magnum, and another which joins cuneiform to unciform.

The **external lateral ligament** (lig. collaterale carpi radiale, Fig. 227) e between contiguous rough areas on the radial aspects of the scaphoi trapezium. By its margins it is continuous both with the palmar and ligaments.

The **internal lateral ligament** (lig. collaterale carpi ulnare, Fig. 227) is ar like the former in regard to its margins, and by its ends it is attached to th tiguous rough ulnar surfaces of the cuneiform and unciform bones.

Both of these lateral ligaments are directly continuous with the corresp lateral ligaments of the radio-carpal joint.

An **interosseous ligament** (Fig. 227) is occasionally found within the c extending across the joint cavity between the os magnum and the scaphoid.

The **pisi-cuneiform articulation** is an arthroidal diarthrosis. The articular surfaces of the two bones are flattened and circular, and only perm small amount of gliding movement.

The joint is provided with a thin but complete **capsule** of fibrous tissue, is specially strengthened inferiorly by two strong bands, viz. **pisi-unciform** (lig hamatum) and **pisi-metacarpal** (lig. pisometacarpeum, Fig. 226). Both of bands extend from the lower and inner aspect of the pisiform to adjoining p the hook of the unciform and base of the fifth metacarpal bone respectively. great extent these ligamentous bands may be regarded as extensions of t sertion of the tendon of the flexor carpi ulnaris muscle which is attached upper part of the pisiform bone. Looked at as ligaments, however, th specially strong to prevent the displacement of the pisiform bone during c tion of the muscle inserted into it.

The **synovial membranes** (Fig. 227) of the carpal joints are two in numbe these, one is restric the pisi-cuneiform ar tion, and is correspon simple, although occasi the joint cavity ma municate with that radio-carpal joint.

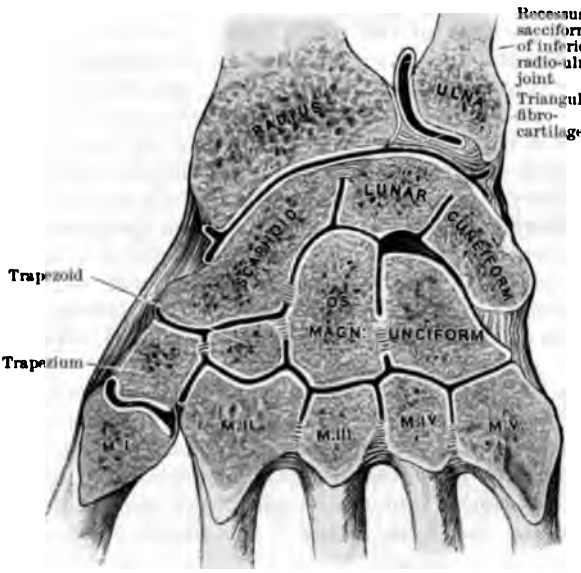

FIG. 227.—CORONAL SECTION through the radio-carpal, carpal, carpo-metacarpal, and intermetacarpal joints, to show joint cavities and interosseous ligaments (diagrammatic).

The other synovial brane is associated wi transverse carpal joint extends transverse tween the two rows of bones, with prolon into the vertical in between the adjoinin of each row, *i.e.* the carpal articulations. therefore, an elaborate which may be still extended, by the abs interosseous ligament to reach the radio-car carpo-metacarpal se joints. The first co is rare, but the second is not uncommon, and results from the absence of th osseous ligament between trapezium and trapezoid, or of that between tr and os magnum.

INTERMETACARPAL JOINTS.

The four inner metacarpal bones articulate with each other at their proximal ends or bases, between the opposing surfaces of which joint cavities are found—arthrodial diarthroses. These cavities are continuous with the carpo-metacarpal joint (not yet described), and hence the ligamentous arrangements only enclose three aspects of each joint.

Three strong **transverse ligaments** (Figs. 226 and 227) bind adjacent palmar, dorsal, and interosseous areas of the bases of the metacarpal bones, and hence they are called **ligamenta basium** (ossa metacarp.) **volaria, dorsalia et interossea.** A synovial membrane is associated with each of these joints, but it may be regarded as a prolongation from the carpo-metacarpal articulation.

CARPO-METACARPAL JOINTS.

The articulation of the metacarpal bone of the thumb with the trapezium differs in so many respects from the articulation between the other metacarpal bones and the carpus, that it must be considered separately.

(*A*) The **articulatio carpo-metacarpea pollicis** (Figs. 226 and 227) is the joint between the infero-external surface of the trapezium and the superior surface of the base of the first metacarpal bone. Both of these surfaces are saddle-shaped, and they articulate by mutual co-aptation.

The joint-cavity is surrounded by a fibrous **capsule**, in which we may recognise palmar, dorsal, external, and internal lateral bands, the last being the strongest and most important.

Synovial membrane lines the capsule, and the joint-cavity is isolated and quite separate from the other carpal and carpo-metacarpal articulations.

At this joint movements occur about at least three axes. Thus, around a more or less transverse axis, **flexion** and **extension** take place; in an antero-posterior axis **abduction** and **adduction** (movements which have reference to the middle line of the hand) are found; while a certain amount of **rotation** is possible in the longitudinal axis of the digit. The very characteristic movement of **opposition**, in which the tip of the thumb may be applied to the tips of all the fingers, results from a combination of flexion, adduction, and rotation, and by combining all the movements possible at the various axes a considerable degree of **circumduction** may be produced, in spite of the fact that this is not a ball-and-socket joint.

(*B*) The **articulationes carpo-metacarpeæ digitorum** are the joints between the bases of the four inner metacarpal bones and the four bones of the distal row of the carpus. They are all arthrodial diarthroses, and the opposed articular surfaces present alternate elevations and depressions which form a series of interlocking joints. The joint cavities between the carpal bones of the distal row, and also the more extensive intermetacarpal joint cavities, open into this articulation.

This series of joints is invested by a common capsule which is weakest on its radial side, but is otherwise well defined. Its fibres arrange themselves in small slips, which pass obliquely in different directions, and vary in number for each metacarpal bone. Thus the **oblique palmar ligaments** (ligamenta carpo-metacarpea volaria, Fig. 225) usually consist of one slip for each metacarpal bone, but there may be two slips, and the third metacarpal bone frequently has three, of which one lies obliquely in front of the tendon of the flexor carpi radialis muscle.

The **oblique dorsal ligaments** (ligamenta carpo-metacarpea dorsalia) are similar short bands, of greater strength and clearer definition, by which the index metacarpal is bound to the trapezium and trapezoid; the middle metacarpal to the os magnum, and frequently to the trapezoid; the ring metacarpal to the os magnum and unciform, and the metacarpal of the minimus to the unciform.

Interosseous ligaments, one or sometimes two in number, occur within the capsule. They are usually situated in relation to one or both of the contiguous margins of the bases of the third and fourth metacarpal bones, from which they extend upwards to adjacent margins of the os magnum and unciform. Occasionally they are sufficiently developed to divide the joint cavity into radial and ulnar sections.

The **synovial membrane** (Fig. 227) is usually single and lines the capsule, b as already explained, it has prolongations into the intermetacarpal and int carpal series of joints. In connexion with the latter, the frequent absence the interosseous ligament between the trapezium and trapezoid permits the f communication of this joint-cavity with that of the transverse carpal joint.

METACARPO-PHALANGEAL JOINTS.

In the case of the pollex this joint is constructed on the plan of a ginglym diarthrosis; the four corresponding joints of the fingers are also diarthroses o slightly modified ball-and-socket variety. With the exception of the metacar bone of the pollox, each metacarpal bone has a somewh spherical head articulating with a shallow oval cup up the base of the first phalanx. It is important to note th the articular surface upon the head of each of these me carpal bones is wider on the palmar aspect and narro on the dorsal aspect. The articulation in the thu presents features similar to those of an inter-phalang joint.

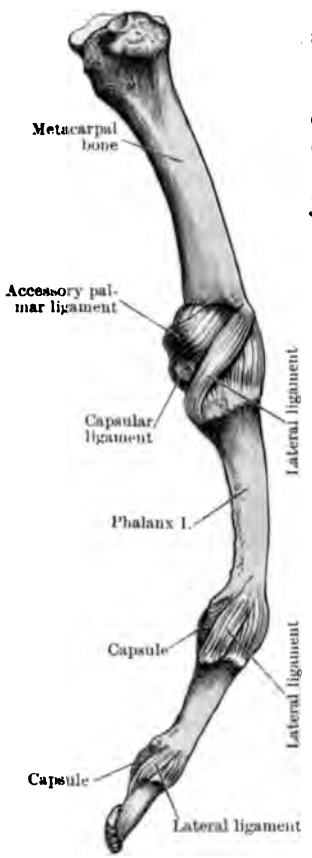

FIG. 228.—METACARPO-PHALANGEAL AND INTERPHALANGEAL JOINTS.

Each joint possesses an articular capsule (Fig. 22 which presents very different degrees of strength different aspects of the articulation. Thus, on the dor aspect, it cannot be demonstrated as an independe structure, but the necessity for dorsal ligaments is to large extent obviated by the presence of the stro flattened expansions of the extensor tendons.

The **internal** and **external lateral ligaments** (ligamen collateralia, Fig. 228) are strong cord-like bands whi pass from the tubercles and adjacent depressions on t sides of the heads of the metacarpal bones to the contiguo non-articular areas on the bases of the proximal phalang They are intimately connected on their anterior aspe with the palmar ligaments.

The **palmar ligaments** consist of thick plates of fib cartilage loosely connected to the metacarpal bones, b firmly adherent to the phalanges. They are plac between the lateral ligaments, to both of which they a in each case connected. Each plate is grooved on t palmar surface for the long flexor tendons, whilst on reverse or joint surface it supports and glides upon t head of the metacarpal bone during flexion and extensi of the joint. In the case of the thumb this plate fibro-cartilage usually develops to sesamoid bones, a in the case of the index finger one such sesamoid nod is frequently found at the radial side of the plate.

An important accessory ligament is found in connexion with the four in metacarpo-phalangeal articulations, viz. :—

The **Transverse Metacarpal Ligament.**—This structure binds together the dis extremities of the four inner metacarpal bones. The name is applied to three s of transverse fibres of great strength which are situated in front of the three in interosseous spaces. These fibres are continuous with the palmar metacar phalangeal ligaments at their lateral margins.

A **synovial membrane** lines the investing capsule of each joint.

INTERPHALANGEAL JOINTS.

Of these joints there are two for each finger and one for the thumb. They correspond, in being ginglymus diarthroses in which the trochlear character of t articular surfaces is associated with one axis of movement directed transversely

In their general arrangement they correspond with each other, and to a l extent with the metacarpo-phalangeal series already described. Each is provi

with a **definite capsule** (Fig. 228), of which the palmar and cord-like lateral portions are well marked, while on the dorsal aspect the extensor tendons act as the chief support. The palmar ligaments are fibrous plates of considerable thickness, and are attached to the two lateral ligaments and to the intervening rough surface on the distal phalanges, while their proximal margins are not attached to bone. Each ligament has its lateral margins prolonged proximally to the adjacent sharply-defined lateral ridges on the phalangeal shafts.

The **lateral ligaments** (Fig. 228) are strong, rounded, short bands, continuous with the preceding, and attached to adjacent non-articular lateral aspects of the phalanges.

Each joint possesses a **synovial membrane** which lines its capsule, but its arrangement presents no special peculiarity.

Movements of the Carpal, Intermetacarpal, Metacarpo-phalangeal and Interphalangeal Joints.

The amount of movement which is possible at individual joints of the intercarpal, intermetacarpal, and carpo-metacarpal series is extremely limited, both on account of the interlocking nature of the articular surfaces and the restraining character of the ligamentous bands. Taken as a whole, however, the movements of the carpus and metacarpus enable the hand to perform many varied and important functions. This is largely due to the greater mobility of those joints on the radial and ulnar borders of the hand, as well as to the general elasticity of the arches formed by the carpus and metacarpus. These conditions particularly favour the movements of opposition and prehension. In the opposite direction, *i.e.* when pressure is applied from the palmar aspect, the metacarpal and carpal arches tend to become flattened, but great elasticity is imparted by the tension of the various ligaments.

The four inner metacarpo-phalangeal joints are ball-and-socket joints, and movements of **palmar-flexion** and **extension** are freely performed about a transverse axis. In exceptional cases a certain amount of **dorsi-flexion** is possible. About an antero-posterior axis movements occur which are usually referred to the middle line of the hand, and hence called **abduction** and **adduction**, but in consequence of the difference in the width of the articular surface on the dorsal and palmar aspects of the heads of the four inner metacarpal bones it is only possible to obtain abduction when the joints are extended, while in the flexed position the joints become locked and abduction is impossible.

The movements of the index finger are less hampered than in the case of the others, but each of them can perform a modified kind of **circumduction**.

The metacarpo-phalangeal joint of the thumb and all the interphalangeal joints are uniaxial or hinge-joints acting about a transverse axis, which permits of **palmar-flexion** and **extension** being freely performed, but **dorsi-flexion** is, as a rule, entirely prevented by the palmar and lateral ligaments.

ARTICULATIONS AND LIGAMENTS OF THE PELVIS.

Although we may consider the pelvis as a separate part of the skeleton, yet it is essential to remember that the bones which enter into its composition belong to the spinal column (sacrum, coccyx) and the lower limb (innominate bone). Accordingly, the articulations, with their corresponding ligaments, may be arranged as follows:—

(*a*) Those by which the segments of the coccyx are joined together (already described, *v.* p. 264);

(*b*) That by which the sacrum articulates with the coccyx (already described, *v.* p. 264);

(*c*) Those by which the sacrum articulates with the last lumbar vertebra (Lumbo-sacral joints);

(*d*) Those by which the innominate bones are attached to the spinal column (Sacro-iliac joints);

(*e*) That by which the innominate bones are attached to each other (Symphysis pubis).

LUMBO-SACRAL JOINTS.

The articulation of sacrum with the fifth lumbar vertebra is constructed precisely on the principle of the articulations between two typical vertebræ, and the usual ligaments associated with such joints are repeated. There is, however, an additional accessory ligament, termed the **lateral lumbo-sacral ligament** (Fig. 229).

This extends from the front of the inferior border of the transverse process of the last lumbar vertebra, downwards and slightly outwards, to the front of the lateral aspect of the ala of the sacrum, close to the sacro-iliac joint. Further, a variable membranous band extends between the lateral aspect of the lower part of the body of the last lumbar vertebra and the front of the ala of the sacrum. This band lies in front of the anterior primary division of the fifth lumbar nerve.

SACRO-ILIAC JOINT.

Each innominate bone articulates with the sacral section of the spinal column on each side through the intervention of a diarthrosis, termed the **sacro-iliac joint** (articulatio sacro-iliaca).

This joint is formed between the contiguous auricular surfaces of the sacrum and ilium. Each of these surfaces is more or less completely clothed by hyaline articular cartilage. The joint cavity, which is little more than a capillary interval, may be crossed by fibrous bands.

The joint cavity is surrounded by ligaments of varying thickness and strength,

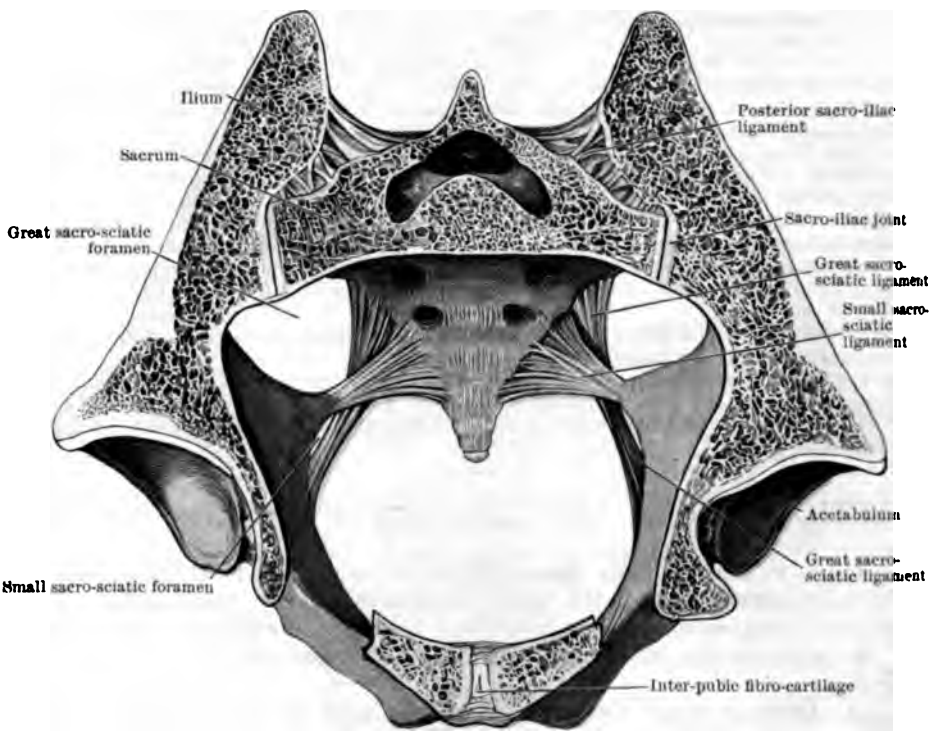

FIG. 229.—CORONAL SECTION OF PELVIS.

which constitute its **capsule**. Thus the anterior part of the investing capsule is thin, and consists of short but strong fibres which pass between adjoining surfaces on the ala of the sacrum and the iliac fossa of the innominate bone; they form the **anterior sacro-iliac ligament** (lig. sacro-iliacum anterius, Fig. 229). On the posterior aspect there are two ligaments. The **short posterior sacro-iliac ligament** (lig. sacro-iliacum posterius breve, Fig. 230) consists of numerous strong fasciculi, which pass from the rough area on the inner aspect of the ilium, above and behind its auricular surface, downwards and inwards to the transverse tubercles and the depressions behind the first and second segments of the sacrum. This ligament is of great strength, and with its fellow it is responsible for suspending the sacrum and the weight of the superimposed trunk from the innominate bones.

The **long** or **oblique posterior sacro-iliac ligament** (lig. sacro-iliacum posterius longum, Fig 230) is a superficial thickened portion of the preceding ligament.

It consists of a definite band of fibres passing from the postero-superior iliac spine to the transverse tubercles of the third and fourth segments of the sacrum.

The **synovial cavity** of this joint is very imperfect and rudimentary.

Several accessory ligaments are associated with the articulation of the innominate bone to the sacral section of the spinal column.

The **ilio-lumbar ligament** (lig. ilio-lumbale, Fig. 229), which is merely the

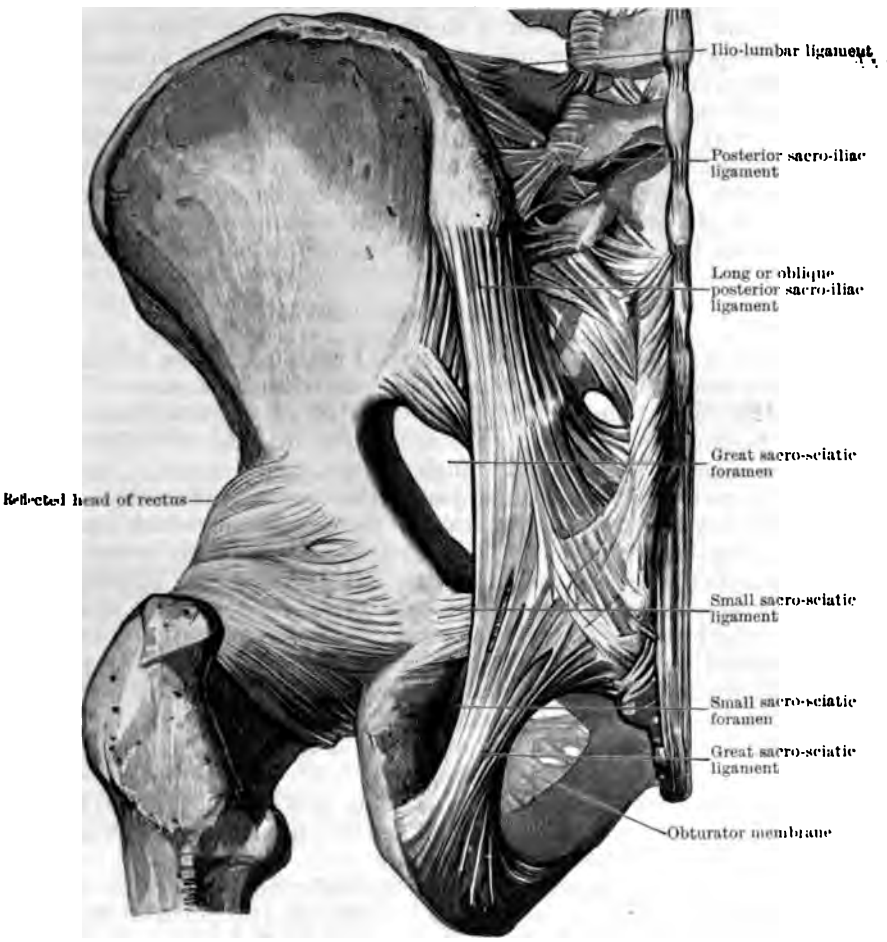

FIG. 230.—POSTERIOR VIEW OF THE PELVIC LIGAMENTS AND OF THE HIP-JOINT.

thickened anterior lamina of the fascia lumborum, extends from the tip of the transverse process of the last lumbar vertebra, almost horizontally outwards, to the inner lip of the iliac crest at a point a short distance behind its highest level. A proportion of these fibres is attached to the inner rough surface of the ilium between the iliac crest and the auricular impression. To these the name of the **lig. ilio-lumbale inferius** is applied.

The **great** or **posterior sacro-sciatic ligament** (lig. sacro-tuberosum, Fig. 230) is somewhat triangular in outline. It occupies the interval between the sacrum and the innominate bone, and is attached mesially to the posterior inferior spine of the ilium; to the posterior aspect of the transverse tubercles and lateral margins of the third, fourth, and fifth segments of the sacrum, as well as to the side of the first segment of the coccyx. It passes downwards and outwards, becoming narrower as it approaches the ischium, near to which, however, it again expands, to be attached to the inner side of the ischial tuberosity, immediately below the groove for the tendon of the obturator internus muscle, *i.e.* the lesser sciatic notch. A continuation of the *inner border* of the ligament—the **processus**

falciformis (Fig. 230)—runs upwards and forwards on the inner aspect of the ramus of the ischium.

The great sacro-sciatic ligament is believed by many to represent the original or proximal end of the long or ischial head of the biceps flexor cruris muscle.

The **small or anterior sacro-sciatic ligament** (lig. sacro-spinosum, Figs. 229 and 230) is situated in front, and in a measure under cover of the great sacro-sciatic ligament. Triangular in form, it is attached by its base to the last two segments of the sacrum and the first segment of the coccyx, and by its pointed apex to the tip and upper aspect of the ischial spine. This ligament is intimately associated with the coccygeus muscle, and by some it is regarded as being derived from it by fibrous transformation of the muscle fasciculi.

By the great and small sacro-sciatic ligaments the two sciatic notches of the innominate bone are converted into foramina. Thus the small sacro-sciatic ligament completes the boundaries of the great sciatic foramen (foramen ischiadicum majus); while the great sacro-sciatic ligament, assisted by the small sacro-sciatic ligament, closes the small sciatic foramen (foramen ischiadicum minus).

SYMPHYSIS PUBIS.

The anterior wall of the osseous pelvis is completed by the articulation of the bodies of the two pubic bones constituting the **symphysis pubis**. This joint conforms in its construction to the general plan of an amphiarthrosis. Thus it is mesial in position; each pubic bone is covered by a layer of hyaline cartilage, which closely adapts itself to the rough tuberculated surface of the pubic bone; while between these two hyaline plates there is an interposed fibro-cartilage (lamina fibro-cartilaginea interpubica), in the interior of which there is usually a vertical antero-posterior cleft. This cavity, which is placed nearer the posterior than the anterior aspect of the joint, does not appear until between the seventh and tenth years, and as it is not lined by a synovial membrane, it is supposed to result from the breaking down of the interpubic lamina.

The **anterior pubic ligament** (lig. pubicum anterius, Fig. 229) is a structure of considerable thickness and strength. Its superficial fibres, which are derived very largely from the tendons and aponeuroses of adjoining muscles, are oblique, and form an interlaced decussation. The deeper fibres are short, and extend transversely from one pubic bone to the other.

The **posterior pubic ligament** (lig. pubicum posterius, Fig. 230) is very weak, and consists of scattered fibres which extend transversely between contiguous pubic surfaces posterior to the articulation.

The **superior pubic ligament** (lig. pubicum superius, Fig. 229) is likewise weak, and consists of transverse fibres passing between the two pubic crests.

The **inferior** or **subpubic ligament** (lig. pubicum inferius vel lig. arcuatum pubis, Fig. 230) occupies the arch of the pubis, and is of considerable strength. It gives roundness to the pubic arch and forms part of the pelvic outlet. It has considerable vertical thickness immediately below the interpubic disc to which it is attached. Laterally it is attached to adjacent sides of the descending rami of the pubis. Its lower border is free, and separated from the triangular ligament of the perineum by a transverse oval interval through which the dorsal vein of the penis passes backwards to the interior of the pelvis.

The Triangular Ligament of the Perineum.

The **triangular ligament of the perineum** is a membranous structure which occupies the pubic arch below and distinct from the subpubic ligament. It assists in completing the pelvic walls anteriorly in the same manner that the obturator membrane does laterally. Indeed, these two structures occupy the same morphological plane. The triangular ligament presents two surfaces—one superficial or perineal; the other deep, or pelvic, and both of these surfaces are associated with muscles. Its lateral borders are attached to the sides of the pubic arch while its base is somewhat ill-defined, by reason of its fusion with the fascia of Colles in the urethral region of the perineum.

The apex of the triangular ligament is truncated, free, and well defined, constituting the **transverse perineal ligament**, above which there is the interval for the dorsal vein of the penis. It is pierced by a number of vessels and nerves, but the principal opening is situated mesially one inch below the pubic arch, and transmits the urethra.

The Obturator Membrane.

The **obturator membrane** (membrana obturatoria, Fig. 232) occupies the obturator or thyroid foramen. It is attached to the pelvic aspect of the circumference of this foramen. It consists of fibres irregularly arranged and of varying strength, so that sometimes it almost appears fenestrated. At the highest part of the foramen it is incomplete and forms a U-shaped border, between which and the bony circumference of the foramen, the obturator canal (canalis obturatorius) is formed. In this position the membrane is continuous with the parietal pelvic fascia which clothes the inner side of the obturator internus muscle, above the upper free margin of the muscle. From the outer or crural aspect of the membrane some of its fibres are prolonged to the antero-inferior aspect of the capsule of the hip-joint.

Mechanism and Movements of the Pelvis.—The human pelvis presents a mechanism the principal requirement of which is stability and not movement, for, through the pelvis, the weight of the trunk, superimposed upon the sacrum, is transmitted to the lower limbs. Moreover, its stability is largely concerned in the maintenance of the erect attitude. The movements of its various parts are therefore merely such as are consistent with stability, without producing absolute rigidity.

The two innominate bones, being bound together by powerful ligaments at the pubic articulation, constitute an inverted arch, of which the convexity is directed downwards and forwards, while its piers are turned upwards and backwards, and considerably expanded in relation to the hinder parts of the iliac bones. Between the piers of this inverted arch the sacrum is situated. This bone is in no sense a key-stone to an arch, because, as may readily be seen in antero-posterior transverse section, the sacrum is wider in front than behind, and the superposed weight naturally tends to make the sacrum fall towards the pelvic cavity, and so fit less closely between the innominate bones. The sacrum is in reality an oblique platform, in contact with each innominate bone through its articular auricular surfaces, and in this position it is suspended by the posterior sacro-iliac ligaments, and kept securely in place by the "grip" due to the irregularity of the opposed surfaces of the two sacro-iliac articulations. Since the weight of the trunk is transmitted to the anterior and upper end of this sacral platform, there is a natural tendency for the sacrum to revolve upon the transverse axis which passes through its sacro-iliac joints. If this were permitted, the promontory of the sacrum would rotate downwards and forwards towards the pelvic cavity, as really does occur in certain deformities. This revolution or tilting downwards of the fore-part of the sacrum is prevented by the action of the great and small sacro-sciatic ligaments, extending from the ischial tuberosity to the hinder and lower end of the suspended platform of the sacrum. Not only so, but these ligaments, acting on a rigid sacrum, tend to hold up the weight upon the sacral promontory.

The various ligaments passing between the last lumbar vertebra and the sacrum and ilium retain the weight of the trunk in position upon the anterior end of the sacrum, and resist its tendency to slip forwards and downwards towards the pelvic cavity. The entire weight of the trunk and pelvis is transmitted to the heads of the thigh bones in the most advantageous position, both for effectiveness and the strengthening of the inverted innominate arch, for it will be evident that the heads of the femora thrust inwards upon the convex side of the arch, very much at the place where the arches are weakest, viz. at the springing of the arch from its piers. The forces which tend to cause movement of the pelvic bones during parturition act from within the pelvis, and have for their object the increase of the various pelvic diameters, in order that the fœtal head may more readily be transmitted. For this purpose the wedge-like dorsal surface of the sacrum is driven backwards, and a certain amount of extra space may thereby be obtained. An important factor, however, in the increase of the pelvic capacity at this period is found in the relaxation of its various ligaments.

THE ARTICULATIONS OF THE LOWER EXTREMITY.

THE HIP-JOINT.

The human body provides no more perfect example of an enarthrodial diarthrosis than the hip-joint (articulatio coxæ). Combined with all that variety of movement which characterises a multi-axial joint, it nevertheless presents great stability, which has been obtained by simple arrangements, for restricting the range of its natural

movements. This stability is of paramount importance for the maintenance of the erect attitude, and the mechanical adaptations whereby this result is obtained are such that the erect attitude may be preserved without any great degree of sustained muscular effort.

Articular Surfaces.—The head of the femur is globular in shape, and considerably exceeds a hemisphere. It is clothed by hyaline articular cartilage on those parts which come into direct contact with the acetabulum. There is frequently more or less of extension of the articular cartilage from the head to the adjoining anterior part of the neck, an extension which is accounted for by the close and constant apposition of this portion of the neck with the hinder aspect of the ilio-femoral ligament. The limit of the articular cartilage covering the head is indicated by a sinuous border. Further, there is an absence of articular cartilage from the pit or depression on the head of the femur.

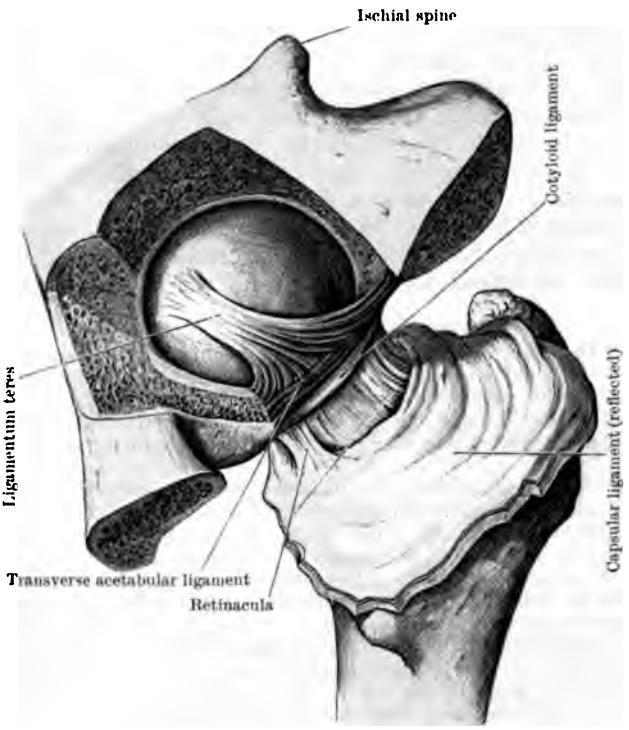

FIG. 231.—DISSECTION OF THE HIP-JOINT.
Bottom of the acetabulum removed, and capsule of the joint thrown outwards towards the trochanters.

The acetabulum is a deep cup-shaped cavity which presents an interruption or notch on its antero-inferior margin. The interior of the cup is lined by a ribbon-like band of articular cartilage which extends to the brim of the cavity, but does not cover the floor of the cup. This articular ribbon-shaped band is widest on its supero-posterior aspect, and narrowest at the anterior margin of the notch.

The **transverse ligament** (lig. transversum acetabuli, Fig. 231) bridges the acetabular notch, and consists of strong transverse fibres which are attached to both of its margins, but more extensively to the postero-inferior. This ligament does not entirely fill the notch, but leaves an open interval between its lower border and the bottom of the notch through which vessels and nerves enter the cup. The acetabular aspect of this ligament constitutes an articular surface.

The acetabulum is deepened by the **cotyloid ligament** (labrum glenoidale, Figs. 231 and 232), which consists of a strong ring of fibro-cartilaginous tissue attached to the entire rim of the cup. The attached surface of the ring is broader than its free edge, and, moreover, the latter is somewhat contracted, so that the ligament grasps the head of the femur which it encircles. Its fibres are partly oblique and partly circular in their direction. By the former it is firmly implanted on the rim of the acetabulum and the transverse ligament of the notch; by the latter the depth of the cup is increased through the elevation of its edge, and its mouth slightly narrowed. By one surface this ligament is also articular.

A **capsule** (capsula articularis, Figs. 230 and 232) completely invests the joint cavity. This is a fibrous membrane of great strength, although it is not of equal thickness throughout, being considerably thicker on the supero-anterior aspect than at any other part. Unlike the corresponding structure of the shoulder-joint, it does not permit of the withdrawal of the head of the femur from contact with the acetabular articular surfaces, except to a very limited extent. Its fibres are arranged

both in the circular and in the longitudinal direction, the former, known as the **zona orbicularis**, being best marked posteriorly, while the longitudinal fibres stand out more distinctly in front, where they constitute special ligaments. Looked at as a whole, the capsule has the following attachments: *superiorly* it surrounds the acetabulum, on the upper and hinder aspects of which it is attached directly to the innominate bone, while on the front and lower aspects it is attached to the non-articular surfaces of the cotyloid and transverse ligaments; *inferiorly* it encircles the neck of the femur, where it is attached in front to the anterior intertrochanteric line; above, to the inner aspect of the root of the great trochanter; below, to the lower part of the neck of the femur, in close proximity to the small trochanter; behind, to the line of junction of the outer and middle thirds of the neck of the femur. It is a matter of some importance to note that only part of the posterior surface of the neck of the femur is enclosed within the capsule. The femoral attachments of the capsule vary considerably in their strength, being particularly firm above and in front, but much weaker below and behind, where the orbicular fibres are well seen. Many fibres of the capsule are reflected from its deep aspect upwards upon the neck of the femur, where they form ridges, and to these the term **rectinacula** (Fig. 231) is applied.

The longitudinal fibres of the capsule are arranged so as to form certain definite bands, viz:—

(1) The **ilio-femoral ligament** (lig. ilio-femorale, Fig. 232) consists of a triangular set of fibres attached above, by their apex, to the lower part of the anterior inferior iliac spine and the immediately adjoining part of the rim of the acetabulum, and below, by their base, to the anterior intertrochanteric line of the femur. This ligament is the thickest part of the capsule, but its sides are more pronounced than its centre, especially towards its base. Consequently the ilio-femoral band presents some resemblance to an inverted Y (λ), and therefore it is very generally known as the Y-shaped ligament of Bigelow.

The outer or upper limb of the ilio-femoral ligament may be somewhat extended by the inclusion of additional longitudinal fibres, and described as the **ilio-trochanteric** ligament (lig. ilio-trochantericum). This band arises from the anterior part of the dorsum of the acetabulum, and extends to the femoral neck, close to the anterior end of the inner surface of the great trochanter.

(2) The **pubo-femoral** or **pubo-capsular ligament** (lig. pubo-femorale v. pubo-capsulare, Fig. 232) is composed of some bands of fibres of no great strength, which extend from the outer end of the horizontal ramus of the pubis, the ilio-pectineal eminence, the obturator crest and the obturator membrane, to lose themselves for the most part in the capsule, although a certain proportion of them may be traced to the inferior aspect of the femoral neck, where they adjoin the lower attachment of the Y-shaped ligament.

(3) The **ischio-capsular ligament** (lig. ischio-capsulare, Fig. 230) consists of a broad band of short, fairly strong longitudinal fibres, which, by their upper ends, are attached to the ischium between the small sciatic notch and the obturator foramen, while their lower ends become merged in the zona orbicularis of the general capsule.

Within the capsule, and quite distinct from it, there are the ligamentum teres and the Haversian gland.

The **interarticular ligament** (lig. teres femoris, Fig. 231) is a strong, somewhat flattened band of fibrous tissue, attached by one end to the upper half of the pit or depression on the head of the femur. By its inner end it is attached to the lower edge of the articular surface of the transverse ligament, with extensions to the opposite borders of the acetabular notch, but chiefly to the hinder or ischial border. This ligament varies very greatly in its strength and development in different subjects, and in certain rare cases it is absent.

The so-called **Haversian gland** occupies the bottom or non-articular area of the acetabulum. It consists of a mass of fat covered by synovial membrane. This pad of fat is continuous with the extra-capsular fat through the passage subjacent to the transverse ligament of the notch.

A synovial membrane lines the capsule from which it is reflected to the neck of the femur along a line which corresponds to the femoral attachments of the

capsule. Thus the synovial membrane clothes more of the femoral neck ante than in any other position. Posteriorly, where the capsule is feebly attach

ments, upon which it is continued as a lining for their acetabular or art surfaces, and further, it provides a covering for the fat at the bottom o acetabular fossa, as well as a complete tubular investment for the ligamentum

Occasionally the **synovial bursa**, which is subjacent to the tendon of th psoas muscle, communicates with the interior of the hip-joint through an op in the anterior wall of the capsule (Fig. 232), situated between the pubo-fe ligament and the inner or lower limb of the ilio-femoral ligament.

Movements at the Hip-Joint.—The movements which occur at the hip-joint are t a multiaxial joint. These are **flexion, extension, abduction, adduction, rotation,** and **circumd** The range of each of these movements is less extensive than in the case of the shoulder-joi cause, at the hip, the freedom of movement is subordinated to that stability which is essentia for the maintenance of the erect attitude and for locomotion. When standing at rest in th attitude the hip-joint occupies the position of **extension,** and as the weight of the trunk is mitted in a perpendicular which falls behind the centres of the hip-joints, both the erect a and the extended position are maintained to a large extent mechanically, without sustaine cular action, by means of the tension of the ilio-femoral ligament. Moreover, the tension ligament is sustained by the pressure of the front of the head and neck of the femur aga synovial surface. In this association of parts it is important to note that the articular ca of the femoral head may be, and in certain races is, prolonged to the front of the femoral and further, that the constant friction does not destroy the synovial lining of the c Again, the same mechanism which preserves the erect attitude prevents an excessive de extension or dorsiflexion. In movement forwards, *i.e.* ventral **flexion,** the front of the is approximated to the anterior abdominal wall. The amount of this movement depend the position of the knee-joint, because when the latter is flexed the thigh may be brougl contact with the abdominal wall, whereas when the knee-joint is straightened (*i.e.* ext the tension of the hamstring muscles greatly restricts the amount of flexion at the hi **Abduction** and **adduction** are likewise much more restricted than at the shoulder-joint. tion is brought to a close by the tension of the pubo-femoral band and the lower part capsule, and, in addition, the upper aspect of the neck of the femur locks against the of the acetabulum. Excessive **adduction** is prevented by the tension of the upper band ilio-femoral ligament and the upper part of the capsule. **Rotation** or movement in a tudinal axis may be either inwards, *i.e.* towards the front, or outwards, *i.e.* toward the

In the former the movement is brought to a close by the tension of the ischio-capsular ligament and back part of the capsule, aided by the muscles on the back of the joint; in the latter—rotation outwards—the chief restraining factor is the outer or upper limb of the ilio-femoral ligament. The total amount of rotation is probably less than 60°.

Circumduction is only slightly less free than at the shoulder, but it is complicated by the preservation of the balance upon one foot.

The value and influence of the ligamentum teres are not easily estimated, because it may be absent without causing any known interference with the usefulness of the joint. In the erect attitude this ligament lies lax between the lower part of the femoral head and the acetabular fat. In the act of walking it is rendered tense at the moment when the pelvis is balanced on the summit of the supporting femur. Analysis of this position shows the femur to be adducted, with probably, in addition, a small amount of flexion (*i.e.* bending forwards) and internal rotation. Again, this ligament is said to be tense when the thigh is rotated outwards. The equivalent of this movement is doubtless found in the rotation of the pelvis, which occurs in the act of walking at the moment of transition from the toe of the supporting foot to the heel of the advancing foot. The interest connected with this ligament is perhaps morphological rather than physiological. It is believed by some to represent the tendon of a muscle which in birds occupies a position external to the joint capsule.

THE KNEE-JOINT.

The knee-joint (articulatio genu) is the largest articulation in the body, and its structure is of a very elaborate nature. The part it plays in maintaining the erect attitude materially influences its construction, and special arrangements are provided for the mechanical retention of the joint in the extended position, in view of the fact that the line of gravity falls in front of the centre of the articulation. Its principal axis of movement is in the transverse direction, consequently it belongs to the ginglymus or hinge variety of the diarthroses. At the same time a slight amount of rotation of the tibia in its long axis is permitted during extreme flexion; but while this fact is of considerable importance in the study of certain accidents to which the joint is liable, as well as in the study of its comparative morphology, it is not sufficiently pronounced to interfere with its classification as a hinge-joint.

Articular surfaces pertaining to the femur, tibia, and patella, enter into the formation of the knee-joint. The articular surface of the femur extends over a large part of both condyles, and may be divided into patellar and tibial portions by faintly-marked, almost transverse grooves, which pass across the articular surface immediately in front of the intercondylar notch. As a rule marginal indentations of the articular surface render the positions of these transverse grooves more distinct.

The **patellar portion** (Fig. 233) is situated anteriorly, and is common to both condyles, although developed to a larger extent in association with the outer condyle, on which it ascends to a higher level than on the inner condyle. This surface is trochlear, and forms a vertical groove bordered by prominent lateral borders.

The **tibial portion** of the articular surface of the femur is divided into two articular areas, in relation to the inferior aspects of the two condyles, by the wide non-articular intercondyloid notch. These two surfaces are for the most part parallel, but in front the internal tibial surface turns obliquely outwards as it passes into continuity with the patellar trochlea, while posteriorly, under certain circumstances, *e.g.* the squatting posture, the articular surface of the inner condyle may extend to the adjoining portion of the popliteal area of the bone.

When the joint is in the position of extreme flexion, the patella is brought into direct contact with that part of the articular surface on the inner condyle which bounds the intercondyloid notch upon its inner and anterior aspects. This relationship is indicated by the presence of a distinct semilunar facet on the cartilage in that situation (Fig. 233). The articular surface of the femur may therefore be regarded as presenting **femoro-patellar** and **femoro-tibial areas**.

The **patella** presents on its posterior aspect a transversely-elongated oval articular facet and an inferior rough, triangular, non-articular area. The articular facet is divided into two principal lateral portions by a prominent rounded vertical ridge. Of these the outer is the wider. A less pronounced and nearly vertical ridge marks off an additional facet called the internal perpendicular facet, close to the inner margin of the articular surface. Two faint transverse ridges cut off

narrow upper and lower facets from the general articular surface without encroaching on the narrow innermost vertical facet (Goodsir) (Fig. 233).

The head of the **tibia** presents on its superior aspect two condylar articular surfaces, separated from each other by a non-articular antero-posterior area, which is wider in front and behind than in the middle, where it is elevated to form a bifid tibial spine.

The **external condylar facet** is slightly concavo-convex from before backwards, and slightly concave transversely. This surface is almost circular, and extends to the free external border of the tibial head, where it is somewhat flattened. Posteriorly the articular surface is prolonged downwards on the tuberosity in relation to the position occupied by the tendon of the popliteus muscle. The

internal condylar facet is oval in outline, and distinctly concave both in its antero-posterior and transverse diameters.

Ligaments.—Like all diarthroses, this joint is invested by an envelope or **capsule** (capsula articularis), which does not, however, entirely surround the joint cavity, for it is absent as a fibrous membrane above the joint cavity, subjacent to the tendon of the quadriceps extensor muscle. Its specially named bands are not of themselves sufficient to form a complete investment, and a capsular membrane, which largely consists of augmentations from the fascia lata and the tendons of surrounding muscles, supplies the defective areas. Thus, anteriorly, on each side of the patella and the ligamentum patellæ, expansions of the vasti tendons and fascia lata, constituting **lateral patellar ligaments**, are evident. On the outer side of the joint the external lateral ligament is hidden within a covering derived from the ilio-tibial band of the fascia lata. On the inner side expansions from the tendons of the sartorius and semi-membranosus muscles augment the capsule, which here becomes continuous with the internal lateral ligament. Posteriorly the capsule also receives augmentation from the tendon of the semi-membranosus muscle, but it is very thin subjacent to the origins of the gastrocnemius muscle, where it covers the hinder parts of the condyles. Not unfrequently the capsule presents an opening of communication between the interior of the joint cavity and a bursa which lies under cover of the inner head of the gastrocnemius muscle.

The **anterior ligament** (lig. patellæ, Fig. 233), also called the ligamentum patellæ, is a powerful flattened band, attached superiorly to the apex and adjoining margins of the patella, and inferiorly to the rough anterior tuberosity at the upper end of the shaft of the tibia. This ligament also serves as a tendon of insertion for the quadriceps extensor muscle, and a certain number of the fibres of the tendon may be observed to descend as a thin fibrous covering for the anterior surface of the patella. The deep surface of the tendon is separated from the front of the head of the tibia by a synovial bursa, and above this it rests upon the infrapatellar pad of fat, which is placed between the tendon and the synovial membrane of the joint.

The **posterior ligament** (Fig. 234) is a compound structure of unequal strength,

and those portions by which it establishes continuity with the lateral parts of the capsule are remarkably thin. It is attached superiorly to the popliteal surface of the femur, close to the intercondyloid notch, with lateral extensions to the non-articular areas immediately above the posterior articular margins of the two condyles, where it is closely associated with the origins of the gastrocnemius muscle.

Inferiorly it is attached to the rough non-articular posterior border of the head of the tibia, where, to its fibular side, it presents an opening of exit for the tendon of the popliteus muscle (Fig. 234).

The tendon of insertion of the semi-membranosus muscle contributes an important expansion which augments the posterior ligament on its superficial aspect. This expansion—**ligamentum posticum Winslowii**—passes obliquely upwards and outwards to lose itself in the general ligament, but it is most distinct in the region between the femoral condyles, where it may present upper and lower arcuate

borders. A number of vessels and nerves perforate this ligament, and hence presents a number of apertures.

The **internal lateral ligament** (lig. collaterale tibiale, Figs. 233 and 235) is a wel defined, strong, flat band which is applied to the inner side of the knee-joint, and rather wider in the middle than at either end. It is frequently regarded as consistin of two portions—an anterior or long portion, and a posterior or short one. The tv parts arise close together from the non-articular inner surface of the inner condyl immediately below the adductor tubercle. The **short** or **posterior portion** descen slightly backwards, to be attached to the postero-internal aspect of the inner part the tibia above the groove for the semi-membranosus tendon. The **long** or **anteri portion** inclines somewhat forwards, and descending superficially to the tendon the semi-membranosus, it is continued downwards, to be attached to the upper part the inner surface of the shaft of the tibia below the level of the anterior tuberosit

On its superficial aspect the internal lateral ligament is augmented by prolong tions from the tendons of the semi-membranosus and sartorius muscles, but separated by a bursa from the tendons of adductor-gracilis, semi-tendinosus, an sartorius. Its deep surface is adherent to the convex edge of the internal semilun cartilage, but lower down the inferior internal articular vessels intervene betwee the ligament and the shaft of the tibia.

The **external lateral ligament** (lig. collaterale fibulare, Figs. 233 and 235), sometim called the ligamentum laterale externum longum, is a distinct rounded band whic is under cover of the ordinary capsule, and yet well separated from the joint cavity b intervening objects. It is attached superiorly to a tubercle on the outer surface the external condyle, immediately above the groove occupied by the tendon of th popliteus muscle, superficial to which the ligament descends. By its lower end it attached to the outer side of the head of the fibula, in front of the styloid proces In its course vertically downwards it splits the tendon of insertion of the bicep flexor cruris (Fig. 233), the portions of which are fixed to the head of the fibula o either side of the ligament, and a bursa may intervene between the tendon and th ligament. The inferior external articular vessels pass forwards subjacent to th ligament and above the head of the fibula. Unlike the internal ligament, it is n attached to the corresponding semilunar cartilage.

The **ligamentum laterale externum breve seu posticum** (Fig. 234) is an inconstant structu which is attached by its upper end immediately behind the preceding, and subjacent to t outer head of the gastrocnemius muscle. It likewise descends superficial to the popliteal tend and is affixed inferiorly into the styloid process of the fibula.

The **intra-articular structures** of the knee-joint are more important and mo numerous than in any other joint of the body.

The **crucial ligaments** (ligamenta cruciata genu) are two strong, rounded, tendino bands, which extend from the non-articular area on the upper surface of the he of the tibia to the non-articular sides of the intercondyloid notch of the fem These interarticular ligaments are distinguished from each other as the anterior external and the posterior or internal. They cross each other like the limbs an X, yet they remain distinct throughout, and each has its own partial synov covering. They lie within the capsule of the joint, and extend between no articular surfaces in relation to the longitudinal axis of the limb.

The **ligamentum cruciatum anterius** (Figs. 233, 235, and 236) is attached inferio to the inner part of the rough, depressed area in front of and close to the spine the tibia. It passes obliquely upwards, outwards, and backwards to the inn non-articular surface of the external condyle, where it finds attachment far back the posterior part of the intercondyloid notch. This ligament is tense in the positi of extension, and therefore it assists in maintaining the erect attitude.

The **ligamentum cruciatum posterius** (Figs. 233, 235, and 236) is somewhat shor than the preceding. It is attached inferiorly to the hinder part of the depress surface behind the spine of the tibia and close to the popliteal notch. Its fib pass obliquely upwards, forwards, and inwards, to be inserted into the outer no articular surface of the inner condyle, far forwards towards the anterior margin the intercondyloid notch. It is rendered tense in the position of flexion.

The semilunar interarticular fibro-cartilages are two in number—an inner and an outer—placed horizontally between the articular surfaces of the femur and tibia. In general outline they correspond to the circumferential portions of the tibial facets upon which they rest. Each has a thick, convex, fixed border in relation to the periphery of the joint, and a thin, concave, free border directed towards the interior of the joint. Neither of them is sufficiently large to cover the whole of the tibial articular surface upon which it rests. The upper and lower surfaces of each semilune are smooth and free, and each cartilage terminates in an anterior and a posterior fibrous horn or cornu.

The **internal semilunar fibro-cartilage** (meniscus medialis, Figs. 235 and 236)

forms very nearly a semicircle. It is attached by its anterior horn to the non-articular surface on the head of the tibia, in front of the tibial attachment of the anterior crucial ligament, and by its posterior horn to the non-articular surface immediately in front of the tibial attachment of the posterior crucial ligament. The deep or hinder part of the internal lateral ligament is attached to its periphery.

The **external semilunar fibro-cartilage** (meniscus lateralis, Figs. 235 and 236) is attached by its anterior horn to the non-articular surface of the tibia in front of the tibial spine, where it is placed to the outer side, and partly under cover of the tibial end of the anterior crucial ligament. By its posterior horn it is attached to the interval between the two tubercles which surmount the tibial spine, *i.e.* in front of the attachment of the posterior horn of the internal semilunar cartilage. This fibro-cartilage, with its two horns, therefore forms almost a complete circle. Posteriorly it is attached by its periphery to the *posterior* ligament, but on the outer side it

is separated from the external lateral ligament by the tendon of the popliteus muscle, and on this aspect its periphery is free.

The two horns of the external semilune are embraced by the two horns of the internal one, and, while the anterior crucial ligament has its tibial attachment almost between the anterior horns of the two semilunes, the tibial attachment of the posterior crucial ligament is situated behind the posterior horns of the two semilunes.

Both semilunes possess certain accessory attachments. Thus the external semilune sends a large bundle of fibres from its convex posterior border to augment the posterior aspect of the posterior crucial ligament, by which these fibres are conducted to the femur. Again, the convex or peripheral margins of each semilune possess certain attachments to the deep surface of the capsule on its inner and posterior aspects, as has already been explained, but, in addition, they are attached to the non-articular circumference of the tibial head by short fibrous bands known as the **ligamenta coronaria**. Lastly, a rounded band which varies in strength, the **transverse ligament** (lig. transversum genu, Figs. 233 and 236), stretches between the anterior convex margins of the two semilunes, crossing the front part of the non-articular area on the tibial head in its course.

The **synovial membrane** of the knee-joint is not only the largest, but the most elaborately arranged of its kind in the body. It not only lines the capsule, but it forms a more or less extensive covering for the intracapsular ligaments and the free surface of the **infra-patellar pad of fat**. This pad acts as a wedge which fits into the interval between the patella, tibia, and femoral condyles, and the synovial membrane upon its surface forms a band or fold which extends from below the level of the patellar articular surface to the anterior part of the intercondyloid notch. This is in no sense a ligament, although it is named the **ligamentum mucosum**, or plica synovialis patellaris. At its femoral end it is narrow and attenuated, but at its patellar end it expands laterally to form wing-like fringes or membranes—the **alar ligaments** (plicæ alares)—which are often distinguished from each other as the inner (plica aliformis medialis) and the outer (plica aliformis lateralis). These folds are more or less loaded with fat.

Apart from these special foldings, the synovial membrane lines the deep surface of the common extensor tendon, and extends upwards for a variable distance above the patella. This extension of the joint cavity almost always communicates with a large bursa situated still higher on the front of the femur. Tracing the synovial membrane downwards, it will be found to cover both surfaces of the semilunar fibro-cartilages. The peripheral or convex margins of these cartilages are only covered by this membrane where they are unattached to the capsule. A prolongation invests the intracapsular portion of the tendon of the popliteus muscle, and separates this tendon from the back part of the tibial head, besides intervening between the external semilune and the head of the tibia.

From the back part of the joint cavity the synovial membrane extends forwards,

provides a partial covering for the crucial ligaments between which a bursa may ound.

This somewhat complicated arrangement of the synovial membrane may be lily comprehended if it be borne in mind that it really represents the fusion of e separate synovial cavities, which in some animals are permanently distinct. se are indicated in the two femoro-tibial and the single femoro-patellar parts of articulation.

The joint cavity may communicate with **bursæ** situated in relation to the inner d of the gastrocnemius muscle and the tendon of the semi-membranosus muscle, ides the large supra-patellar bursa already described. Lastly, there may be ercommunication between this joint cavity and that of the superior tibio-fibular iculation.

Movements at the Knee-Joint.—In studying the movements which may occur at the nan knee-joint, it is necessary to bear in mind that the lower limb of man is primarily required purposes of support and locomotion. The principal requirement of the former function is ility accompanied by rigidity, whereas in the latter function the special desideratum is regu-d and controlled mobility. Thus, in the same joint, two entirely opposite conditions have be provided. The stable conditions of support are chiefly concerned in the maintenance he erect attitude, and the mechanism associated therewith does not call for the exertion of a e degree of sustained muscular effort.

In standing erect the attitude of the limb is that of extension, which mainly concerns the oro-tibial parts of the joint. In this position the force of gravity acts along a vertical line ich falls in front of the transverse axis of the joint, and therefore any tendency to flexion, *i.e.* ding backwards, is mechanically counteracted by the application of a force which tends to duce bending forwards (so-called over-extension). This, however, is absolutely prohibited in mal states of the joint, by the tension of the posterior and lateral ligaments aided by the erior crucial ligament. The value of this fact may be seen by observing the effect produced by ing the joint a sudden push from behind, which causes an immediate reversal of the positions of transverse and vertical axes, whereby the body weight at once produces flexion of the joint.

The semilunar cartilages and the infra-patellar pad of fat also assist in maintaining extension, reason of their close adaptation to, and packing round the condyles as these rest upon the tibia. e anterior margin of the intercondyloid fossa is also brought into contact with the front of anterior crucial ligament.

In the position of extension the patella is retained at a high level in relation to the trochlear sur-e of the femur, so that the lower articular facets of the patella are in contact with the trochlea.

During locomotion the movements of the knee-joint are somewhat intricate, for both the oro-tibial and the femoro-patellar sections of the joint are brought into action. The principal vement which results is flexion, with which there is associated, both at its beginning and ding, a certain amount of screw movement or rotation. Flexion and rotation occur at the oro-tibial sections of the joint, whereas the movement at the femoro-patellar portion produces gulating and controlling influence upon flexion.

Taking these factors separately, we observe that each condyle adapts itself to a shallow cup med by the head of the tibia and the corresponding semilunar cartilage, and as the two ndyles move simultaneously and parallel to each other, there is more than the characteristic nge-joint action, for each condyle glides and rolls in its cup "like a wheel restrained by a ag" (Goodsir) when the movement of bending occurs. Thus the different parts of the condyles successively brought into relation with the transverse axis of the joint while it passes from tension to flexion and *vice versa*. From the fact that the internal condyle is longer than the ternal, it is believed that extension is completed by a movement of rotation whereby the joint omes locked, and the anterior crucial, the posterior and the lateral ligaments, become tense. A ilar rotation initiates the movement of flexion, and unlocks the joint by relaxing the liga-nts just mentioned.

Since the tibia and foot are fixed in the act of walking, it is the femur which rotates upon tibia in passing from extension to flexion and *vice versa*; and as relaxation of the ilio-femoral ment is essential for this rotation, some observers are of opinion that the body weight falls ind the transverse axis of the knee-joint, as in the case of the hip-joint, and consequently that ension of the knee-joint is maintained by the ilio-femoral ligament, as it is not possible to d the knee without first having bent the hip-joint.

During flexion and extension the semilunar cartilages glide along with the condyles, so as to ntain their close adaptation and preserve their value as packing agents. When the movement exion is completed, the condyles are retained upon the tibia, and prevented from slipping off he tension of the posterior crucial ligament. In this position a small degree of rotation of tibia, both inwards and outwards, is also permissible.

The regulating and controlling influence of the femoro-patellar portion of the articulation is ght into play during the movements of flexion and extension. In the latter position the rior pair of patellar facets is in apposition with the upper part of the femoral trochlea. As on advances, the middle pair of facets adapt themselves to a deeper area of the trochlea, into h the patellar keel fits. When flexion is still further advanced, the upper pair of patellar s will be found fitting into that *part of the trochlea* adjoining the intercondyloid notch,

and finally, when flexion is complete, the patella lies opposite the intercondyloid notch, while the forward thrust of the longer internal condyle brings its semilunar facet (Goodsir) into apposition with the somewhat vertical facet at the inner border of the patella. The wedge-like influence of the patella is most marked, for it is only in the position of extension that it can be moved from side to side. The movements of the patella may be described as gliding and co-aptation, as it slips or rocks from one pair of facets to another in its progress along the trough of the femoral trochlea.

THE TIBIO-FIBULAR JOINTS.

The upper and lower ends of the fibula articulate with the tibia. Primarily, the fibula is required to form a strong lateral support for the ankle-joint, and therefore its articulations are so arranged as to provide a certain amount of elasticity without any sacrifice of the rigidity necessary for security. Hence the amount of movement is very small, but what there is enables these joints to be classified as arthrodial diarthroses.

The **superior tibio-fibular joint** (articulatio tibio-fibularis) is formed, on the one hand, by a flat oval or circular facet which is situated upon the postero-external aspect of the outer tuberosity of the head of the tibia, and is directed downwards and backwards; on the other, by a similar facet on the upper surface of the head of the fibula in front of the styloid process.

A fibrous **capsule** (capsula articularis, Fig. 234) invests the joint, and it may be regarded as holding the articular surfaces in apposition, although certain special bands receive separate designations. Occasionally there is an opening in the capsule by which communication is established between the joint cavity and the knee-joint through the intermediation of the synovial prolongation, subjacent to the tendon of the popliteus muscle.

The **anterior superior tibio-fibular ligament** (lig. capituli fibulæ anterius, Fig. 233) is a strong flat band whose fibres extend from the anterior aspect of the fibular head, upwards and inwards, to the adjoining part of the tuberosity of the tibia.

The **posterior superior tibio-fibular ligament** (lig. capituli fibulæ anterius Fig. 234) is a similar, but weaker band, passing upwards and inwards from the posterior aspect of the fibular head to the posterior aspect of the outer tuberosity of the tibia, where they are attached immediately below the opening in the capsule of the knee-joint, from which the tendon of the popliteus muscle escapes.

Equally strong but much shorter bands are found on the superior and inferior aspects of the joint. The former is intimately associated with the tendon of the biceps flexor cruris muscle which strengthens the upper aspect of the joint, and here also is found the occasional opening by which it communicates with the knee-joint.

The **synovial membrane** is in certain cases continuous with that of the knee-joint in the manner already described.

The **interosseous membrane** (membrana interossea cruris, Figs. 234 and 237) plays the part of an accessory ligament both for the upper and the lower tibio-fibular joint. It is attached to the interosseous borders on the shafts of the tibia and fibula, and binds them together. The general direction of its fibres is from the tibia downwards and outwards to the fibula, but many fibres pass in the opposite direction. The membrane may extend upwards until it comes into contact with the ligaments of the superior tibio-fibular joint, but there is always a vertical oval aperture in its upper part for the forward passage of the anterior tibial vessels. This aperture (Fig. 234), which is about one inch long, adjoins the shaft of the fibula at a point rather less than one inch below its head. Towards the lower end of the leg the distance between the tibia and the fibula rapidly diminishes, and consequently the width of the interosseous membrane is correspondingly reduced so that it is tense throughout its entire length. In the lower part of the membrane there is a small opening for the passage of the anterior perforating vessels. There is no sharply-marked demarcation between the interosseous membrane and the interosseous ligament which connects the lower ends of the tibia and fibula—the one, indeed, may be said to run into the other.

The **inferior tibio-fibular joint** (syndesmosis tibio-fibulare) is not on all occasions provided with articular cartilage, so that it may either be a separate articu

lation, or it may merely present a series of ligaments which are accessory to the ankle-joint, because it is clear that, under any circumstances, the object aimed at in this articulation is to obtain additional security for the ankle-joint. The articular surface on the tibia, when present, constitutes a narrow articular strip on the outer side of the lower end of the bone, and the joint-cavity is practically an upward extension of the ankle-joint. The corresponding fibular facet is continuous with the extensive articular area, by means of which the fibula articulates with the astragalus. By far the greater part of the opposing surfaces of tibia and fibula are, however, non-articular and rough.

The supporting **ligaments** are of great strength.

FIG. 237.—ANKLE-JOINT DISSECTED FROM BEHIND WITH PART OF THE CAPSULAR LIGAMENT REMOVED.

The **anterior inferior tibio-fibular ligament** (lig. malleoli lateralis anterius, Fig. 240) consists of strong fibres which pass obliquely downwards and outwards from the front of the lower end of the tibia to the front of the external malleolus.

The **posterior inferior tibio-fibular ligament** (lig. malleoli lateralis posterius, Figs. 237 and 238) is equally strong, and passes in a similar direction between corresponding posterior surfaces.

A **transverse inferior tibio-fibular ligament** (Figs. 237 and 238) stretches, in the direction indicated by its name, between the posterior inferior border of the tibia and the upper end of the pit on the inner and posterior aspect of the external malleolus.

An **interosseous ligament**, powerful and somewhat extensive, connects the contiguous rough non-articular surfaces. Superiorly, as already mentioned, it is continuous with the interosseous membrane. Anteriorly and posteriorly it comes into contact with the more superficial ligaments. Inferiorly it descends until it comes into intimate association *with the joint-cavity.*

A **synovial membrane** is found lining the small joint-cavity, but it is always a direct prolongation from that which lines the ankle-joint.

JOINTS OF THE FOOT.

THE ANKLE-JOINT.

The ankle-joint (articulatio talo-cruralis) is a ginglymus variety of a diarthrosis. The bones which enter into its formation are the lower ends of the tibia and fibula with the articular areas on the upper, lateral, and mesial surfaces of the astragalus. The tibia and fibula, aided by the transverse inferior tibio-fibular ligament, form a three-sided socket within which the astragalus is accommodated. The roof of the highest part of the socket, which is wider in front than behind, is formed chiefly by the quadrilateral articular surface which characterises the lower end of the tibia, but towards its postero-external margin the transverse inferior tibio-fibular ligament assists in its formation. Here also the tibial articular surface is continuous with the narrow articular facet already described as forming part of the inferior tibio-fibular joint. The inner wall of the socket is formed by the articular facet on the outer side of the internal malleolus, and there is no interruption of the articular cartilage between the roof and inner wall. The outer wall of the socket is quite separate from the foregoing parts, and consists of a large triangular facet upon the inner side of the external malleolus. This facet is situated immediately in front of the deep pit which characterises the posterior part of this surface of the fibula.

A small lunated facet is frequently found upon the anterior surface of the lower end of the tibia, particularly among those races characterised by the adoption of the "squatting" posture. When this facet exists it is continuous with the anterior margin of the roof of the socket, and articulates with a similar facet upon the upper surface of the neck of the astragalus in the extreme flexion of the ankle-joint which "squatting" entails.

The articular surface upon the body of the astragalus adapts itself to the tibio-fibular socket, and presents articular facets corresponding to the roof and sides of the socket. Thus the superior surface of the astragalus possesses a quadrilateral articular area, wider in front than behind, distinctly convex in the antero-posterior direction, and slightly concave transversely. In addition, towards its postero-external margin, there is also a narrow antero-posterior facet corresponding to the transverse inferior tibio-fibular ligament. The articular cartilage of this upper surface is continued without interruption to the tibial and fibular sides of the bone, although the margins of the superior area are sharply defined from the lateral facets, the outer of which is triangular in outline, while the inner is pyriform, but in each case the surface is vertical.

Ligaments.—The ligaments form a complete investment for the joint, *i.e.* a **capsule** in which the individual parts vary considerably in strength, and are described under separate names.

The **anterior ligament** is an extremely thin membrane, containing very few longitudinal fibres. It extends from the lower border of the tibia to the upper border of the head of the astragalus, passing in front of a pad of fat which fills up the hollow above the neck of that bone.

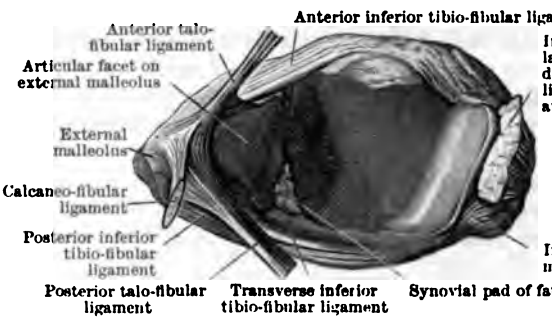

FIG. 238.—ARTICULAR SURFACES OF TIBIA AND FIBULA WHICH ARE OPPOSED TO THE ASTRAGALUS.

The **posterior ligament** is attached to contiguous non-articular borders of the tibia and astragalus. Many of its fibres radiate inwards from the external malleolus. This aspect of the joint is strengthened by the strong, well-defined, transverse ligament already described in connexion with the inferior tibio-fibular joint.

The **external lateral ligament** (Figs. 237, 238, and 240) is very powerful, and is divisible into three fasciculi, which are distinguished from each other by names descriptive of their chief points of attachment.

The *anterior fasciculus* (lig. talo-fibulare anterius) is the shortest. It extends from the anterior border of the external malleolus to the astragalus immediately in front of its external articular surface.

The *middle fasciculus* (lig. calcaneo-fibulare) is a strong and rounded cord. It is attached by one end to the front of the tip of the external malleolus, and by the other to the outer side of the os calcis, immediately above the groove for the peroneal tendons.

The *posterior fasciculus* (lig. talo-fibulare posterius) is the strongest. It runs transversely between the lower part of the fibular or digital fossa on the inner aspect of the malleolus and the posterior surface of the astragalus, where it is attached

FIG. 239.—ANKLE AND TARSAL-JOINTS FROM THE TIBIAL ASPECT.

to the external tubercle and the adjoining rough surface. Sometimes this tubercle is detached from the astragalus, and represents a separate bone—the *os trigonum*.

The **internal lateral ligament** (lig. deltoideum, Figs. 238 and 239) has the general shape of a delta, and is even stronger than the external ligament. It is attached above to a marked impression on the lower part of the internal malleolus, and below, in a continuous layer, to the scaphoid, astragalus, and os calcis. In it we may recognise the following special bands—(*a*) the *lig. talo-tibiale anterius*, which extends from the front of the inner malleolus to the neck of the astragalus; (*b*) the *lig. talo-tibiale posterius*, stretching between the back of the inner malleolus and the postero-internal rough surface of the astragalus; (*c*) the *lig. tibio-naviculare*, which extends from the tip of the inner malleolus to the inner side of the scaphoid; (*d*) the *lig. calcaneo-tibiale*, which extends between the tip of the inner malleolus and the inner side of the sustentaculum tali; (*e*) *lig. talo-tibiale profundum*, which consists of deeper fibres extending from the tip of the internal malleolus to the inner side of the astragalus.

Synovial membrane lines the capsular ligament, and, as already described, the joint-cavity communicates directly with the inferior tibio-fibular joint. Both at the front and back of the ankle-joint, as well as superiorly in the angle formed by the three bones, the synovial *membrane covers pads* of fat.

Movements at the Ankle-Joint.—In the erect attitude the foot is placed at right angles to the leg; in other words, the normal position of the ankle-joint is **flexion**. Those movements which tend to diminish the angle so formed by the dorsum of the foot and the front of the leg are called **dorsiflexion**, while those which tend to increase the angle, *i.e.* to straighten the foot upon the leg, are called **extension**. As a matter of fact neither dorsiflexion nor extension is ever completely carried out, and the range of movement of which the foot is capable is limited to about 90°. These movements occur about an obliquely transverse axis, as is indicated by the natural outward pointing of the toes. The weight of the body falls slightly anterior to the ankle-joint, so that a certain amount of muscular action is necessitated in order to maintain the foot at right angles to the leg; but additional stability is obtained from the obliquity above mentioned.

When the foot is raised from the ground, muscular action tends naturally to produce a certain amount of extension. When the foot is extended, as in standing on the toes, the hinder narrow part of the astragalus moves forwards into the wider part of the interval between the tibia and fibula, whereas in dorsiflexion, as in raising the fore part of the foot from the ground, the widest part of the astragalus is forced back between the tibia and fibula; but notwithstanding the difference between these two movements, the fibula remains in close contact with the astragalus by reason of the action of the transverse inferior tibio-fibular ligament and the posterior talo-fibular ligament, so that lateral movement is prevented.

It is doubtful whether lateral movement at the ankle-joint can be obtained by any natural movement of the foot, although it is generally believed that in the position of partial extension a small amount of lateral movement may be produced by the application of external force. "This apparent play" of the ankle-joint during extension "is really due to oscillation of the small bones of the foot on each other, largely of the scaphoid on the astragalus, but also of the cuboid on the calcaneum. Excessive mobility of these latter is restrained by an important function of the posterior tubercle of the cuboid which locks into a notch in the os calcis" (Blake).

INTERTARSAL JOINTS.

These joints (articulationes intertarseæ) are all diarthroses in which the gliding movement is characteristic, as in the carpus. With the view of obtaining a proper con-

FIG. 240.—LIGAMENTS ON THE OUTER ASPECT OF THE ANKLE-JOINT AND ON THE DORSUM OF THE TARSU

ception of the many beautiful mechanical principles involved in the construction of th foot, it is necessary to study these articulations with considerable attention to detai

Articulatio Talo-calcanea.—The astragalus and os calcis articulate with eac other in the articulatio talo-calcanea or calcaneo-astragaloid joint.

This joint is situated between the inferior facet on the body of the astragalu

a corresponding facet on the upper aspect of the hinder part of the os calcis. each bone the articulation is limited in front by a wide, deep groove which s obliquely across each bone from within outwards and forwards.

The supporting and investing ligaments form a **capsule**, consisting for the most t of short fibres, but the joint derives additional strength from the external and ernal lateral ligaments of the ankle-joint. The capsule is subdivided into the owing astragalo-calcaneal or talo-calcaneal bands:—

The **anterior talo-calcaneal ligament** consists of a band of short fibres ced immediately in relation to the anterior end of the deep groove which inds the articular facets. ey are attached to the tero-external aspect of e neck of the astragalus, om which they extend wnwards to the adjacent perior surface of the os lcis.

The **external talo-calcaneal ligament** (Fig. 240) in continuity with the nder border of the preding ligament, and it is aced parallel to, but on deeper plane than, the iddle fasciculus of the cternal lateral ligament the ankle-joint. It consts of short fibres passing etween the adjacent rough uter margins of the two ones.

FIG. 241.—THE COMPOSITE ARTICULAR SOCKET FOR THE HEAD OF THE ASTRAGALUS.

The **posterior talo-calcaneal ligament** (Fig. 240) loses the joint-cavity on its osterior aspect. It consists of fibres which radiate from the posterior aspect of he external tubercle of the astragalus to the upper surface of the os calcis, immediately behind the articular facet.

The **internal talo-calcaneal ligament** lies obliquely on the inner side of the joint, nd consists of fibres which extend from the inner posterior tubercle of the stragalus to the hinder roughened border of the sustentaculum tali. Some of its bres become continuous with the internal calcaneo-scaphoid ligament.

The **interosseous talo-calcaneal ligament** (Fig. 240) closes the antero-internal spect of the joint. It is the strongest of the series of ligaments entering into the apsule. Compared with it the other bands are, comparatively speaking, insignicant. Its attachments are to the bottom of each groove, so that it occupies the rsal canal formed by these opposing grooves.

A **synovial membrane** lines the capsule, and it is distinct from other tarsal novial membranes.

Articulatio Talo-calcaneo-navicularis.—This is one of the most important of e joints of the foot, not only because the astragalus is here situated in relation the summit of the antero-posterior arch of the foot, but because the head of e astragalus is received into a composite socket made up of sustentaculum tali, aphoid, and the inferior or internal calcaneo-scaphoid ligament.

The articular surface on the head of the astragalus presents anteriorly a nvex rounded facet for articulation with the scaphoid, inferiorly a convex facet nich rests upon the sustentaculum tali, and intermediate between these two there a triangular facet which articulates with the inferior calcaneo-scaphoid ligament. l these facets are in continuity with each other, and are in front of the tarsal ove on the under surface of the astragalus. Occasionally a fourth narrow facet is

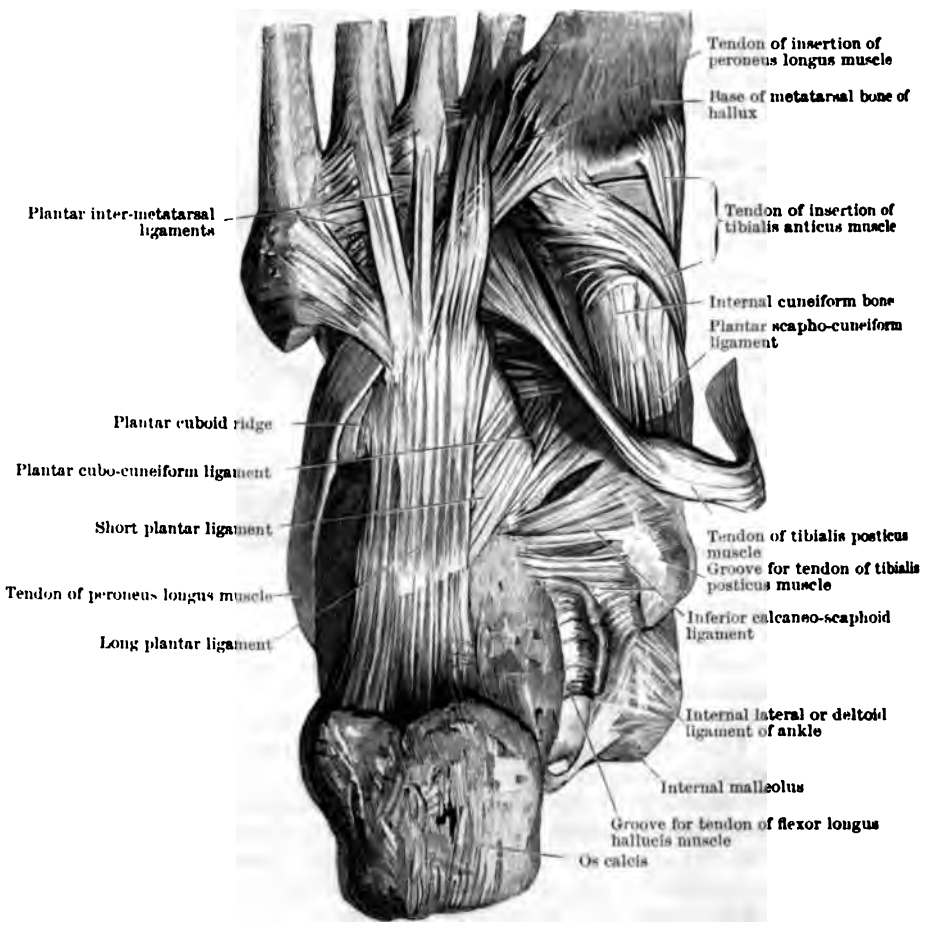
found along the outer and hinder part of the articular surface of the head of the astragalus, whereby it articulates with superior or external calcaneo-scaphoid ligament.

The scaphoid or navicular bone presents a shallow, cup-shaped, articular cavity towards the head of the astragalus.

The articular surface of the sustentaculum tali is concave, and is usually marked off into two facets.

Two ligaments play an important part in binding together the os calcis and the scaphoid, although these bones do not directly articulate; and further, these ligaments provide additional articular surfaces for the head of the astragalus. These are the two following:--

(*a*) The **inferior** or **internal calcaneo-scaphoid ligament** (Figs. 239 and 242) is as



Tendon of insertion of peroneus longus muscle
Base of metatarsal bone of hallux
Plantar inter-metatarsal ligaments
Tendon of insertion of tibialis anticus muscle
Internal cuneiform bone
Plantar scapho-cuneiform ligament
Plantar cuboid ridge
Plantar cubo-cuneiform ligament
Short plantar ligament
Tendon of tibialis posticus muscle
Groove for tendon of tibialis posticus muscle
Tendon of peroneus longus muscle
Inferior calcaneo-scaphoid ligament
Long plantar ligament
Internal lateral or deltoid ligament of ankle
Internal malleolus
Groove for tendon of flexor longus hallucis muscle
Os calcis

FIG. 242.—PLANTAR ASPECT OF TARSAL AND TARSO-METATARSAL JOINTS.

extremely powerful fibro-cartilaginous tie-band. It extends between the anterior margin of the sustentaculum tali and the inferior surface of the scaphoid bone. Certain of its upper fibres radiate upwards on the inner surface of the scaphoid, and become continuous with the tibio-navicular portion of the deltoid ligament of the ankle-joint. The plantar aspect of this ligament is in contact with the tendon of the tibialis posticus muscle, through which the head of the talus receives great support. Superiorly it contributes an articular surface which forms a triangular portion of the floor of the composite socket in which the head of the talus is received.

(*b*) The **superior** or **external calcaneo-scaphoid ligament** (Fig. 241) lies deeply in the front part of the sinus tarsi, *i.e.* the interval between the astragalus and os calcis. Its fibres are short, and extend from the dorsal surface of the front part of the os calcis, immediately to the outer side of the sustentacular facet, forwards to the outer side of the scaphoid bone. Frequently the ligament presents a surface

uich articulates with the head of the astragalus, and in these cases it forms a part the composite socket.

The cavity of the talo-calcaneo-navicular joint is closed posteriorly by the terosseous talo-calcaneal ligament already described. On its inner and outer ferior aspects it is closed by the calcaneo-scaphoid ligaments.

The superior and lateral aspects are covered by an **astragalo-scaphoid membrane ligament.** This ligament is thin, and extends from the upper non-articular area i the head of the astragalus to the dorsal surface of the scaphoid bone. It may ; subdivided into *dorsal* (superior), *lateral* (external), and *medial* (internal), **tragalo-scaphoid ligaments** (Fig. 239), which, with the calcaneo-scaphoid and terosseous talo-calcaneal ligaments, complete the capsular investment of the joint.

A distinct **synovial membrane** lines all parts of the capsule of the joint.

Articulatio Calcaneo-cuboidea.—This is situated between the anterior concavo-onvex surface of the os calcis and the posterior similar surface of the cuboid.

The **ligaments** which invest this joint constitute a **calcaneo-cuboid capsule,** whose arts are arranged in relation to the four non-articular sides of the cuboid bone, nd are especially strong upon the plantar aspect, in relation to their great import-nce in resisting strains.

The **internal calcaneo-cuboid ligament** occupies part of the interval between he astragalus and os calcis—sinus tarsi. It is sometimes called the interosseous alcaneo-cuboid ligament, and, in conjunction with the superior or external alcaneo-scaphoid ligament, it forms a V-shaped structure, of which the single end s attached to the os calcis, and the double ends separate to reach contiguous reas on the scaphoid and cuboid respectively.

The **dorsal calcaneo-cuboid ligament** (Fig. 240) is a broad portion of the capsule xtending between the dorsal surfaces of the two bones.

The **external calcaneo-cuboid ligament** is another but narrower part of the apsule which extends from the outer aspect of the os calcis to the outer side of he cuboid, immediately behind the facet on the tuberosity.

The **inferior calcaneo-cuboid ligaments** are two in number—a superficial and a eep. The superficial series of fibres, the **long plantar ligament** (Fig. 242), is ttached to the under surface of the os calcis in front of its tuberosities. It forms long powerful structure which runs forwards to be fixed to the under surface of the uboid ridge, but many of its fibres pass superficial to the tendon of the peroneus ongus, and extend to the bases of the third, fourth, and fifth metatarsal bones.

The deep series of fibres, the **short plantar ligament** (Fig. 242), is distinctly separated rom the former by a layer of areolar tissue. It forms a broad but short band of great trength, which is attached to the under surface of the front end of the os calcis, nd extends to the under surface of the cuboid just behind the ridge. Both of hese ligaments are of great importance in maintaining the longitudinal arch of the oot, and in this respect are only second to the inferior calcaneo-scaphoid ligaments.

A **synovial membrane** lines the capsule.

Transverse Tarsal Articulation.—This is a term sometimes applied to the stragalo-scaphoid and calcaneo-cuboid joints. These articulations do not com-unicate with each other; and although there is an occasional direct articula-ion between the scaphoid and cuboid, it does not constitute an extension of the ransverse tarsal joint, but is a prolongation from the series of scapho-cuneiform nd cuneo-cuboid articulations.

Nevertheless there is always a set of **ligaments** which bind the scaphoid and uboid bones together, and these may be regarded as accessory to the various ransverse tarsal joints.

The **dorsal scapho-cuboid ligament** (Fig. 240) consists of short oblique fibres which ttach the contiguous dorsal surfaces of the cuboid and scaphoid bones.

The **plantar scapho-cuboid ligament** is transverse in direction, and extends etween adjacent plantar areas of the cuboid and scaphoid bones.

The **interosseous scapho-cuboid ligament** intervenes between contiguous surfaces the same bones. When there is an extension of the scapho-cuneiform joint back-ards between the scaphoid and cuboid, it is situated in front of the last-men-oned ligament, and is called the **articulatio scapho-cuboidea.** Around this joint

the preceding ligaments are grouped. Since, however, the joint is inconstant while the ligaments are always present, it is preferable to consider them as above indicated.

Scapho-cuneiform Articulation (articulatio cuneo-navicularis).—This joint is situated between the scaphoid and the three cuneiform bones. The anterior surface of the scaphoid presents facets for each of the cuneiform bones, but its articular surface is not interrupted. These facets form a somewhat convex anterior surface which fits into the shallow articular concavity presented by the proximal ends of the three cuneiform bones. This joint may be extended by the occasional scapho-cuboid articulation already referred to.

The **capsule** is composed of short, strong bands which are distinctly visible on all sides except towards the cuboid bone, where the joint may communicate with the cuneo-cuboid and scapho-cuboid joints. Anteriorly the joint communicates with the intercuneiform articulations. The dorsal parts of the capsule are short longitudinal bands termed **dorsal scapho-cuneiform ligaments** (Figs. 239 and 240). These extend without interruption to the inner aspect of the joint. Inferiorly there are similar bands, known as **plantar scapho-cuneiform ligaments**, also longitudinal in direction, but intimately associated with offsets from the tendon of the tibialis posticus muscle.

The **synovial membrane** which lines the capsule sends prolongations forwards on each side of the middle cuneiform bone, and in addition it often communicates with the cuneo-cuboid joint cavity, and it always communicates with the scapho-cuboid cavity when that joint exists.

Intercuneiform Articulations.—These are two in number, and exist between adjacent contiguous surfaces of the three cuneiform bones. These surfaces are partly articular and partly non-articular. The small size of the middle cuneiform bone allows the internal cuneiform as well as the external cuneiform to project forwards beyond it on both sides, and therefore the articular surfaces turned towards the middle cuneiform are not entirely occupied by that bone. They form a recess towards the metatarsus, into which the base of the second metatarsal bone is thrust.

Dorsal intercuneiform ligaments constitute fairly strong transverse bands which extend between adjacent dorsal surfaces and invest the joint cavities in this direction.

The plantar or **interosseous intercuneiform ligaments** are two strong bands which pass from the rough non-articular areas on opposite sides of the middle cuneiform to the opposing surfaces of the inner and outer cuneiform bones. These ligaments shut in the joint cavities inferiorly, and also anteriorly in the case of the outer of the two joints.

The **synovial membrane** is an extension of that which lines the scapho-cuneiform joint; but while it is restricted to the outer of the two joints, in the case of the inner one it is prolonged still farther forward to the tarso-metatarsal series of joints.

Cubo-cuneiform Articulation.—This occurs between the rounded or oval facet on the opposing surfaces of the cuboid and external cuneiform.

The **dorsal cubo-cuneiform ligament** is a flat, somewhat transverse band which closes the joint on its superior aspect, and extends between the dorsal surfaces of the two bones.

The **plantar cubo-cuneiform ligament** is difficult to determine. It is situated subjacent to the long plantar ligament, and extends between adjacent rough surfaces of the two bones.

The **interosseous cubo-cuneiform ligament** is the strongest. It closes the joint cavity anteriorly, and is attached to the contiguous non-articular surfaces of the two bones.

The **synovial membrane** is frequently distinct, but at other times the joint cavity communicates with those of the scapho-cuneiform and scapho-cuboid articulations.

Synovial Membranes of the Intertarsal Joints.—Four and sometimes five distinct and separate synovial membranes may thus be enumerated in connexion with the tarsal articulations, viz.: (1) talo-calcaneal; (2) talo-calcaneo-navicular; (3) calcaneo-cuboid; (4) scapho-cuneiform and its extensions; (5) occasionally cubo-cuneiform.

TARSO-METATARSAL JOINTS.

The tarso-metatarsal joints are found between certain articular facets on the boid and three cuneiform bones on the one hand, and others on the bases of the e metatarsal bones. These articulations are associated with three distinct novial cavities—namely, an inner, middle, and outer.

(1) The **inner tarso-metatarsal articulation** occurs between the distal convex niform surface of the internal cuneiform bone and the concavo-reniform surface n the proximal aspect of the base of the first metatarsal bone.

Ligaments which form a **capsule** surround the articulation. In the capsule the **orsal** and **plantar tarso-metatarsal bands** are its strongest parts, but it is not efficient either on the inner or on the outer aspects.

A separate **synovial membrane** lines the capsule.

(2) The **middle tarso-metatarsal articulation** is an elaborate joint. It nvolves the three cuneiform bones and the bases of the second, third, and part of he fourth metatarsal bones.

The articulation presents the outline of an indented parapet both on its tarsal nd its metatarsal aspects. Thus, on its tarsal side, the inner and the outer cunei- orm bones project in front of the middle cuneiform, so that the latter only presents distal surface to the articulation; while the internal cuneiform presents a portion f its external surface, and the external cuneiform presents both its distal and portions of its outer and inner surfaces, since it projects in front of the cuboid one. On its metatarsal side the base of the second metatarsal bone fits into the ndentation between the outer and inner cuneiforms, to which it presents external nd internal articular facets, but its proximal facet rests upon the distal facet of the middle cuneiform. The base of the third metatarsal bone rests its proximal facet upon the outer cuneiform. The fourth metatarsal base presents part of its internal facet to the external side of the outer cuneiform. In this way the indentations alternate on the two sides of the articulation, and an extremely powerful interlock- ing of parts is provided, which places any marked independent movement of these metatarsal bones entirely out of the question.

The **dorsal tarso-metatarsal ligaments** are broad, flat bands which represent the most distinct part of an investing **capsule**. They pass from behind forwards, and while the second metatarsal bone receives three, *i.e.* one from each cuneiform, the third metatarsal only receives one—from the external cuneiform.

The **plantar tarso-metatarsal ligaments** correspond with the foregoing in their general arrangement, but they are weaker. That for the second metatarsal is the strongest. Oblique bands extend from the inner cuneiform bone to the second and third metatarsals.

The **interosseous cuneo-metatarsal ligaments** are three in number. The *inner* connects the outer side of the internal cuneiform with the inner side of the base of the second metatarsal bone. The *middle* connects the inner side of the external cuneiform with the outer side of the base of the second metatarsal. The *outer* connects the adjacent outer sides of the external cuneiform and third metatarsal.

The **synovial membrane**, which lines this articulation, sends a prolongation back- wards between the inner and middle cuneiform bones, where it opens into the scapho-cuneiform joint. It is likewise prolonged forwards upon both sides of each of the bases of the second and third metatarsal bones.

(3) The **external tarso-metatarsal articulation** is found between the proximal surfaces of the bases of the fourth and fifth metatarsal bones and the distal surface of the cuboid.

The investing **capsule** may be resolved into the following ligaments:—

The **dorsal tarso-metatarsal ligaments** resemble those already described. The base of the fourth metatarsal receives one from the external cuneiform and one from the cuboid. The base of the fifth metatarsal receives one from the cuboid.

The **plantar tarso-metatarsal ligaments** are the weakest bands of the series, and consist of scattered fibres passing from the cuboid to the bases of the two metatarsals. Some fibres, which are almost transverse, extend from the

external cuneiform to the fifth metatarsal, and additional fibres reach the meta tarsals in question from the long plantar ligament (calcaneo-cuboid).

Occasionally the tarsal end of the external interosseous (cuneo-metatarsal) liga ment is attached to the inner margin of the cuboid.

The **synovial membrane** is restricted to this articulation, and merely sends a prolongation forwards between the opposing articulate aspects of the fourth and fifth metatarsal bases.

INTERMETATARSAL JOINTS.

The intermetatarsal articulations are found between adjacent lateral aspects o the bases of the four outer metatarsal bones. The articular facets are small, oval or rounded surfaces which occupy only a limited portion of the flattened contiguous surfaces of the bones. Each joint is provided with a **capsule**, which, however, is not a complete investment, because the three joint cavities are in free communication on their proximal aspects with the tarso-metatarsal joint cavities—one with the outer and two with the middle. The definite fibres of each capsule are situated chiefly in the transverse direction.

The **dorsal ligaments** are short bands which extend from one base to the other.

The **plantar** and **interosseous ligaments** are similarly arranged, but the latter are the strongest and most important members of this series.

The **synovial membranes** are extensions from those which line the outer and middle tarso-metatarsal joint cavities.

Frequently a bursa is found between the bases of the first and second metatarsal bones. It produces an appearance of indistinct facetting upon these bones, and it may communicate with the inner tarso-metatarsal (cuneo-metatarsal) joint.

The **transverse metatarsal ligament** lies upon, and is attached to, the non articular plantar aspects of the heads of all the metatarsal bones. It differs from the corresponding ligament in the palm in the fact that it binds all the metatarsal bones together, whereas in the palm the thumb is left free. It is closely associated with the plantar fibrous plates of the metatarso-phalangeal joints to the plantar surfaces of which it contributes prolongations termed ligamenta accessoria plantaria.

METATARSO-PHALANGEAL JOINTS.

Each of these joints is a modified ball-and-socket in which a shallow cup upon the bases of the first phalanges receives the somewhat globular head of a metatarsal bone.

Each joint retains a modified **capsule** which invests the joint. Its only distinct bands are the **ligamenta collateralia**. These are strong cord-like bands which are situated on the inner and outer sides of each joint, where they extend between adjacent rough surfaces.

On the dorsal aspect ligaments distinct from the dorsal expansion of the ex tensor tendons can hardly be said to exist. The plantar aspect of the capsule consists of a thick **fibrous plate**, which in the case of the great toe present developed within it two large sesamoid bones. In the other toes this plate remains fibrous throughout, and is grooved on its plantar aspect for the accommodation of the long flexor tendons. It will thus be seen that the metatarso-phalangeal joints are constructed upon a plan very similar to that of the corresponding joints in the hand.

A **synovial membrane** lines the capsule of each articulation.

INTERPHALANGEAL JOINTS.

Each toe possesses two interphalangeal joints except the great toe, which has only one. Not unfrequently in the little toe the distal joint is obliterated through ankylosis. All the joints of this series are uniaxial or hinge joints. The natural of the articular surfaces closely resembles the corresponding joints in the fingers.

Each joint possesses a **capsule** which is either very thin or limited to synovial membrane on the dorsal aspect. The plantar surface of the capsule is strengthl

ned by a **fibrous plate.** The **lateral ligaments** (ligamenta collateralia) are well-lefined bands similar to those already described in connexion with the metatarso-)halangeal joints.

A **synovial membrane** lines each capsule in the series.

Mechanism of the Foot.—The bones of the foot are arranged in the form of a longitudinal nd a transverse arch. The longitudinal arch is built on a very remarkable plan. Posteriorly he mass of the os calcis constitutes a rigid and stable pier of support, while anteriorly, by increasing he number of component parts, the anterior pier acquires great flexibility and elasticity without acrificing strength or stability. The summit of the arch is formed by the astragalus, which receives the weight of the body from the tibia, and the resilience of the arch is assured by the calcaneo-scaphoid and calcaneo-cuboid ligaments, together with the plantar fascia, which act as powerful braces or tie bands, preventing undue separation of the piers of the arch, and consequent flattening of the foot. The weight of the body is distributed over all the five digits, owing to the arrangement of the bones of the foot in two parallel columns, an **inner** and an **outer.** The former, consisting of the astragalus, scaphoid, and the three cuneiforms, with the three inner metatarsal bones, distributes weight through the talo-scaphoid joint, while the latter (*i.e.* the outer column), comprising the calcaneum, cuboid, and the two outer metatarsal bones, acts in a similar manner through the talo-calcanean joint. The main line of immobility of this arch passes from the heel forwards through the middle toe, but its anterior section, which is slender, is supported on either side by two metatarsal bones, with their proximal tarsal associations, in all of which greater freedom of movement is found. The transverse arch is most marked at the level of tarso-metatarsal articulations. The intersection of these two arches at right angles to each other introduces an architectural feature of great importance in connexion with the support of heavy weights. These longitudinal and transverse arches of the foot are in effect "vaults" intersecting each other at right angles, and in relation to the area which is common to both "vaults" the body weight is superposed exactly as the dome of a cathedral is carried upon two intersecting vaults.

Movements at the Joints of Tarsus, Metatarsus, and Phalanges.—Considered in detail, the amount of movement which takes place between any two of these bones is extremely small, and, so far as the tarsus and metatarsus are concerned, it is mostly of the nature of a gliding motion.

At the metatarso-phalangeal and interphalangeal joints movement is much more free, and is of the nature of **flexion** (bending of the toes towards the sole of the foot, *i.e.* plantar flexion) and **extension.** The latter movement when continued so as to raise the toes from the ground, and bend or approximate them towards the front of the leg, is termed **dorsiflexion.** Coincident with dorsiflexion there is always associated a certain amount of spreading of the toes, which is called **abduction,** and similarly with prolonged flexion there follows a diminution or narrowing of the transverse diameter of the front part of the foot by drawing the toes together—a movement termed **adduction.** In the foot the movements of abduction and adduction take place in regard to a plane which bisects the foot antero-posteriorly through the second toe, for this toe carries the first and second dorsal interosseous muscles.

Notwithstanding the small amount of possible movement in connexion with individual tarsal and metatarsal joints, yet the sum total of these movements is considerable as regards the entire foot. In this way the movements of **inversion** and **eversion** of the foot result. By inversion we mean the raising of the inner border of the foot so that the sole looks inwards, while the toes are depressed towards the ground, and the outer border of the foot remains downwards. This takes place chiefly at the talo-calcanean joint, but the transverse tarsal joints also participate.

Eversion is chiefly the opposite of inversion, and the return of the foot to the normal position of the erect attitude; but under certain conditions it may be carried further, so that the outer border of the foot is raised from the ground, while the inner border is depressed. In both of these movements there is **rotation** between the astragalus and os calcis about an oblique axis which passes from the inner side of the neck of the astragalus to the outer and lower part of the os calcis.

Of course all the movements of the foot are subordinated to its primary functions as an organ of support and progression. For these purposes its longitudinal and transverse arches are of extreme importance. The longitudinal arch resting on the os calcis behind and the heads of the metatarsal bones in front receives the weight of the body, as already explained, on the summit of the astragalus in the line of the third toe. Hence it is that the inner malleolus appears to be unduly prominent on the inner side of the ankle. The transverse arch buttresses the longitudinal one, and therefore, whether the body weight fall to the outer or the inner side of the longitudinal arch, it is supported by a mechanism at once stable, flexible, and elastic, or resilient, and capable of reducing to a minimum all jars that may be received by the fore-part of the foot. As the heel is raised in the act of walking, the weight is gradually transferred from the outer to the inner side of the foot, until the foot finally leaves the ground with a propulsive movement, which results from flexion of the phalanges of the great toe. In this connexion it is worthy of note that the longitudinal line of greatest strength is on the inner side of the longitudinal arch, *i.e.* in relation to the great toe.

THE MUSCULAR SYSTEM.

MYOLOGY.

By A. M. PATERSON.

THE movements of the various parts and organs of the body are brought about by the agency of muscle-cells, which are characterised by a special histological structure and by the special function of contracting in length under the influence of a proper stimulus.

There are three classes of muscle-cells: (1) the striated, and usually voluntary muscle-cells, out of which the skeletal muscular system is constructed; (2) the non-striated, involuntary muscle-cells, occurring in the walls of vessels and hollow viscera, etc.; and (3) the cardial muscle-cells, striated but involuntary, of which the substance of the heart is composed.

The following section deals solely with the skeletal muscles, the structure, arrangement, and mechanical action of which are based upon a common plan.

The cells of which the skeletal muscles are composed are long, narrow, and characterised by a peculiar striation, which is different from the striation of the muscle-cells of the heart; they also differ both in structure and function from the non-striated muscle-cells which occur in viscera and vessels.

A **typical skeletal muscle** consists of a fleshy mass enveloped in a membranous aponeurosis or fascia, and provided at its extremities or borders with membranous or tendinous attachments to bone, cartilage, or fascia.

Each muscle is made up of a number of **fasciculi** or bundles, arranged together in different muscles in different ways, so as to give rise to the particular form of the muscle in question. These fasciculi are connected together by a delicate connective tissue, the **perimysium externum**, continuous externally with the aponeurosis enclosing the muscle.

Each muscular bundle or fasciculus is composed of a number of narrow, elongated **muscle-cells** or fibres, held together by a still more delicate connective tissue, the **perimysium internum**. This tissue is connected on the one hand with the **sarcolemma** or cell-wall of the muscle-cell, and on the other hand with the coarser tissue of the perimysium externum enclosing the muscular bundles.

By means of these connective tissue envelopes the muscle-cells, the essential agents of motor activity, are brought into firm and intimate relation with the osseous or other attachments of the muscle. Through the agency of sarcolemma, perimysium internum, perimysium externum, aponeurosis, and tendon, the muscle-cell when it contracts can produce a precise and definite effect upon the weight to be moved.

Each muscle is supplied by one or more nerves, which, in their course through the muscle, separate into smaller and smaller branches, ultimately, by their terminal filaments (axons), forming special end-organs in relation to each muscle-cell.

While a muscle may thus be looked upon as an organ endowed with particular properties, and executing a definite movement in response to a stimulus by the simultaneous contraction of its constituent cells, the various muscles may further be considered in groups, associated together by mode of development, nerve-supply, and co-ordination of action. For example, we speak of the hamstring muscles of

the thigh, the muscles of the back, and the prævertebral muscles—groups in which separate muscles are associated together by development, nerve-supply, and action. In their development the separate muscles arise from the subdivision of a larger stratum, as in the limbs, or from the fusion of segmental elements (myotomes), as in the case of the axial muscles; the peripheral nerves supplying skeletal muscles are distributed, through the plexuses or directly, so as to associate particular muscles morphologically and physiologically, and to secure a co-ordinated movement by the simultaneous contraction of several muscles together.

FASCIÆ.

Beneath the skin there are two (or in some regions three) layers of tissue which require consideration: the superficial fascia (panniculus adiposus), the deep fascia (fascia lata), and, in animals, the panniculus carnosus (rudimentary in man, and represented chiefly by the *platysma myoides* in the neck).

Superficial Fascia.—The superficial fascia is a continuous sheet of areolar tissue which underlies the skin of the whole body. It is closely adherent to the cutis vera, and is sometimes termed **panniculus adiposus**, from the fact that, except beneath the skin of the eyelids, penis, and scrotum, it is always more or less impregnated with fat. It is traversed by the cutaneous vessels and nerves; and its deep surface, membranous in character, is in loose connexion with the subjacent deep fascia. It is in this layer that dropsical effusions chiefly occur.

Deep Fascia.—Underneath the skin and superficial fascia is a fibrous membrane, bluish white in colour, devoid of fat, and in closest relation to skeleton, ligaments, and muscles. This is the deep fascia. It covers, invests, and in some cases forms the means of attachment of the various muscles. It has a special tendency to become attached to all subcutaneous bony prominences, and to be continuous with the connecting ligaments. It forms septal processes, which separate groups of muscles and individual muscles; enclose glands and viscera; and form sheaths for vessels and nerves. Around joints it gives rise to bands which strengthen the capsule or limit the mobility of the joint, or, as in the case of annular ligaments, bind down the tendons passing over the joint. It not only unsheathes vessels and nerves, but is perforated by those which pass between superficial and deeper parts.

The term **aponeurosis** is used in relation to muscles. It is synonymous with deep fascia, either as an investing fascia, or as a membranous layer which (*e.g.* vertebral aponeurosis) performs at one and the same time the purpose of a deep fascia and the expanded membranous attachment of a muscle.

The **panniculus carnosus** is a thin muscular layer enveloping the trunk of animals with a hairy or furry coat. It is strongly developed in the hedgehog. In man it is represented mainly in the (rudimentary) platysma myoides. It is placed between the superficial and the deep fascia.

Bursæ.—Where a tendon passes over a bony surface, or where the superficial fascia and skin cover a bony prominence, there is generally formed a synovial sac, or bursa, containing fluid, for the purpose of lubricating the surface over which the tendon or fascia glides. Allied to these are the synovial sheaths which envelop tendons beneath the annular ligaments in relation to the several joints.

Description of Muscles.—In studying the muscular system it is necessary to note the following characters in reference to each individual muscle: (1) The *shape* of the muscle—flat, cylindrical, triangular, rhomboidal, etc.—and the character of its extremities—membranous, tendinous, or fleshy. (2) The *attachments* of the muscle. The *origin* is the more fixed or central attachment: the *insertion* is the more movable or peripheral attachment. (3) The *relations* of the surfaces and borders of the muscle to bones, joints, other muscles, and other important structures. (4) Its *vascular* and *nervous supply*: and (5) *its action*. It must be borne in mind that hardly any single muscle acts alone. Each muscle, as a rule, forms one of a group acting more or less in harmony with, and antagonised by, other and opposite groups.

DESCRIPTION OF THE MUSCLES.

The skeletal muscles may be divided into two series: axial and appendicular. The **axial** muscles comprise the muscles of the trunk, head, and face, including the **panniculus carnosus** (platysma myoides). These muscles are more or less segmental in arrangement, grouped around the axial skeleton. The **appendicular muscles**, the muscles of the limbs, are grouped around the appendicular skeleton. They are not segmental in arrangement, they are clearly separate from the axial muscles, and they are arranged in definite strata in relation to the bones of the limbs.

APPENDICULAR MUSCLES.

THE UPPER LIMB.

FASCIÆ AND SUPERFICIAL MUSCLES OF THE BACK.

Fasciæ.

The **superficial fascia** of the back presents no peculiarity. It is usually of considerable thickness, and contains a quantity of fat.

The **deep fascia** closely invests the muscles. It is attached in the middle line of the back to the ligamentum nuchæ, supraspinous ligaments, and vertebral spines; laterally it is attached to the spine of the scapula and the clavicle, and is continued over the deltoid region to the arm. In the neck it is attached above to the superior curved line of the occipital bone, and is continuous laterally with the deep cervical fascia. Below the level of the arm it is continuous round the border of the latissimus dorsi muscle, with the fascia of the axilla and of the abdominal wall. In the back and loin it constitutes the **vertebral aponeurosis** or aponeurosis of the latissimus dorsi. It conceals the erector spinæ muscle, forming the posterior layer of the **lumbar fascia**, and it is attached internally to the vertebral spines, and externally to the angles of the ribs, to the lumbar fascia, and to the iliac crest.

The Superficial Muscles of the Back.

The muscles of the back are arranged in four series according to their attachments: (1) vertebro-scapular and vertebro-humeral; (2) vertebro-costal; (3) vertebro-cranial; and (4) vertebral. The first of this series consists of the posterior muscles connecting the upper limb to the trunk, and comprises the first two layers of the muscles of the back—(1) trapezius and latissimus dorsi, and (2) levator anguli scapulæ and rhomboidei (major and minor). The deeper (axial) muscles of the back are dealt with later.

The **trapezius** (m. trapezius, cucullaris) is a large triangular muscle occupying the upper part of the back. It **arises** from the superior curved line of the occipital bone in its inner third, from the external occipital protuberance (Fig. 312, p. 397), from the ligamentum nuchæ, from the spines of the seventh cervical and all the thoracic vertebræ, and the corresponding supra-spinous ligaments. The origin is by direct fleshy attachment, except in relation to the occipital bone, the lower part of the neck, and the lower thoracic vertebræ, in which places the origins are tendinous. From their origin the muscular fibres converge towards the bones of the shoulder to be **inserted** continuously from before backwards as follows: (1) The occipital and upper cervical fibres—into the posterior surface of the clavicle in its outer third (Figs. 243, p. 319, and 248, p. 324); (2) the lower cervical and upper thoracic fibres—into the inner border of the acromion process, and the upper border of the spine of the scapula; and (3) the lower thoracic fibres, by a triangular flat tendon, beneath which a bursa is placed—into a rough tuberosity at the base of the spine of the scapula (Fig. 299, p. 383). The fibres inserted into the clavicle, acromion, and the upper border of the spine of the scapula, spread over the adjacent subcutaneous surfaces of these bones for a variable distance

he occipital portion of the muscle may be in the form of a separate slip, or may e entirely absent.

The trapezius is superficial in its whole extent. Its upper lateral border forms he posterior limit of the posterior triangle of the neck. The lower lateral border, passing over the upper edge of the latissimus dorsi and the vertebral border of the scapula, forms a boundary of the so-called *triangle of auscultation* completed below by the latissimus dorsi, and externally by the vertebral border of the scapula. This space is partly filled up by the rhomboideus major. The deep surface of the muscle is in contact with the complexus, splenius capitis, omohyoid, supraspinatus, levator anguli scapulæ, rhomboidei, serratus posticus superior, erector spinæ, and latissimus dorsi muscles. The spinal accessory nerve, branches of the cervical plexus (C. 3. 4.), and of the superficial cervical and posterior scapular arteries, are situated beneath the muscle.

The **latissimus dorsi** is a large triangular muscle occupying the lower part of the back. It has a triple origin. The greater part of the muscle **arises**—(1) from

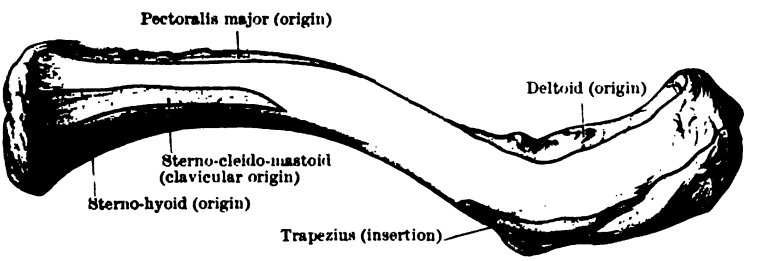


FIG. 243.—MUSCLE-ATTACHMENTS TO THE CLAVICLE (Upper Surface).

the *vertebral aponeurosis* (posterior layer of the lumbar fascia or aponeurosis of the latissimus dorsi). This is a thick membrane which conceals the erector spinæ in the lower part of the back. Through it the latissimus dorsi gains attachment to the spines of the lower six thoracic vertebræ, the spines of the lumbar vertebræ, and the tendon of the erector spinæ with which the aponeurosis blends below. It also arises more externally by fleshy fibres from the posterior part of the iliac crest. From this origin the muscle is directed upwards and outwards, its fibres converging to the lower angle of the scapula. In relation to its upper and outer borders additional fibres arise. (2) *Along the outer border* muscular slips arise from the lower three or four ribs, inter-digitating with the origins of the obliquus externus abdominis. (3) As *the upper border* of the muscle passes horizontally over the lower angle of the scapula, an additional fleshy slip usually takes origin from this part of the bone to join the muscle on its deep surface (Fig. 245, p. 321).

Beyond the lower angle of the scapula the latissimus dorsi, greatly narrowed, curves spirally round the teres major muscle, and forms the prominence of the posterior axillary fold. It ends in a ribbon-like tendon, closely adherent at first to the teres major, which is **inserted** into the floor of the bicipital groove of the humerus, extending for about three inches below the lower and outer part of the lesser tuberosity (Fig. 253, p. 329). It is placed behind the coraco-brachialis and biceps, and the axillary vessels and nerves, and in front of the insertion of the teres major, from which it is separated by a bursa.

In the back the latissimus dorsi is superficial, except in its upper part, which is concealed by the trapezius. It lies upon the lumbar fascia, serratus posticus inferior, the ribs, and lower angle of the scapula, and at its borders two triangular spaces are formed; at the upper border is the so-called *triangle of auscultation*; at the outer border is the *triangle of Petit*, a small space bounded by the iliac crest, the latissimus dorsi, and the obliquus externus abdominis. This is the site of an occasional lumbar hernia.

The **levator anguli scapulæ** (levator scapulæ) is a strap-like muscle, **arising** by tendinous slips from the posterior tubercles of the transverse processes of the first three or four cervical vertebræ, between the attachments of the scalenus medius in front and the splenius colli behind. It is directed downwards along the

side of the neck, to be **inserted** into the vertebral border of the scapula in its upper fourth, from the superior angle to the spine (Fig. 245, p. 321). It is concealed in its upper third by the sterno-mastoid and deep muscles of the neck. In its middle third it occupies the floor of the posterior triangle. In its lower third it is again

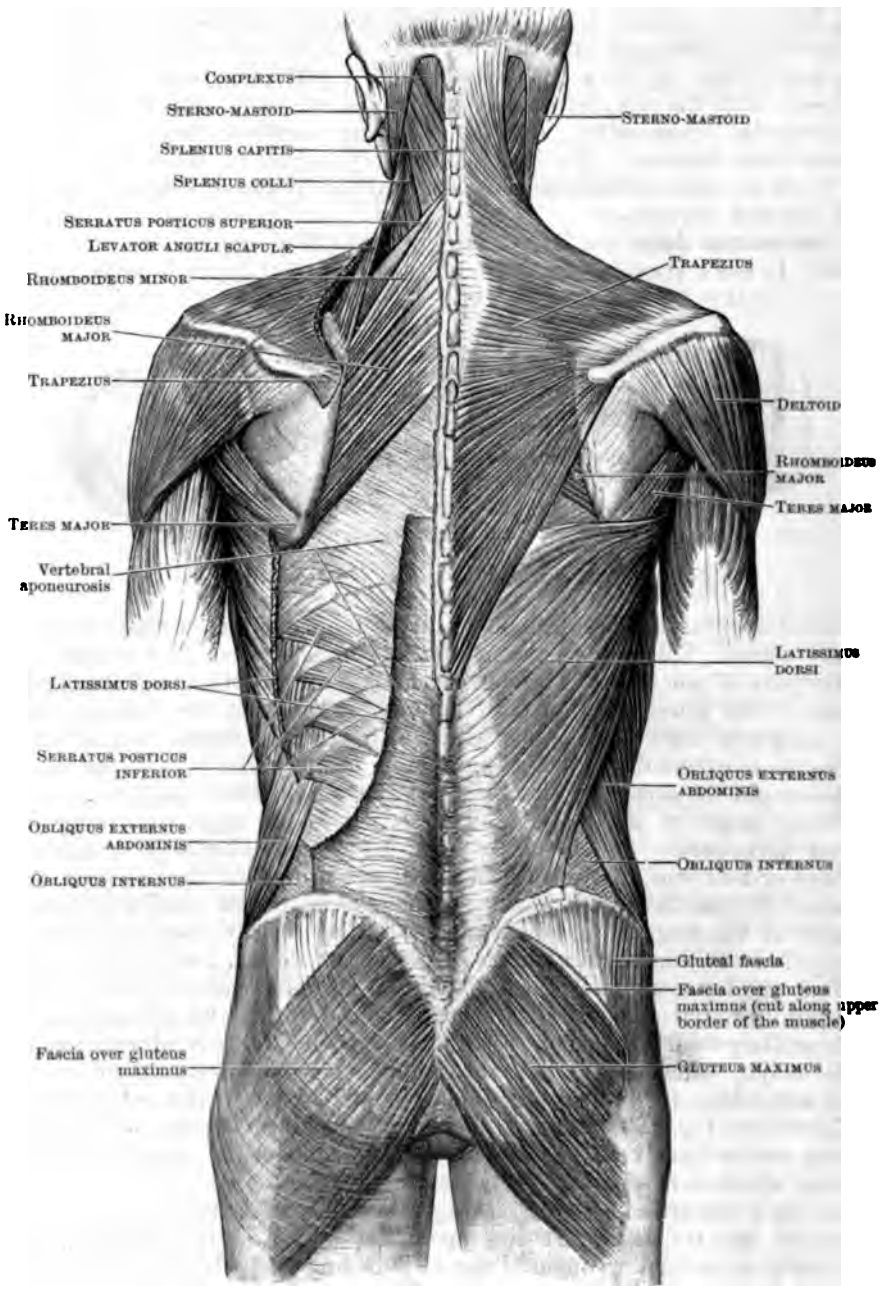

Fig. 244.—Superficial Muscles of the Back.

hidden from view by the trapezius. It conceals the splenius colli and cervical ascendens muscles.

The **rhomboideus minor** may be regarded as a separated slip of the rhomboideus major, with which it is often continuous. It **arises** from the *ligamentum nuchæ* and the spines of the seventh cervical and first thoracic vertebræ. Passing obliquely downwards and outwards, it is **inserted** into the vertebral border of the

apula below the levator anguli scapulæ muscle, and opposite to the base of the pine (Fig. 245, p. 321).

The **rhomboideus major arises** from the spinous processes of the thoracic vertebræ from the second to the fifth inclusive, and from the corresponding supraspinous ligaments. Passing downwards and outwards, it is **inserted** below the rhomboideus minor into the vertebral border of the scapula, between the spine and the lower angle (Fig. 245, p. 321). The muscle is only inserted directly into the scapula by means of its lower fibres. Its upper part is attached to a membranous band, which, connected for the most part by loose areolar tissue to the vertebral border of the scapula, is fixed to the bone at its extremities, above near the base of the spine, and below at the inferior angle.

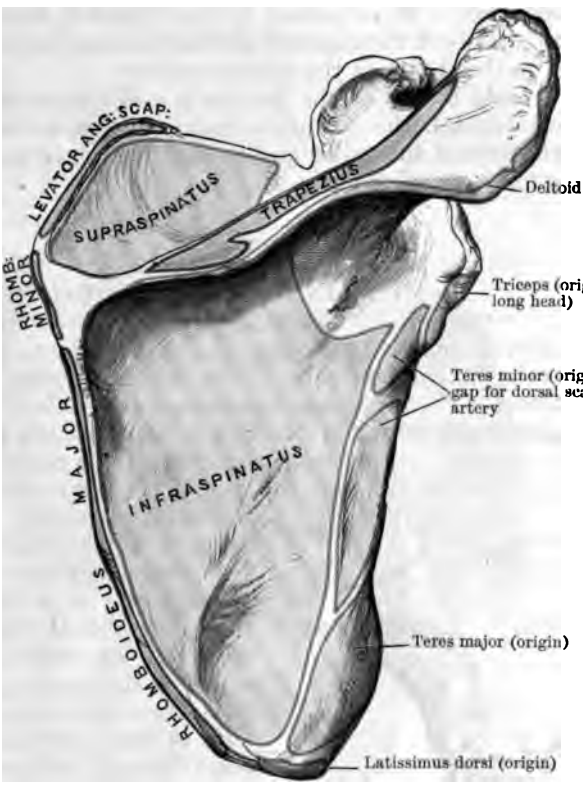

FIG. 245.—MUSCLE-ATTACHMENTS TO THE SCAPULA (Posterior Surface).

The rhomboid muscles are concealed for the most part by the trapezius. The lower part of the rhomboideus major is superficial in the *triangle of auscultation*. The muscles cover the serratus posticus superior and vertebral aponeurosis.

THE FASCIÆ AND MUSCLES OF THE PECTORAL REGION.

FASCIÆ.

The **superficial fascia** of the chest usually contains a quantity of fat, in which the mamma is embedded. The origin of the platysma myoides muscle lies beneath its upper part.

The **deep fascia** is attached above to the clavicle, and internally to the sternum. Below it is continuous with the fascia of the abdominal wall. It gives origin to the platysma myoides, and invests the pectoralis major. At the outer border of the great pectoral muscle it is thickened, and forms the floor of the axillary space **(axillary fascia)**, continued posteriorly on to the posterior fold of the axilla (teres major and latissimus dorsi), and externally into connexion with the deep fascia of the arm.

Costo-Coracoid Membrane.—Beneath the pectoralis major a deeper stratum of fascia invests the pectoralis minor muscle. At the upper border of this muscle it forms the costo-coracoid membrane, which passes upwards to the lower border of the subclavius muscle, where it splits into two layers, attached in front of and behind that muscle to the borders of the under surface of the clavicle. The membrane traced inwards along the subclavius muscle is attached to the first costal cartilage; passing outwards along the upper border of the pectoralis minor it reaches the coracoid process. The part of *the membrane* extending directly between the first

costal cartilage and the coracoid process is thickened and forms the **co ligament.** The costo-coracoid membrane is otherwise thin and of coı small importance. It is pierced by the cephalic vein, thoracic axis vein, and branches of the external anterior thoracic nerve. By its deep connected to the sheath of the axillary vessels.

At the lower border of the pectoralis minor there is a further exten deep fascia beneath the pectoralis major. It passes downwards to joi forming the floor of the axilla, and is continued externally into the fasc the biceps and coraco-brachialis muscles.

MUSCLES OF THE PECTORAL REGION.

The anterior muscles connecting the upper limb to the axial skeletc the pectoralis major, pectoralis minor, subclavius, serratus magnus, ε cleido-mastoid. The last is described in a later section.

The **pectoralis major** is a large fan-shaped muscle **arising** in three *a clavicular portion* arising from the front of the clavicle in its inner l thirds (Figs. 248, p. 324, and 243, p. 319); (2) *a costo-sternal portion*, part of the muscle, arising from t surface of the pre-sternum and me by tendinous fibres decussating wit the opposite muscle (Fig. 246, p. more deeply from the cartilages of t ribs; (3) *an abdominal portion*, a separate slip, arising from the apo the obliquus externus muscle. The slip, at first separate, soon merges costo-sternal portion, but a distinc usually remains between the two f parts of the muscle. The fibres conve the upper part of the arm, and are blended at a point half an inch fro sertion into the humerus. The muscl into (1) the outer border of th groove of the humerus, extending the great tuberosity, and blending with the insertion of the deltoid, with the insertion of the latissimus 253, p. 329); (2) from the upper bo insertion a membranous band exten to the capsule of the shoulder-joint, at the same time the tendon of the l (3) from the lower border a band of fi downwards to join the fascia of the a

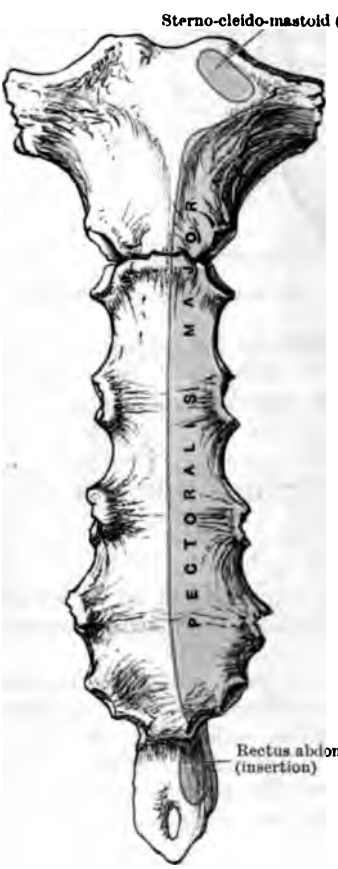

FIG. 246.—MUSCLE-ATTACHMENTS TO THE FRONT OF THE STERNUM.

The arrangement of the fibres of at its insertion is peculiar. The muscl on itself, so that the lower (*costo-ste* are directed upwards and outwards upper (*clavicular*) part of the muscle quence the clavicular part is attac humerus lower down than the co portion, and is inserted also into the f arm. The twisting of the fibres is specially found in the lower costo-st of the muscle and the abdominal fibres. These curve upwards behind costo-sternal fibres, and are inserted highest to the shaft of the humerus form the fascial expansion which extends upwards over the biceps ten capsule of the shoulder-joint. In this way a bilaminar tendon is produ

ng its lower border; and consisting of a superficial lamina formed by the upper sto-sternal fibres, blending for the most part with the tendon of the clavicular rtion; and a deep lamina, composed of the twisted lower costo-sternal and dominal fibres. The disposition of the muscular fibres at their insertions is the

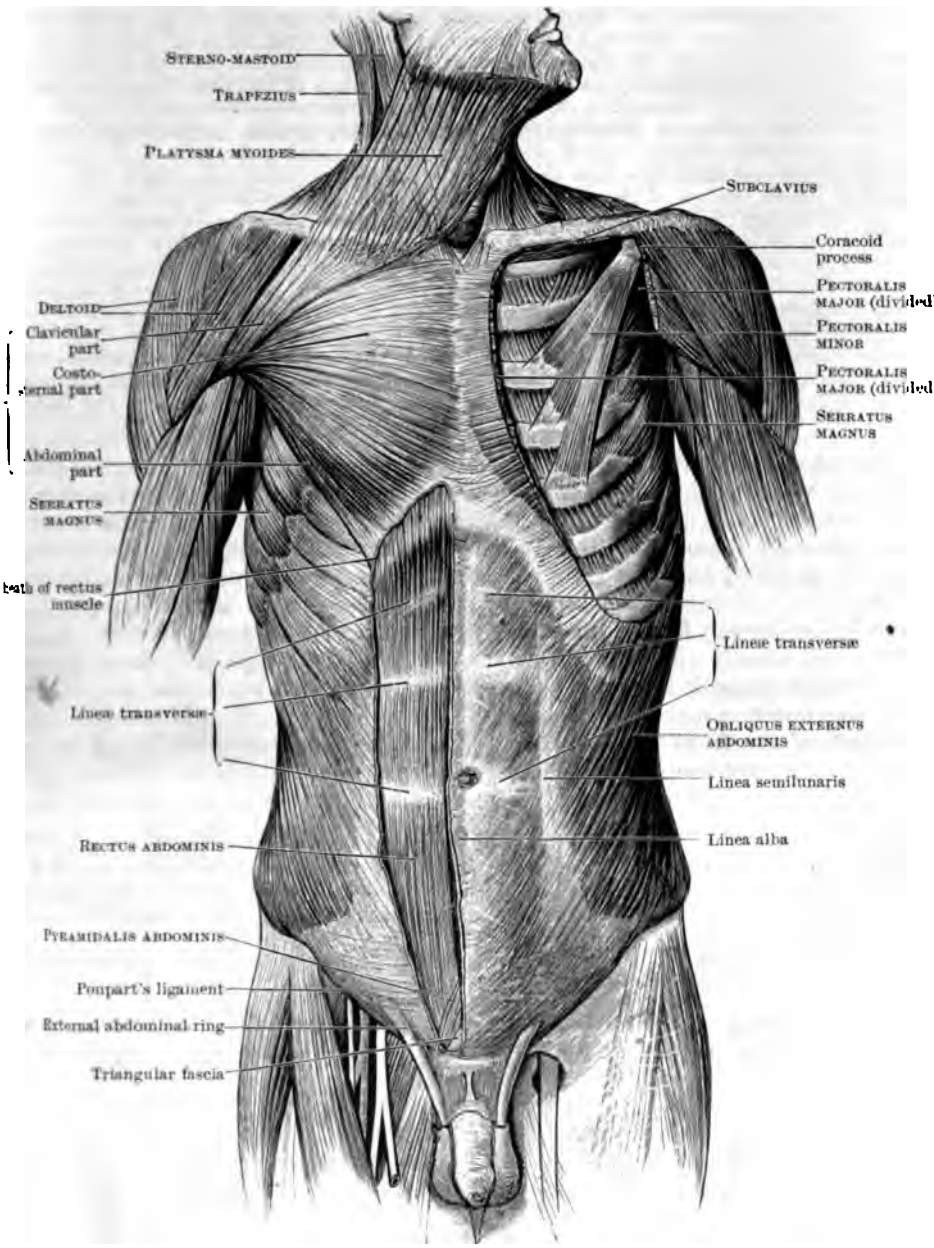

Fig. 247. Anterior Muscles of the Trunk.

ason for the application of the terms *portio attollens* to the clavicular portion, d *portio deprimens* to the costo-sternal and abdominal portions of the muscle.

Placed superficially on the chest wall, the pectoralis major forms the front ll of the axilla, and by its lower or outer border, the anterior fold of the space. s upper border is separated from the edge of the deltoid muscle by an interval which lie the cephalic vein and humeral artery. Its deep surface is in lation with the ribs and intercostal muscles, the costo-coracoid membrane and

the structures piercing it, the pectoralis minor, the axillary vessels, and the nerves of the brachial plexus.

Sternalis muscle.—The sternalis is an occasional muscle placed, when present, parallel to the sternum upon the sterno-costal origin of the pectoralis major. It has attachments which are very variable both above and below, to the costal cartilages, sternum, rectus sheath, sterno-mastoid, and pectoralis major. Its **nerve-supply** is from one or both of the anterior thoracic nerves. In certain rare cases it has been said to be innervated by intercostal nerves. It is present in 4·4 cases out of 100, and it is slightly more frequent in the male than in the female. It has been regarded by different observers as (1) a vestige of the panniculus carnosus, (2) a homologue of the sterno-mastoid, or (3) a displaced slip of the pectoralis major.

Chondro-epitrochlearis, dorso-epitrochlearis, axillary arches, costo-coracoideus.—One or other of the above-named slips is occasionally present, crossing the floor of the axilla in the interval between the latissimus dorsi and the pectoralis major. They take **origin** from the costal cartilages, ribs, or borders of the pectoralis major (*chondro-epitrochlearis, axillary arches, costo-coracoideus*), or from the border of the latissimus dorsi (*dorso-epitrochlearis, axillary arches, costo-coracoideus*). Their **insertion** is variable. The *chondro-epitrochlearis* and *dorso-epitrochlearis* are inserted into the fascia of the arm on the inner side, the internal intermuscular septum, or the internal condyle of the humerus. The *axillary arches* are inserted into the border of the pectoralis major, the fascia of the arm, or the coraco-brachialis or biceps muscle. The *costo-coracoideus*, arising from the ribs or the aponeurosis of the obliquus externus, or detaching itself from the border of the pectoralis major or latissimus dorsi, is attached to the coracoid process, alone or along with one of the muscles attached to that bone. These variable slips of muscle are supplied by the internal anterior thoracic nerve, the lesser internal cutaneous nerve, or the intercosto-humeral.

The **pectoralis minor** is a narrow, flat, triangular muscle. It **arises** from (1) the outer surfaces and upper borders of the third, fourth, and fifth ribs near their anterior ends, and (2) from the fascia covering the third and fourth intercostal spaces between these ribs. It may have an additional origin from the second rib (Fig. 330, p. 420); and that from the fifth rib is often absent. Directed obliquely outwards and upwards, it is **inserted** by a short, flat tendon into the outer half of the anterior (inner) border and upper surface of the coracoid process (Fig. 250, p. 325), and usually also into the conjoint origin of the biceps and coraco-brachialis. It is wholly concealed by the pectoralis major, except when the arm is raised, when the outer border of the muscle becomes superficial. It enters into the formation of the front wall of the axilla, and gives attachment along its upper border to the costo-coracoid membrane. It crosses the axillary vessels and the cords of the brachial plexus, and is pierced by branches of the anterior thoracic nerves.

Either in part or wholly the pectoralis minor may pass over the coracoid process of the scapula, separated from it by a bursa, to be inserted into the coraco-acromial ligament, or the acromion process; or piercing the coraco-acromial ligament, it may be attached to the capsule of the shoulder-joint (coraco-humeral ligament).

Pectoralis minimus.—This is a slender slip, rarely present, which extends between the first costal cartilage and the coracoid process.

The **subclavius muscle arises** from the upper surface of the first costal cartilage in front of the costo-clavicular ligament, and from the upper surface of the

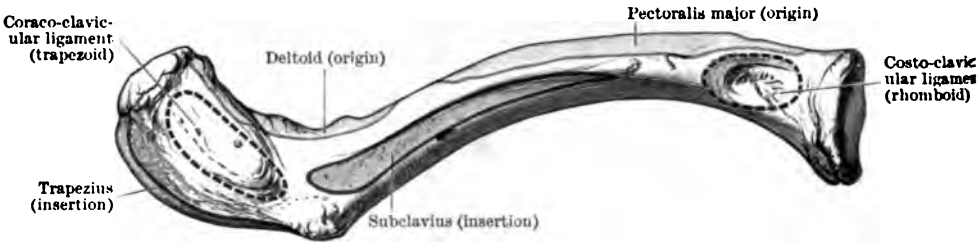

FIG. 248.—MUSCLE-ATTACHMENTS TO THE CLAVICLE (Under Surface).

distal end of the first rib (Fig. 330, p. 420). It is **inserted** into a groove in the middle third of the under surface of the clavicle (Fig. 248, p. 324). The muscle is invested by the fascia which forms the costo-coracoid membrane, and is concealed by the clavicle and the clavicular origin of the pectoralis major.

sterno-clavicularis is a small separate ly present, extending beneath the pector- r from the upper part of the sternum to cle.

serratus magnus (m. serratus r) is a large curved quadrilateral occupying the side of the chest ier wall of the axilla. It **arises** by slips from the external aspect of per eight and occasionally (as in ure) from nine ribs. The first slip uble one, arising from the first two d the fascia covering the inter- space (Fig. 330, p. 420). The n of the muscle is threefold. (1) st portion of the muscle (from the nd second ribs) is directed back- to be inserted into the ventral of the upper angle of the scapula. e next three slips of the muscle he second, third, and fourth ribs) erted into the vertebral border of apula. (3) The last four slips he fifth, sixth, seventh, and eighth re directed obliquely upwards and rds, to be inserted on the ventral aspect of the lower angle of the scapula (Fig. 250, p. 325).

FIG. 249.—THE SERRATUS MAGNUS MUSCLE.

. 250.—MUSCLE-ATTACHMENTS TO THE SCAPULA (Anterior Aspect).

The external surface of the muscle is partly superficial below the axillary space, on the side wall of the chest, where its slips of origin are seen interdigitating with those of the obliquus externus abdominis. Higher up it forms the inner wall of the axilla, and is in contact with the pectoral muscles in front and the subscapularis behind. Its upper border appears in the floor of the posterior triangle, and over it the axillary artery and the cords of the brachial plexus pass in their course through the armpit. The lower border is oblique, and is in contact with the latissimus dorsi muscle. The deep surface of the muscle is in contact with the chest wall, so that the serratus magnus along with the subscapularis muscle separates the scapula from the ribs. The muscle may extend higher than usual, so as to be continuous in the neck with the levator anguli scapulæ.

Nerve-Supply.

The nerves supplying the muscles connecting the upper limb to the trunk are given in the following table:—

Muscles.	Nerves.	Origin.
Trapezius	Spinal accessory nerve	Spinal Cord
	Cervical plexus	C. 3. 4.
Latissimus dorsi	Long subscapular	C. 6. 7. 8.
Levator scapulæ	Cervical plexus	C. 3. 4.
	Posterior scapular	C. 5.
Rhomboidei	Posterior scapular	C. 5.
Pectorales	External anterior thoracic	C. 5. 6. 7.
	Internal „ „	C. 8. T. 1.
Subclavius	Brachial plexus	C. 5. 6.
Serratus magnus	Posterior thoracic	C. 5. 6. 7.

Actions.

The muscles of this group (together with the sterno-cleido-mastoid and omohyoid muscles) act for the most part in the movements of the shoulder girdle at the sterno-clavicular and acromio-clavicular joints. At the former joint they produce the various movements of the clavicle on the sternum, and cause the shoulder to move in an arc the centre of which is the sterno-clavicular joint. At the acromio-clavicular articulation they produce a rotation of the scapula on the clavicle, and a consequent alteration in the direction of the glenoid fossa. At the same time the several muscles are agents in other equally important movements, when the shoulder girdle is fixed; movements of the head and neck; movements of the trunk and ribs; and, in addition in the case of the pectoralis major and latissimus dorsi, important movements of the arm at the shoulder-joint.

1. **Movements of the Shoulder Girdle.**—The action of this group of muscles on the shoulder girdle (mainly corresponding to movements at the sterno-clavicular joint) may be expressed in the following table:—

a. Movement in a Vertical Plane.		*b.* Movement in a Horizontal Plane.	
Elevation.	**Depression.**	**Forwards.**	**Backwards.**
Trapezius (upper fibres)	Trapezius (lower fibres)	Serratus magnus	Trapezius
Levator scapulæ	Subclavius	Pectoralis major	Rhomboidei
Rhomboidei	Pectoralis minor	Pectoralis minor	Latissimus dorsi
Sterno-mastoid	Latissimus dorsi		
Omohyoid	Pectoralis major (lower fibres)	*c.* **Rotation**—a combination of these muscles.	

2. **Movements of the scapula on the clavicle** produce an alteration of the direction of the glenoid fossa of the scapula, and are accompanied by movements, inwards or outwards, forwards or backwards, of the inferior angle of the scapula. By the combined action of the muscles acting upon the shoulder girdle a **rotatory movement** of the scapula at the acromio-clavicular joint is effected, by which the relation of the glenoid fossa to the head of the humerus is preserved in movements of the arm.

3. **In forced inspiration,** the sterno-mastoid, trapezius, levator scapulæ, rhomboidei, subclavius, omohyoid, serratus magnus, pectoral muscles, and latissimus dorsi, acting together, raise and fix the shoulder girdle; while those of them which have costal attachments—subclavius, pectoral muscles, serratus magnus, and latissimus dorsi, simultaneously elevate the ribs and expand the thorax.

4. **Lateral flexion and rotation of the spine** in the neck is effected partly by the action of the trapezius, levator scapulæ, and rhomboid muscles (with the shoulder fixed). The latissimus dorsi and pectoralis major act in climbing in a similar way, raising up the trunk towards the shoulder.

5. **Action on the Upper Limb.**—By reason of their insertion into the humerus the pectoralis major and latissimus dorsi muscles assist the movements of the upper limb. Acting together, the two muscles depress the shoulder, and draw the arm to the side of the body, at the same time rotating the humerus inwards. The two parts of the pectoralis major have slightly different actions on the humerus. The clavicular part of the muscle (*portio attollens*) draws the arm inwards and upwards; the costo-sternal part of the muscle (*portio deprimens*) draws it inwards and downwards. The latissimus dorsi acting alone, besides rotating the limb, draws it inwards and backwards, as in the act of swimming.

FASCIÆ AND MUSCLES OF THE SHOULDER.

The **deep fascia** covering the scapular muscles presents no feature of special ıportance. Attached to the clavicle, acromion, and scapular spine, it is thin over e deltoid muscle. Below the deltoid it is thicker; it encases and gives origin to .e infraspinatus muscle, and is continuous with the fasciæ of the axilla and the ıck.

Muscles.

The **muscles** proper to the shoulder comprise the deltoid, supraspinatus, infra-

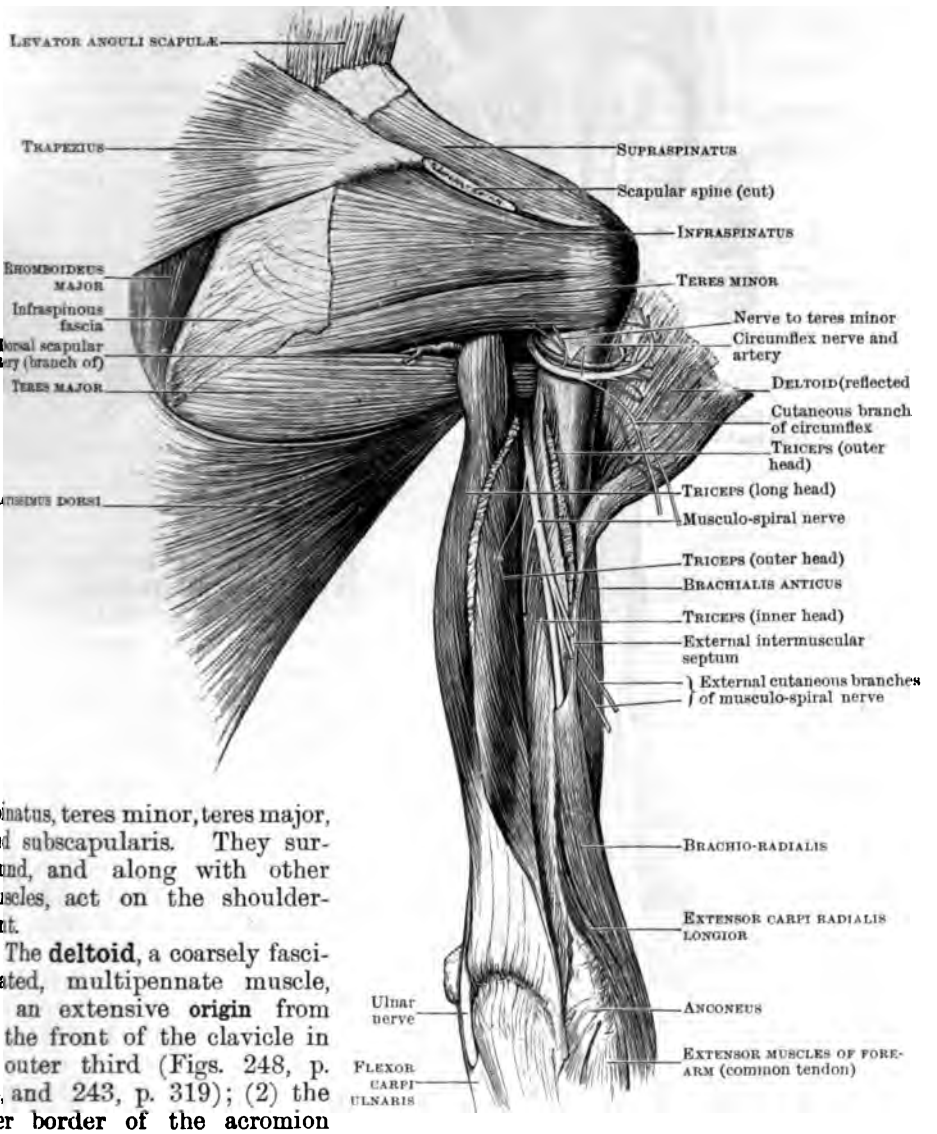

Fig. 251.—Deltoid Region and Back of the Arm.

spinatus, teres minor, teres major, and subscapularis. They surround, and along with other muscles, act on the shoulder-joint.

The **deltoid**, a coarsely fasciculated, multipennate muscle, has an extensive **origin** from (1) the front of the clavicle in its outer third (Figs. 248, p. 324, and 243, p. 319); (2) the outer border of the acromion process; (3) the lower edge of the free border of the spine of the scapula (Figs. 254, p. 330, and 250, p. 325); and (4) from the deep fascia covering the infraspinatus muscle. Its origin embraces the insertion of the trapezius. The fibres of the muscle converge to the outer side of the shaft of the humerus, to be **inserted** into a well-marked V-shaped impression above the spiral groove (Figs. 257 and 258, p. 335). The insertion is partly united with the tendon of the **pectoralis major**. The deltoid is superficial *in its* whole extent, and forms the prom-

inence of the shoulder. Its anterior border is separated from the pectoralis maj by a narrow interval, in which the cephalic vein and humeral artery are placed. Tl deep surface of the muscle is separated by a bursa from the capsule of the shoulde

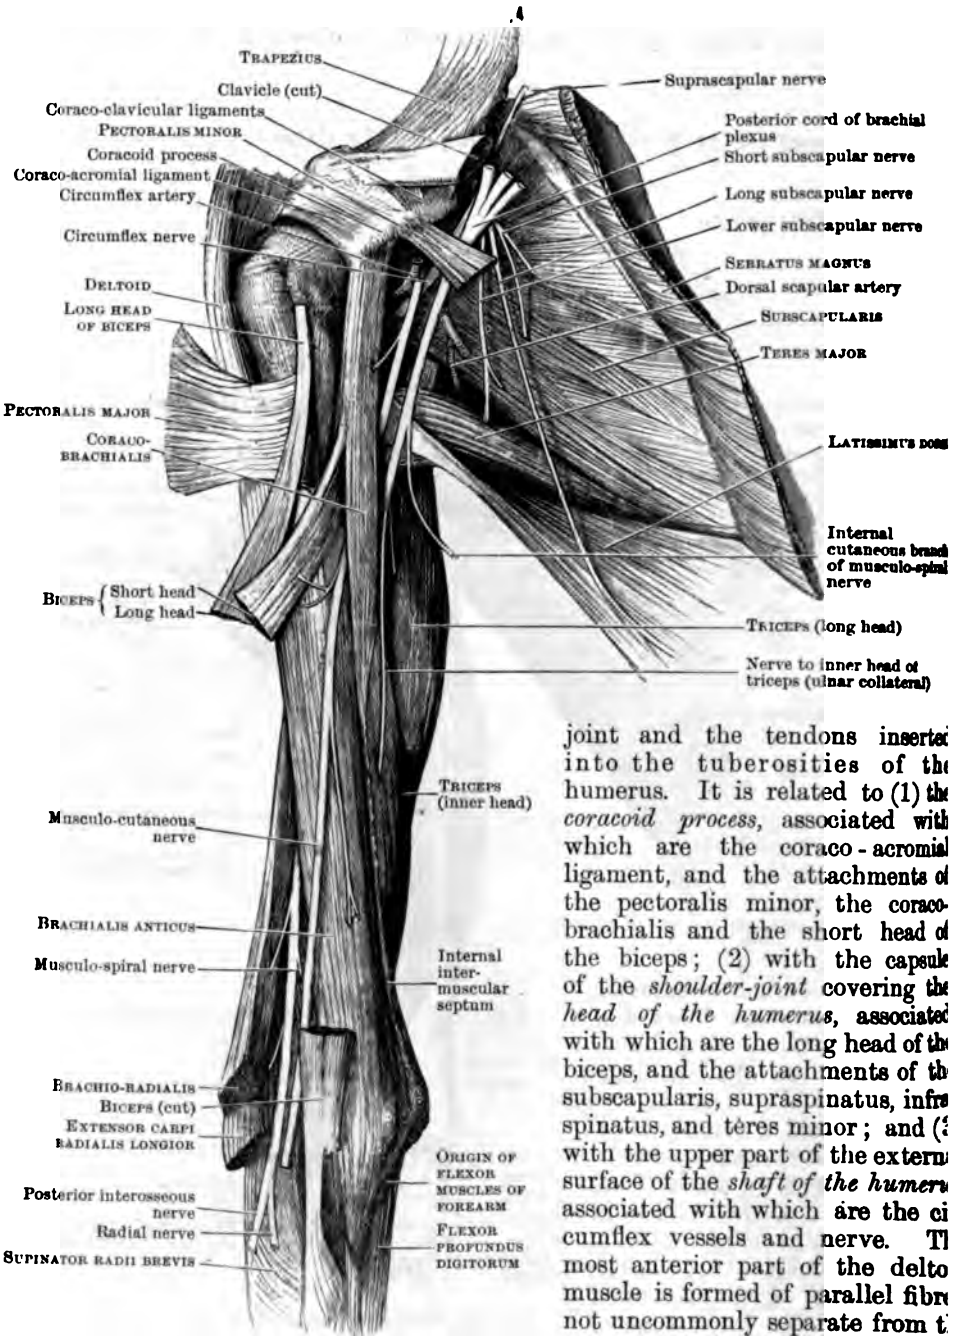

Fig. 252.—The Posterior Wall of the Axilla and the Front of the Arm (the biceps being divided).

joint and the tendons inserte into the tuberosities of th humerus. It is related to (1) th *coracoid process*, associated with which are the coraco-acromia ligament, and the attachments o the pectoralis minor, the coraco-brachialis and the short head o the biceps; (2) with the capsul of the *shoulder-joint* covering th *head of the humerus*, associated with which are the long head of th biceps, and the attachments of th subscapularis, supraspinatus, infra spinatus, and teres minor; and (3 with the upper part of the extern surface of the *shaft of the humer* associated with which are the ci cumflex vessels and nerve. Th most anterior part of the delto muscle is formed of parallel fibr not uncommonly separate from t rest of the muscle at their orig from the clavicle. These fibres m be continuous with the trapezi over the clavicle. The most posterior part arises by a fascial origin from the spi of the scapula and the fascia over the infraspinatus muscle. These portions a attached respectively to the front and back of the main tendon of insertion. Th intermediate fibres are multipennate, attached above and below to three or fo

ndons, which extend for a variable distance from the origin and insertion uscle.

supraspinatus arises by fleshy fibres from the supraspinous fossa (except e neck of the bone) and from the deep fascia over it (Fig. 254, p. 330). rected outwards under the acromion process and coraco-acromial ligament **serted** by a broad thick tendon into the uppermost facet on the great ty of the humerus, and capsule of the shoulder- ig. 253, p. 329).

muscle is entirely con- om view by the trapezius, omion process, and the muscle. It covers the the scapula, the supra- vessels and nerves, and er surface of the capsule houlder-joint.

infraspinatus arises from raspinous fossa of the (excepting near the neck one and the flat surface he axillary border) and ie thick fascia over it 4, p. 330). The fibres of cle converge to the neck capula; and are **inserted** on into the middle facet great tuberosity of the s, and into the capsule shoulder-joint (Fig. 258,

ng it from the infraspinatus and teres major muscles (Fig. 254, p. 330). longside the outer border of the infraspinatus, it is **inserted** under cover eltoid by a thick flat tendon into the lowest of the three facets on the uberosity of the humerus and into the capsule of the shoulder-joint, and y fibres into the posterior aspect of the surgical neck and shaft of the s, below the tuberosity for about an inch (Fig. 258, p. 335). It is d from the teres major by the scapular head of the triceps, and by the r circumflex vessels and the circumflex nerve. Its origin is pierced by

the dorsal scapular artery. The muscle is invested by the deep fascia enclos infraspinatus, and is sometimes inseparable from that muscle.

The **teres major** is much larger than the preceding muscle. It **arises** by fibres from the lower third of the flat surface on the dorsum of the scapula al axillary border (except for a small area at the lower angle), and from fascial which separate it on the one side from the subscapularis, and on the other fr infraspinatus and teres minor (Fig. 254, p. 330). The muscle is directed the axillary border of the scapula to the front of the shaft of the humerus, it is **inserted** by a broad flat tendon into the inner border of the bicipital internal to the latissimus dorsi muscle (Fig. 257, p. 335). Just before its in it is closely adherent to the tendon of the latissimus dorsi.

The teres major helps to form the posterior wall of the axilla. It lies the subscapularis, and is in close relation with the latissimus dorsi muscle, conceals its origi teriorly, winds rou outer border, and pa separates its anteri face from the a vessels and nerves muscle forms the boundary of a lar angular interval, b externally on the po wall of the axilla surgical neck o humerus, and abo the borders of th scapularis and teres muscles. The lon of the triceps passes the teres major an divides this spac two, a quadrilatera limited by the trice surgical neck o humerus for the p of the circumflex and posterior circ vessels, and a smal angular space boun the triceps, subscap and teres major, t dorsal scapular art

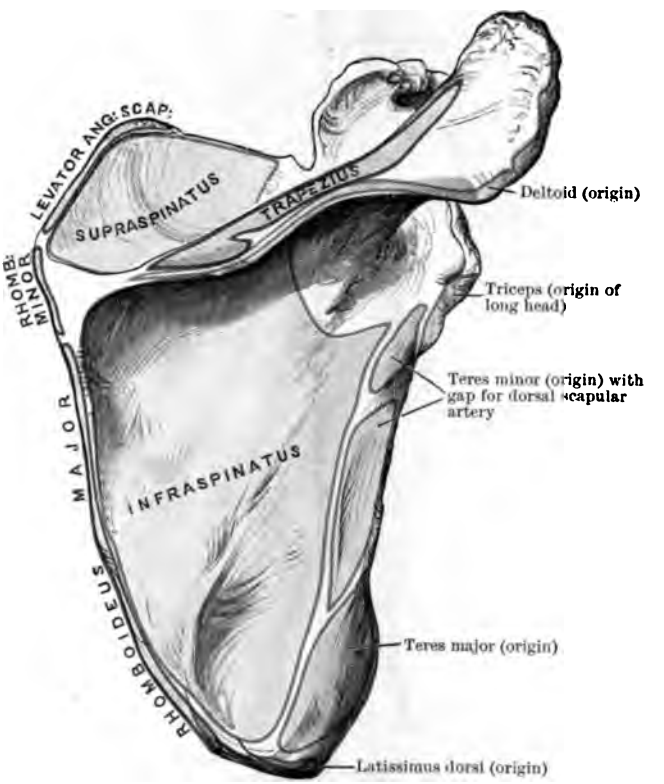

Fig. 254.—Muscle-Attachments to the Scapula (Posterior Surface).

The **subscap** is a large triangular muscle occupying the venter of the scapula. It by fleshy fibres from the whole of the subscapular fossa and the groove the axillary border, excepting the surfaces at the angles of the bone (Fig p. 325). Springing from several ridges in the fossa are septa projectin the substance of the muscle, which increase the extent of its attachment. verging to the head of the humerus, the muscular fibres are **inserted** by a broad tendon into the lesser tuberosity of the humerus and into the capsule of the sho joint, and by fleshy fibres into the surgical neck and the shaft of the hu below the tuberosity for about an inch, under cover of the coraco-brachial short head of the biceps (Fig. 257, p. 335). This muscle forms the greater p the posterior wall of the axilla. Its inner or anterior surface is in contact wi serratus magnus and the axillary vessels and nerves. Its deep surface is sep from the neck of the scapula by a bursa, which is in direct communication wi synovial cavity of the shoulder-joint. Its upper border passes beneath the co process; its outer border is separated from the teres major by the **posterior c**

flex vessels and the circumflex nerve, the long head of the triceps muscle, and the dorsal scapular artery.

The **subscapularis minor** is an occasional muscle situated below the capsule of the shoulder-joint. It **arises** from the axillary border of the scapula below the subscapularis, and is **inserted** into the capsule of the joint or the upper part of the shaft of the humerus.

Nerve-Supply.

The muscles of this group are all supplied by the fifth and sixth cervical nerves, through nerves arising from posterior trunks of the brachial plexus.

Muscles.	Nerves.	Origin.
Deltoid, Teres minor	Circumflex	C. 5. 6.
Supraspinatus, Infraspinatus	Suprascapular	
Teres major	Lower subscapular	
Subscapularis	Lower and upper subscapular	

Actions.

The principal action of this group of muscles is on the shoulder-joint. They have also secondary actions in relation to movements of the trunk and limbs.

1. Movements at the Shoulder-Joint.

a. **Abduction.**	**Adduction.**	*b.* **Flexion** (Forwards).	**Extension** (Backwards).

c. **Rotation Outwards.**	**Rotation Inwards.**
Deltoid (posterior fibres) Infraspinatus Teres minor	Deltoid (anterior fibres) Teres major Pectoralis major Latissimus dorsi

d. **Circumduction**—combination of previous muscles.

The various movements at the shoulder-joint are greatly aided by the muscles acting on the shoulder girdle. In raising the arm above the head, for instance, the humerus is brought to the horizontal position by the deltoid and supraspinatus, and the movement is continued by the elevators of the shoulder girdle. Again, in forward and backward movements at the shoulder-joint, great assistance is derived from muscles acting directly on the shoulder girdle—pectoralis minor and serratus magnus; trapezius and rhomboidei.

2. **In relation to the trunk and limbs,** the shoulder muscles, by fixing the humerus, have auxiliary power on the one hand in movements of the trunk, such as forced inspiration; on the other hand, acting along with muscles fixing the elbow-joint, they stiffen the limb so as to permit of the more refined movements of the wrist and fingers.

FASCIÆ AND MUSCLES OF THE ARM.

FASCIÆ.

The **superficial fascia** presents no features of importance. There is a bur beneath it over the olecranon process, and occasionally another over the inn condyle of the humerus.

The **deep fascia** forms a strong tubular investment for the muscles on the fron and back of the humerus. It is continuous above with the deep fascia of th shoulder and axilla, and is further strengthened by fibres derived from the insertion of muscles attached to the upper part of the humerus, viz., from the pectoralis major, latissimus dorsi, and deltoid. At the elbow it becomes continuous with the deep fascia of the forearm, and gains attachment to the condyles of the humerus and the olecranon process of the ulna; it is strengthened also by important bands associated with the insertions of the biceps in front and the triceps behind, to which reference will be made in the account of these muscles.

About the middle of the upper arm in front of the inner border, the deep fascia is perforated for the passage of the basilic vein and the internal cutaneous nerve.

The **intermuscular septa** are processes of the deep fascia attached to the supracondyloid or epicondylic ridges of the humerus. The **internal** and **stronger septum** is placed between the brachialis anticus in front and the inner head of the triceps behind, and gives origin to both. It extends upwards to the insertion of the coraco-brachialis (which is often continued into it), and the ulnar nerve and inferior profunda vessels pass down over its inner edge. The **external septum** is thinner. It separates the brachialis anticus and brachio-radialis in front from the inner and outer heads of the triceps behind, and gives origin to these muscles. It extends upwards to the insertion of the deltoid, and is pierced by the musculo-spiral nerve and superior profunda vessels.

MUSCLES.

The **coraco-brachialis** is a rudimentary muscle placed on the front and inner aspect of the arm. It **arises** in common with the short head of the biceps from the tip of the coracoid process of the scapula (Fig. 250, p. 325), and is commonly connected at its origin with the insertion of the pectoralis minor. The origin of the muscle is by fleshy fibres attached (1) to the tip of the coracoid process below and internal to the biceps tendon, and (2) to the tendon of the biceps itself. The muscle is partially subdivided into two parts by the musculo-cutaneous nerve, and ends in a flat tendon **inserted** into a faint linear impression about an inch in length on the middle of the inner border of the shaft of the humerus (Fig. 257, p. 335). It is often continued into the internal intermuscular septum.

The muscle lies on the inner side of the biceps, and is concealed at first by the deltoid and pectoralis major. In the lower part of its extent it is superficial, and forms a swelling beneath the skin on the inner side of the arm which serves as a guide to the axillary and brachial arteries.

The **coraco-brachialis** is the remains of a *threefold muscle*, of which only two elements are usually present in man, but of which in anomalous cases all the parts may be more or less fully developed. The passage of the musculo-cutaneous nerve through the muscle is an indication of its natural separation into two parts, which represent the persistent middle and inferior elements. The commonest variety is one in which the more superficial (inferior) part of the muscle extends farther down the arm than usual, so as to be inserted into the internal intermuscular septum, or even into the internal condyle of the humerus. A third slip (**coraco-brachialis superior** or **brevi rotator humeri**) may more rarely be present, forming a short muscle **arising** from the root of the coracoid process, and **inserted** into the inner side of the humerus just below the capsule of the shoulder-joint.

The **biceps** (m. biceps brachii) is the large superficial muscle which lies on the front of the upper arm. It **arises** by two tendinous *heads*. (1) The **short head** (caput breve) is attached in common with the coraco-brachialis to the tip of the coracoid process of the scapula (Fig. 250, p. 325). Tendinous at first, this head forms a separate fleshy belly, which is united to the long head by an investment of the deep fasci

long head (caput longum) arises by a round tendon from the supra-glenoid ɔn at the root of the coracoid process and from the glenoid ligament on ;ide. Its tendon the cavity of the -joint, and emerging e capsule beneath ɜverse ligament (in- y a prolongation of ɔvial membrane), it the bicipital groove umerus, covered by prolongation of the of the pectoralis In the upper arm a fleshy belly united derived from the ad by an envelope ascia.

nsertion of the muscle se twofold. (1) The es become connected strong *tendon*, at- leeply in the hollow elbow to the rough portion of the tubercle of the Figs. 264, p. 343, , p. 351). A bursa s the tendon from rior portion of the (2) From the inner erior part of the and partly in con- vith the fleshy fibres uscle, a strong *mem- band* (the **semilunar ital fascia**) extends rds and inwards over w of the elbow to join fascia covering the f the flexor and pro- uscles of the forearm. r part is thickened e felt subcutaneously centic border.

pt at its origin and the biceps muscle superficially on the the arm, concealing hialis anticus muscle musculo-cutaneous The brachial artery lian nerve lie along border. The origin uscle is deeply placed ɔver of the deltoid ɔoralis major.

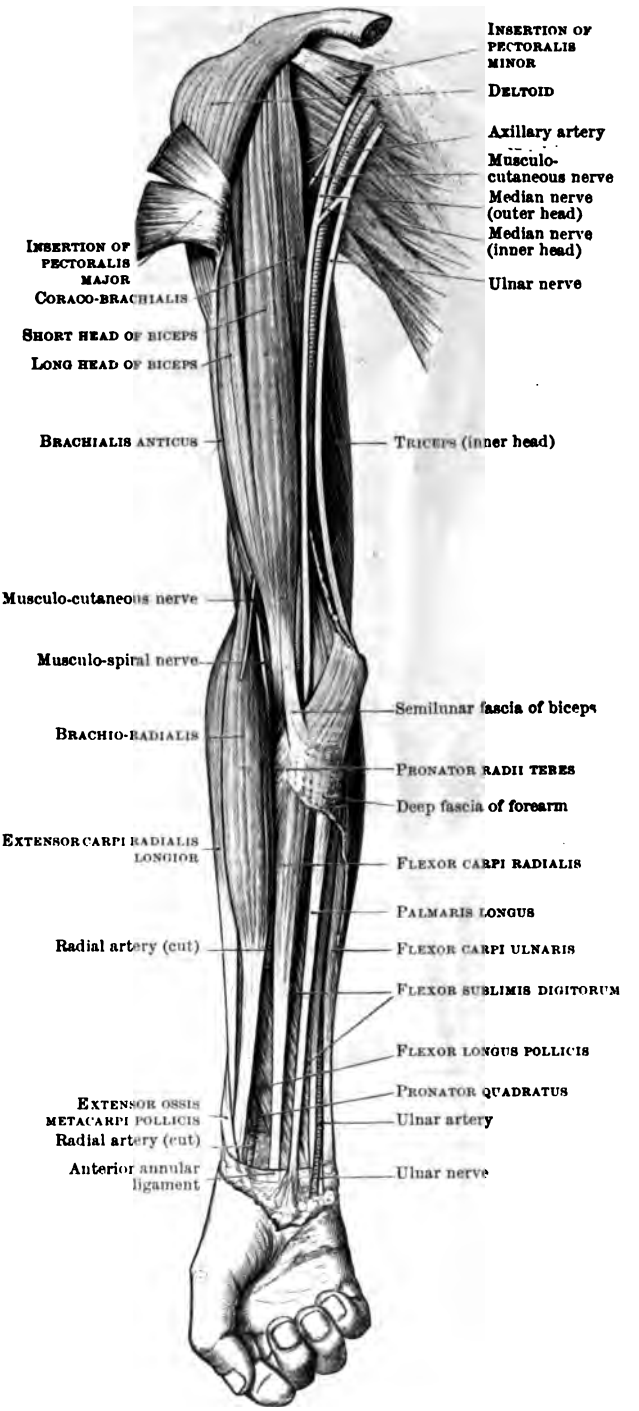

FIG. 255.—SUPERFICIAL MUSCLES ON THE FRONT OF THE ARM AND FOREARM.

The tendon of insertion in the hollow of the elbow lies the end of the brachial and the beginning of the radial artery. The fascia separates the brachial artery from the median basilic vein.

The **biceps** is an extremely variable muscle. Its chief anomalies are due to an increase diminution in the number of origins. A third **head of origin** is common (10 per cent), a usually arises from the humerus, between t insertions of the deltoid and coraco-brachia Two or even three additional heads may present at the same time. The long head the muscle may be absent, or may take orig from the bicipital groove. The muscle m have an additional insertion into the intern condyle of the humerus, or into the fascia the forearm.

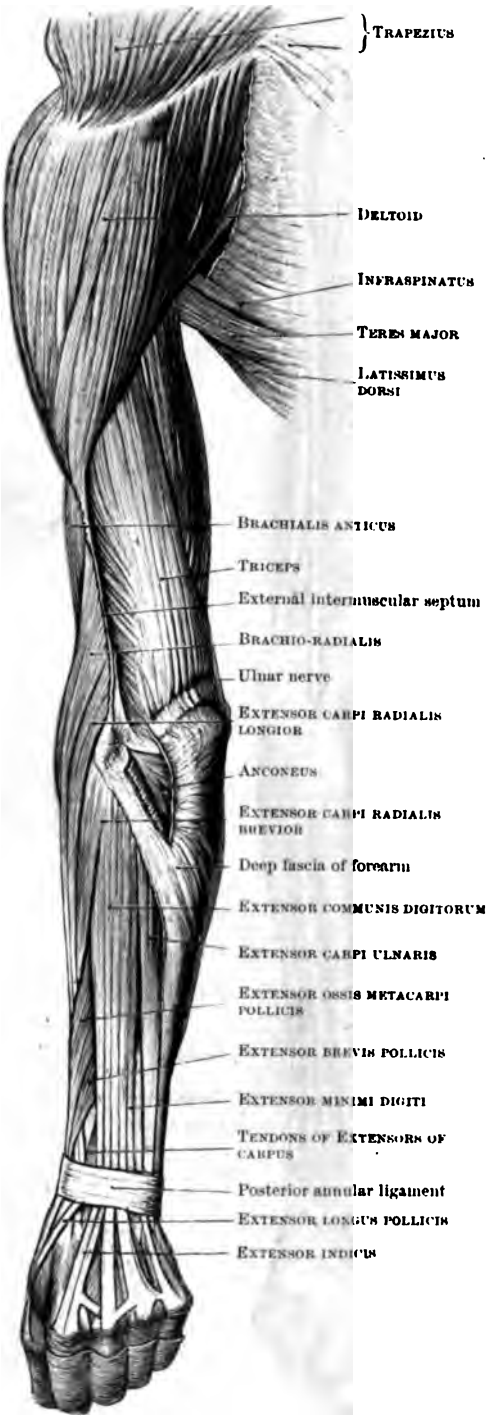

Fig. 256.—The Muscles on the Back of the Arm, Forearm, and Hand.

The **brachialis anticus** (m. brach alis) is a large muscle **arising** fro the lower two-thirds of the front the shaft of the humerus, and fro the inter-muscular septum on ea side (Figs. 257 and 258, p. 33 Clasping the insertion of the delto above, it ends below in a strong tend **inserted** into the rough inferior surfa of the coronoid process of the ulna a into the anterior surface of the shaft the bone immediately below (Fig. 26 p. 343). A few of the deep fibres a inserted into the anterior ligament the elbow-joint. The outer part of t muscle arising from the external ep condylic ridge and external intermu cular septum forms a slip more or le separate, which may be partially fuse with the brachio-radialis muscle.

The brachialis anticus is almo wholly concealed from view by th biceps in front, the brachio-radiali externally, and the brachial vessels i ternally.. It covers the elbow-joint, an forms part of the floor of the hollo of the elbow. It is separated from th brachio-radialis and extensor muscl of the carpus by the musculo-spir nerve.

The **triceps** (m. triceps brachii) the only muscle on the back of t arm. It **arises** by three heads: an out and an inner head, from the humer and a middle or long head from t scapula. (1) The **middle, long or scapu head** (caput longum) begins as a stro tendon attached to a rough triangu surface on the axillary border of t scapula just below the glenoid fo (Figs. 254, p. 330, and 250, p. 32 This gives rise to a fleshy belly wh occupies the middle of the back of t arm. (2) The **outer head** (caput latera is attached by fibres, partly tendin and partly fleshy, to the curved ou border of the humerus from the insertion of the teres minor above to the muscu spiral groove below, and receives additional fibres from the back of the exter intermuscular septum (Fig. 258, p. 335). This origin is thick above and becon

r below. Its fibres are directed downwards and inwards over the musculo-spiral
e and the inner head of the muscle to the tendon of insertion (3) The inner
(caput mediale) arises by fleshy fibres from an elongated triangular area on the
of the humerus, extending upwards to the level of the insertion of the teres
r on the inner side, and downwards nearly to the margin of the olecranon fossa.
258, p. 335). Externally it is limited above by the musculo-spiral groove;

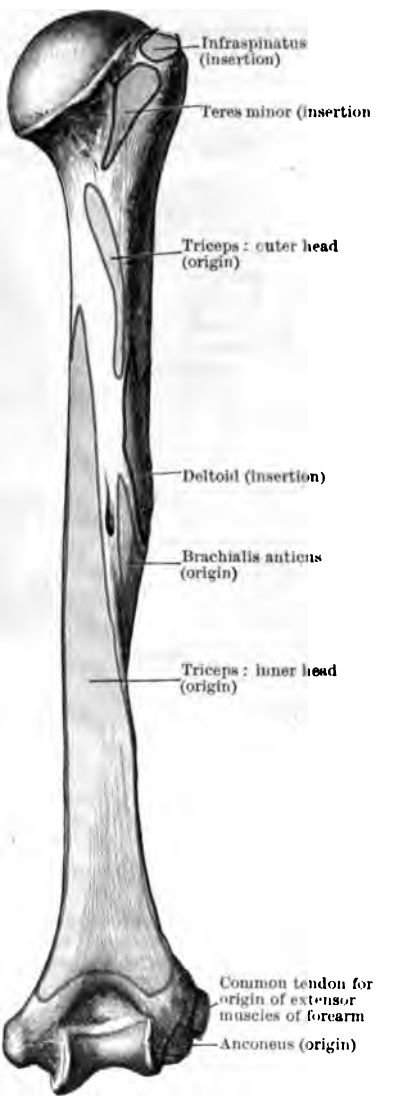

Fig. 258.—Muscle-Attachments to the Back of the Humerus.

below it extends downwards on either side of the olecranon fossa almost to
condyles of the humerus. It also arises on each side from the intermuscular
a,—from the whole length of the external septum, and from the part of the
rnal septum which is below the passage of the musculo-spiral nerve.
The three heads of origin are **inserted** by a common tendon, broad and membranous,
an impression occupying the posterior part of the upper end of the olecranon
ess of the ulna (Fig. 271, p. 351), and into the deep fascia of the forearm
ither side of it. The long and outer heads join the borders of the tendon of

insertion, and the inner head is attached to its deep surface. A small thick-walle bursa separates the tendon of the triceps from the posterior ligament of the elbo joint and the anterior part of the upper end of the olecranon process.

The long head of the triceps is concealed at first by the teres major and tes minor, and by the deltoid muscle. Along with the outer head it conceals the muscul spiral nerve and superior profunda artery, and covers the inner head of the musc The inner is the deep head, and is only visible at the lateral borders of the musc

The **subanconeus** is a small muscle occasionally present, which consists of scattered fib **arising** from the lower end of the humerus beneath the triceps, and **inserted** into the poster ligament of the elbow-joint.

NERVE-SUPPLY.

The following nerves supply the muscles of the arm :—

Muscles.	Nerves.	Origin.
Coraco-brachialis Biceps Brachialis anticus	Musculo-cutaneous	C. 7. C. 5. 6. C. 5. 6.
Brachialis anticus Triceps Outer head Middle and inner heads	Musculo-spiral	C. (5) 6. C. (6) 7. 8. C. 7. 8.

ACTIONS.

(1) The chief action of these muscles (excepting the coraco-brachialis) is on the elbow-joi producing along with other muscles flexion and extension. The flexor muscles are much m powerful than the extensors.

Table of Muscles acting on the Elbow-Joint.

Flexors.	Extensors.
Biceps	Triceps
Brachialis anticus	Anconeus
Brachio-radialis	Extensors of wrist and fingers (in supination)
Pronator radii teres	
Flexors of wrist and fingers	
Extensors of wrist (in pronation)	

(2) **The coraco-brachialis** muscle acts only on the shoulder-joint, assisting the biceps as adductor and flexor of the humerus.

(3) **Subordinate** and **accessory movements** are performed by all the muscles of this gro except the brachialis anticus. The **biceps** supinates the forearm, flexes the elbow, and with t aid of the **coraco-brachialis** adducts and flexes the humerus at the shoulder-joint. The tric through its scapular head adducts and extends the humerus, besides extending the elbow-join

FASCIÆ AND MUSCLES OF THE FOREARM AND HAND.

FASCIÆ.

The **superficial fascia** in the forearm presents no exceptional features. the dorsum of the hand it is loose and thin; in the palm it is generally v furnished with fat, forming pads for the protection of the vessels and nerves. I closely adherent to the palmar fascia and to the skin, especially along the lines flexure.

The **palmaris brevis** is a quadrilateral subcutaneous muscle occupying inner side of the hand under the superficial fascia. It **arises** from the inner bor of the thick central portion of the palmar fascia and from the front of the ante annular ligament of the wrist, and is **inserted** into the skin of the inner borde the hand for a variable distance. It covers the ulnar artery and nerve, branc of which supply it. Its action is to wrinkle the skin of the inner border of

d, and by raising up the skin and superficial fascia, to deepen the hollow of hand.

The **deep fascia** of the forearm and hand is continuous above with the deep ia of the arm. At the upper part of the forearm it is strengthened by additional es around the elbow; in front by fibres from the semilunar fascia of the ps, behind by the fascial insertions of the triceps, and laterally by fibres derived a the humeral lyles in rela- to the com- tendons of gin of the or and ex- or muscles of forearm. It ely invests gives origin hese muscles. attached to posterior ler of the ulna the whole th of the fore- , and affords eased attach- nt to the flexor l extensor pi ulnaris and flexor pro- dus digitorum scles. Above wrist the ia is pierced eriorly by the tendon of the palmaris longus, and by the ulnar artery and nerve. the wrist it gains attachment to the bones of the forearm and carpus, is greatly ngthened by addition of transverse fibres, and constitutes **the annular ligaments.**

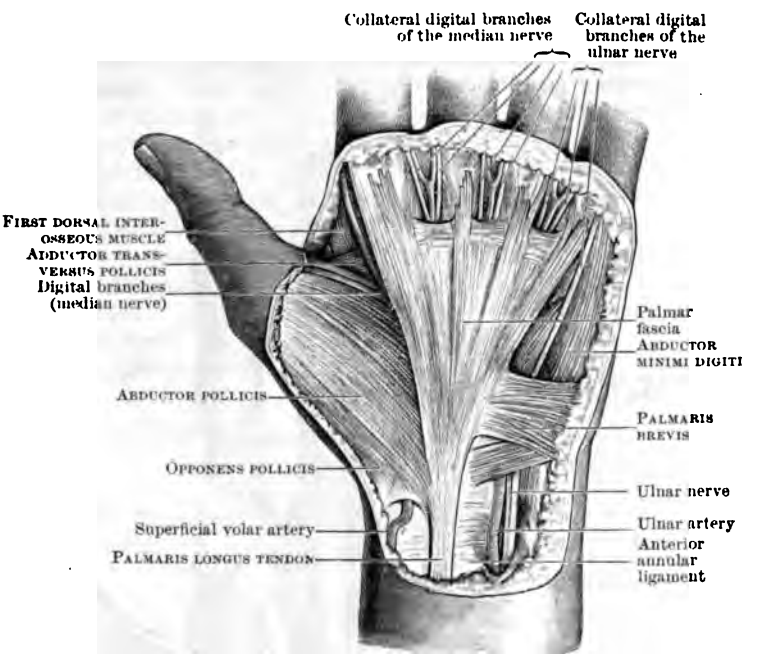

Fig. 259.—The Palm of the Hand (Superficial Dissection).

The **anterior annular ligament** of the wrist is a band about an inch and a f in depth, continuous above and below with the deep fascia of the forearm and palm of the hand. It is attached to the scaphoid and trapezium externally: the pisiform and unciform bones internally; and it forms a membranous arch ding down in the hollow of the carpus the flexor tendons of the fingers and the lian nerve. It is divided into *two compartments*, the larger accommodating the lons of the flexors of the digits and the median nerve, the smaller (placed rnally) containing the tendon of the flexor carpi radialis. There are *three rial membranes* in these compartments: one for the flexor carpi radialis lon, and two others, which often communicate together, enveloping the tendon he flexor longus pollicis and the flexor tendons of the fingers respectively. surface of the ligament is crossed by the palmar branches of the median and r nerves; by the tendon of the palmaris longus muscle, which is attached to urface; and by the ulnar artery and nerve, which are again bridged over and ected by a band of fibrous tissue passing from the pisiform bone and the rficial fascia to the surface of the ligament. To the lower border of the ment are attached the palmar fascia in the centre, and the superficial muscles e thumb and the muscles of the little finger on each side.

The **posterior annular ligament** of the wrist is placed at a higher level the previous ligament. It consists of an oblique band of fibres about an broad, continuous above and below with the deep fascia of the forearm and l. It is attached externally to the outer side of the lower end of the radius, internally to the lower end of the ulna (styloid process), the carpus, and the nal lateral ligament of the wrist. It is covered by veins, by the radial nerve,

and by the dorsal branch of the ulnar nerve. *Six compartments* are f beneath it by the attachment of septal bands to the lower ends of the and ulna. Each compartment is provided with a *synovial membrane*, and serve to transmit the extensor tendons of the wrist and fingers in the foll order from without inwards:—

1. Extensor ossis metacarpi pollicis and extensor brevis pollicis.
2. Extensores carpi radiales, longior and brevior.
3. Extensor longus pollicis.
4. Extensor communis digitorum and extensor indicis.
5. Extensor minimi digiti.
6. Extensor carpi ulnaris.

Fig. 260.—The Muscles and Tendons in the Palm of the Hand.

The thin deep fascia of the dorsum of the hand is lost over the expansi the extensor tendons on the fingers. Between the metacarpal bones a strong of fascia covers and gives attachment to the interossei muscles.

The **palmar fascia** is of considerable importance. In the centre of the it forms a thick triangular membrane, the apex of which joins the lower e the anterior annular ligament, and receives the insertion of the tendon palmaris longus muscle. The fascia separates below into four slips, one fo finger, connected together by transverse fibres, forming beneath the webs fingers the **superficial transverse metacarpal ligament**. Beyond this eac separates into two parts, to be connected to the sides of the metacarpo-phal joints and the first phalanx of the inner four digits. In the cleft between t halves of each slip the **digital sheath** is attached and extends downwards on finger. The lateral borders of this triangular central portion of the palmar

ontinuous with thin layers of deep fascia, which cover and envelop the muscles e thenar and hypothenar eminences. The inner border gives origin to the *aris brevis muscle.*

he **digital sheaths** are tubular envelopes extending along the anterior aspect e digits and enclosing the flexor tendons. Each consists of a fibrous sheath hed to the lateral borders of the phalanges and inter-phalangeal joints, and nuous above with the palmar fascia. Opposite each inter-phalangeal ılation the digital sheath is loose and thin; opposite the first two phalanges irst only in the case of the thumb) it becomes extremely thick, and gives o the **ligamenta vaginalia**, which serve to keep the tendons closely applied e bones during flexion of the fingers. Within each digital sheath are the flexor ns, enveloped in a synovial membrane which not only envelops the tendon, lso lines the interior of the sheath. The synovial membranes of the digital hs extend a short distance upwards in the palm, and in some cases comcate with the large synovial membranes lining the flexor tendons beneath nnular ligament. There may be a separate distinct synovial membrane for digit; but most commonly only the sheaths for the three middle digits have ate synovial membranes; those for the flexor longus pollicis and for the r tendons of the little finger communicate usually with the synovial mem-es placed beneath the anterior annular ligament.

THE MUSCLES ON THE FRONT AND INNER ASPECT OF THE FOREARM.

he pronator and flexor muscles which lie on the front of the forearm occupy rent levels, and are divisible into two main groups, **superficial** and **deep.**

Superficial Muscles.

he **superficial muscles** form the prominence on the front and inner side of forearm, and all take origin in whole or part by means of a common tendon the internal condyle of the humerus. The group comprises five muscles—ator radii teres, flexor carpi radialis, palmaris longus, flexor carpi ulnaris, and r sublimis digitorum.

he **pronator radii teres** (m. pronator teres) is the most external and shortest cle of this group. It has a double **origin**: (1) a *superficial head*, the main origin, ly fleshy, partly tendinous, from the lowest part of the internal supracondyloid e of the humerus and from the internal intermuscular septum, from the internal lyle of the humerus, from the fascia over it, and from an intermuscular septum een it and the flexor carpi radialis (Fig. 257, p. 335); (2) a *deep head*, a ler tendinous slip from the inner side of the coronoid process of the ulna, h joins the superficial origin of the muscle on its deep surface (Fig. 264, 3). The median nerve separates the two heads from one another. The muscle irected downwards and outwards to be **inserted** by tendon into an oval ession on the middle of the outer surface of the shaft of the radius (Figs. p. 343, and 271, p. 351). The fibres of the muscle are twisted on themselves, hat the highest humeral fibres form the lowest fibres of the tendon of tion, and the lowest humeral fibres and those arising from the coronoid ss are highest at the insertion of the muscle.

he muscle forms the inner boundary of the hollow of the elbow. It is superly placed, except near its insertion, where it is covered by the brachio-radialis le and by the radial vessels and nerve. The flexor carpi radialis is on its inner

The muscle conceals the ulnar and radial origins of the flexor sublimis orum, and the median nerve and ulnar artery, which are separated from one her by the deep head of origin.

he **flexor carpi radialis** muscle takes its **origin** from the common tendon from nternal condyle of the humerus, from the fascia over it, and from the interular septa on either side. Its fleshy belly gives place to a strong round on in the lower half of the forearm, which, at the wrist, enters the hand in a

special compartment beneath the anterior annular ligament, and after occ the groove on the trapezium, is **inserted** into the upper ends of the seco third metacarpal bones on their anterior surfaces. The chief tendon is that second metacarpal bone gives off a small slip inner side to be attac the third metacarpal Each is inserted a quarter of an inch be carpo-metacarpal join 267, p. 346).

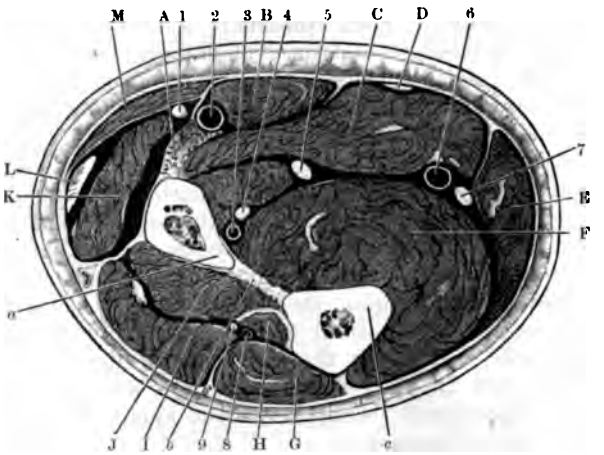

FIG. 261.—SECTION ACROSS THE FOREARM IN THE MIDDLE THIRD.

The flexor carpi ra superficial except near sertion. Its fleshy bell upper half of the fores between the pronato teres and the palmaris and conceals the flex limis digitorum. Its in the lower half of th arm is subcutaneous, outer side of the palmari tendon. It is an im guide to the radial which are placed in the external to it. Just at wrist it crosses obliqu tendon of the flexor pollicis. After passing the anterior annular li the tendon is concealed origins of the short muscles of the thumb, and is crossed from within outw the tendon of the flexor longus pollicis. Besides the synovial bursa env the tendon beneath the annular ligament, another is found beneath the at their insertion.

The **palmaris longus arises** also from the common flexor tendon, fr internal condyle of the humerus, from the fascia over it, and from interm septa on either side. It forms a short fusiform muscle, which ends in the of the forearm in a long flat tendon. This pierces the deep fascia above th and passing over the anterior annular ligament, is **inserted** (1) into the su the anterior annular ligament, and (2) into the apex of the thick central po the palmar fascia. A tendinous slip is frequently sent to the short muscle thumb and the fascia covering them.

The palmaris longus is the smallest muscle of the forearm. It is placed the flexor carpi radialis and the flexor carpi ulnaris, and upon the flexor s digitorum. In the lower third of the forearm its tendon is placed directly median nerve, along the outer border of the tendons of the flexor sublimis dig

The palmaris longus is the most variable muscle in the body, and is often absent (10

The **flexor carpi ulnaris** muscle has a double **origin**, from the humerus a the ulna. (1) It arises from the common tendon attached to the inner condyl humerus, from the fascia over it, and from an intermuscular septum external By means of the deep fascia of the forearm it obtains an attachment to th border of the olecranon process and the posterior border of the ulna in it three-fifths. The fleshy fibres join a tendon which lies on the anterior borde muscle and is **inserted** into the pisiform bone. From the pisiform bone th are continued in the form of two ligamentous bands (pisi-unciform and pi carpal) to be attached to the upper margin of the hook of the unciform b the palmar surface of the upper end of the fifth metacarpal bone (Fig. 267, p

The muscle is superficially placed along the inner border of the forearm. It lies internal to the palmaris longus and flexor sublimis digitorum, and conceals the flexor profundus digitorum muscle. The ulnar nerve (which enters the forearm between the two heads of origin of the muscle) is concealed by it in its whole length. The ulnar artery lies undercover of the muscle in its lower two-thirds. The tendon of the muscle serves as a guide to the artery in the lower half of the forearm.

The **flexor sublimis digitorum** occupies a deeper plane than the four previous muscles. It has a threefold origin, from the humerus, radius, and ulna. (1) The chief or *humeral* origin is from the internal condyle of the humerus by the common tendon, from the internal lateral ligament of the elbow, and from adjacent inter-muscular septa. (2) The *ulnar* origin is by a slender fasciculus from the inner border of the coronoid process of the ulna, above and internal to the origin of the pronator radii teres (Fig. 264, p. 343). (3) The *radial* origin is from the oblique line and middle third of the anterior border of the radius by a thin fibro-muscular attachment (Fig. 264, p. 343).

The muscle divides in the lower third of the forearm into four parts, each provided with a separate tendon which passes beneath the anterior annular ligament, traverses the palm of the hand, and enters the corresponding digital sheath. Within the digital sheath each tendon is split into two parts by the tendon of the flexor profundus digitorum; after surrounding that tendon the two parts are partially re-united on its deep surface, and are **inserted**, after partial decussation, in two portions into the sides of the second phalanx.

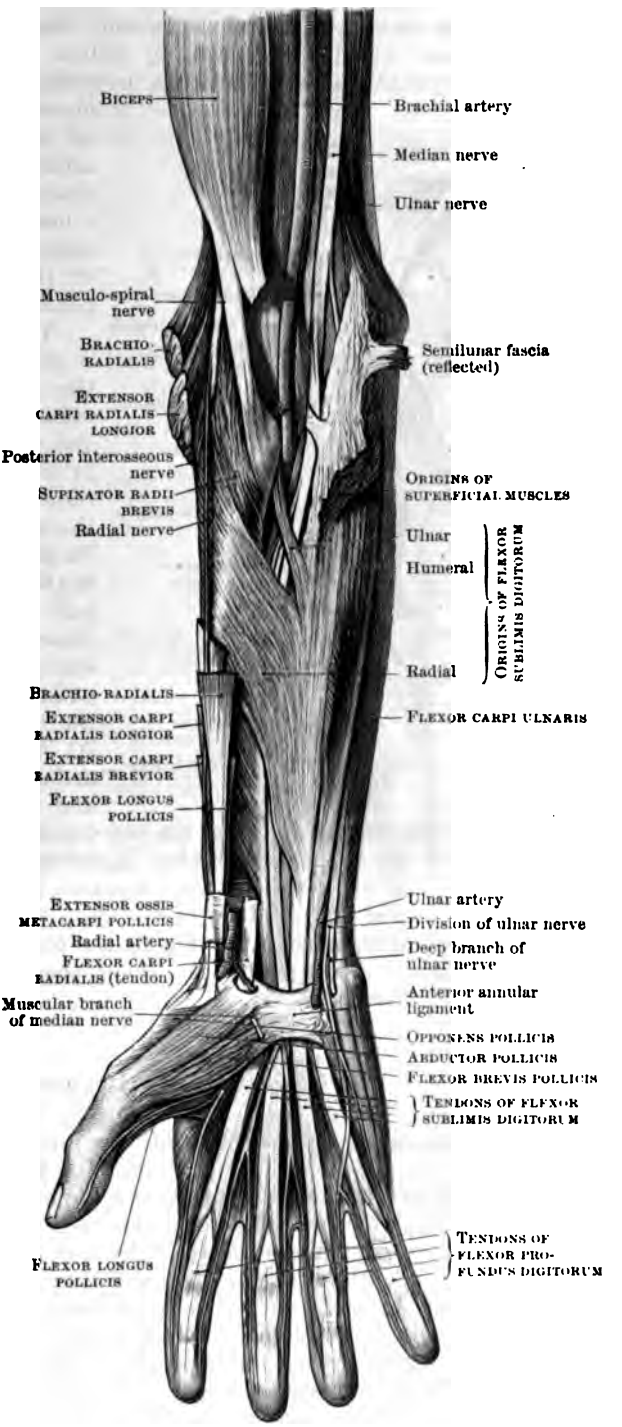

FIG. 262.—THE MUSCLES AND NERVES ON THE FRONT OF THE FOREARM AND HAND.

The pronator radii teres, flexor carpi radialis, and palmaris longus have been removed.

The **vincula accessoria tendinum** form additional insertions of the mu
They consist of delicate bands of connective tissue enveloped in synovial membr
and are known as the **ligamenta longa** and **brevia**. The ligamentum breve i

The flexor sublimis digitorum mus
is partially concealed in the forearm b
the pronator radii teres, flexor ca
radialis, and palmaris longus muscle
and by the radial vessels and nerve
It conceals the flexor profundus digi
torum and flexor longus pollicis muscles
the median nerve, and the ulnar artery.
Its inner border is in contact with the
flexor carpi ulnaris, and in the lower
half of the forearm with the ulnar
vessels and nerve. The median nerve
emerges at its outer border above the
wrist, and separates the muscle from
the tendon of the flexor carpi radialis.
At the wrist the four tendons are
arranged in pairs, those for the middle
and ring fingers in front, those for the
fore and little fingers behind, and are enveloped in a synovial sheath (along with
the tendons of the flexor profundus digitorum) beneath the anterior annular
ligament. In the palm the tendons separate, and lying beneath the superficial
palmar arch conceal the tendons of the deep flexor and the lumbrical muscles.
Within the digital sheaths on the fingers the tendons at first conceal those of the
deep flexor; after being pierced by them, they are in turn concealed by these
tendons at their insertion.

Deep Muscles.

The **deep muscles** on the front of the forearm are three in number: flexor profundus digitorum, flexor longus pollicis, and pronator quadratus.

The **flexor profundus digitorum** is a large muscle **arising** from the ulna, the interosseous membrane, and the deep fascia of the forearm. Its ulnar origin is from the anterior and inner surfaces of the bone in its upper two-thirds, extending up so as to include the inner side of the olecranon process, and to embrace the insertion of the brachialis anticus into the coronoid process. It arises externally from the inner half of the interosseous membrane in its middle third (Figs. 264, p. 343, and 271, p. 351), and internally from the deep fascia of the forearm behind the origin of the flexor carpi ulnaris.

The muscle forms a broad thick tendon which passes beneath the anterior annular ligament, and divides in the palm into four tendons for **insertion** into the terminal phalanges of the fingers. The tendon associated with the forefinger is usually separate from the rest of the tendons in its whole length. Each tendon enters a digital sheath beneath the tendon of the flexor sublimis digitorum, which it pierces opposite the first phalanx, and is finally inserted into the base of the terminal phalanx. Like the tendons of the flexor sublimis, those of the deep

ıre provided with vincula accessoria, viz. **ligamenta brevia** attached to the of the second inter-phalangeal articulation, and **ligamenta longa,** which this case connected to the tendons of the subjacent flexor sublimis ım.

nbricales.—Four small cylindrical muscles are associated with the tendons flexor profundus digitorum in the palm of the hand. *The two outermost* **arise** each by a single head from the radial sides of the tendons of the rofundus digitorum destined ıvely for the fore and middle

The two innermost muscles ıch by two heads, from the t sides of the second and nd third and fourth tendons. hese origins the muscles are l downwards to the radial each of the metacarpo-geal joints, to be **inserted** into sules of these articulations, r border of the first phalanx, iefly into the outer side of ensor tendon on the dorsum phalanx. SHORT MUSCLES OF THE HAND.

Muscles of the Thumb.

The short muscles of the thumb are six in number, abductor, opponens, and flexor brevis (with its deep portion, **interosseus primus volaris**), and two adductor muscles, adductor obliquus, and adductor transversus pollicis.

The **abductor pollicis** (m. abductor pollicis brevis) **arises** by fleshy fibres from the tubercle of the scaphoid, the upper part of the outer surface of the ridge of the trapezium, the upper part of the anterior surface of the anterior annular ligament and its outer end, and from tendinous slips derived from the insertions of the palmaris

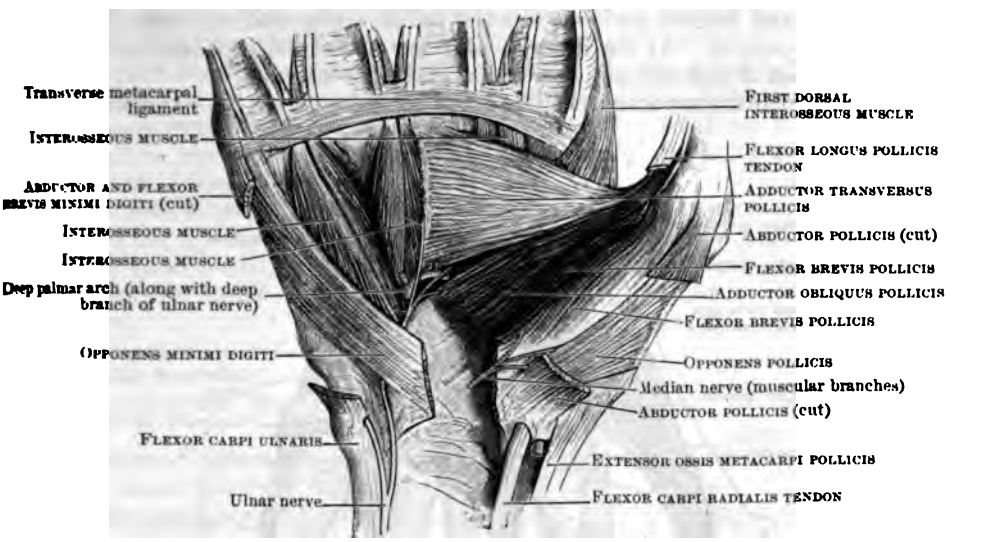

Fig. 266.—Short Muscles of the Hand.

longus and extensor ossis metacarpi pollicis muscles (Fig. 267, p. 346). Strap-like in form, it is **inserted** by a short tendon into the outer side of the first phalanx of the thumb at its upper end, and into the capsule of the metacarpo-phalangeal joint.

It is the most superficial muscle of the thenar eminence, and conceals partially the opponens and the superficial portion of the flexor brevis pollicis.

The **opponens pollicis arises** beneath the preceding muscle by fleshy and tendinous fibres from the lower and outer part of the anterior surface of the anterior annular ligament and from the outer surface of the ridge on the trapezium. Extending downwards and outwards, it is **inserted** into the whole length of the outer border and the radial half of the palmar surface of the first metacarpal bone (Fig. 267, p. 346). The muscle is superficial along the outer border of the abductor pollicis.

The **flexor brevis pollicis** consists of two parts. *a. The superficial part of the muscle* **arises** by fleshy and tendinous fibres from the outer half or two-thirds of the lower border of the anterior annular ligament, and sometimes from the ridge of the trapezium, and is **inserted** into the outer side of the base of the first phalanx of the thumb, a sesamoid bone being present in the tendon of insertion. This part of the muscle, partly concealed by the abductor pollicis, is superficial in the interval between that muscle and the tendon of the flexor longus pollicis.

b. The deep part of the muscle (interosseus primus volaris) **arises** from the ulnar side of the base of the first metacarpal bone, and is **inserted** into the inner side of the base of the first phalanx of the thumb along with the adductor obliquus pollicis. This little muscle is deeply situated in the first interosseous space, in the interval between the adductor obliquus pollicis and the first dorsal interosseous muscle. It may be regarded as homologous with the palmar interossei muscles, with which it is in series.

The **adductor obliquus pollicis arises** by fleshy fibres from the anterior surf of the trapezium, trapezoid, and os magnum, from the sheath of the tendon of flexor carpi radialis, from the basis of the second, third, and fourth metacarpal bo and from the palmar ligaments connecting these bones together (Fig. 267, p. 3 It is **inserted** by a tendon, in which a sesamoid bone is developed, into the in side of the base of the first phalanx of the thumb. At its outer border a slen slip separates from the rest of the muscle, and passing obliquely beneath the ten of the flexor longus pollicis, is inserted into the outer side of the base of the f phalanx along with the superficial part of the flexor brevis pollicis.

The adductor obliquus pollicis lies on the ulnar side of the tendon of the fle longus pollicis, internal to the thenar eminence. It is covered by the flexor tend of the thumb and fingers, and conceals the radial artery and the deep part of t flexor brevis pollicis. At its inner border the radial artery (deep palmar arc appears between it and the adductor transversus pollicis.

The **adductor transversus pollicis arises** by fleshy fibres from the median rid

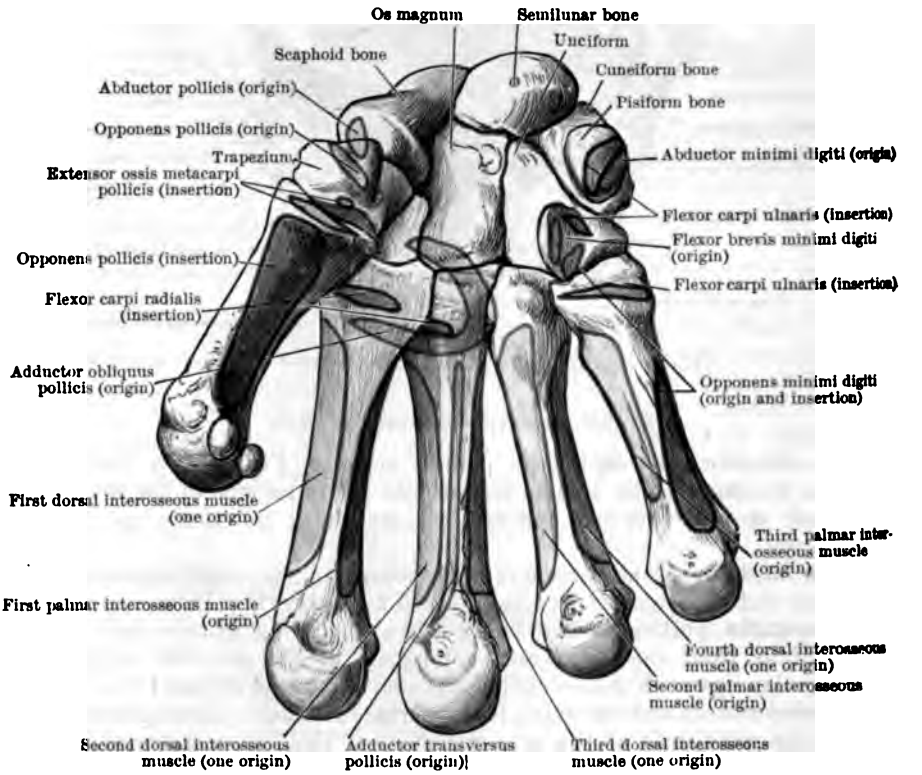

FIG. 267.—MUSCLE-ATTACHMENTS TO THE PALMAR ASPECT OF THE CARPUS AND METACARPUS.

on the front of the shaft of the third metacarpal bone, in its lower two-thi (Fig. 267, p. 346), and from the fascia covering the interosseous muscles in t second and third spaces. Triangular in form, it is directed outwards, to **inserted** by tendon into the inner side of the base of the first phalanx of thumb along with the adductor obliquus. Lying deeply in the palm beneath flexor tendons, this muscle conceals the interossei muscles of the first two spa and the radialis indicis and princeps pollicis arteries. Its upper border separated from the adductor obliquus pollicis by the radial artery (d palmar arch).

MUSCLES OF THE LITTLE FINGER.

The short muscles of the little finger are three in number: **abductor, oppone** and flexor brevis minimi digiti.

ductor minimi digiti (m. abductor digiti quinti) **arises** from the front
ıide of the pisiform bone and from the tendon of the flexor carpi ulnaris
mentous continuations (Fig. 267, p. 346), and is **inserted** by tendon into
side of the base of the first phalanx of the little finger. It lies
y upon the opponens and flexor brevis minimi digiti.

ponens minimi digiti (m. opponens digiti quinti) **arises** by tendinous
the lower part of the anterior surface and from the lower border of the
nular ligament at its inner end, and from the lower border and inner side
)k of the unciform bone, and is **inserted** into the inner margin and
of the palmar surface of the fifth metacarpal bone in its lower
hs (Fig. 267, p. 346).

ncealed by the previous muscle, and may be pierced near its origin for
of the deep branches of the ulnar artery and nerve.

xor brevis minimi digiti (m. flexor digiti quinti brevis) **arises** by
fibres from the inner part of the anterior surface of the anterior annular
nd from the inner side of the hook of the unciform bone (Fig. 267,
d is **inserted** along with the abductor into the inner side of the first

ulnar nerve. Between the two heads of the first dorsal muscle the radial art enters the palm, and the perforating arteries pass between the heads of the ot dorsal muscles.

The interossei muscles of the hand in some cases have a disposition simila that of the corresponding muscles of the foot.

THE MUSCLES ON THE BACK OF THE FOREARM.

The group of muscles occupying the outer side of the elbow and the back of the forearm and hand include the supinator muscles of the forearm and the extensors of the wrist and digits. They are divisible into a **superficial** and a **deep layer.**

Superficial Muscles.

The **superficial layer** comprises seven muscles, viz. from without inwards, the brachio-radialis, the two radial extensors of the carpus, the extensor communis digitorum and extensor minimi digiti, the extensor capri ulnaris, and the anconeus.

The **brachio-radialis** (supinator radii longus) **arises** by fleshy fibres from the anterior aspect of the upper two-thirds of the external supra condyloid ridge of the humerus, and from the front of the external intermuscular septum (Fig. 257, p. 335). Occupying the outer side of the hollow of the elbow, the muscle descends along the outer border of the forearm, and ends about the middle in a narrow flat tendon which is **inserted** under cover of the tendons of the extensor ossis metacarpi pollicis and extensor brevis pollicis, by a transverse linear attachment, into the upper limit of the groove for the above-named muscles on the outer side of the lower extremity of the radius. Some of its fibres gain an attachment to the ridge in front of the groove, and others spread over the surface of the groove for a variable distance (Figs. 271, p. 351, and 264, p. 343).

The muscle is superficial in its whole length. Near its origin it is separated from the brachialis anticus by the musculo-spiral nerve. It forms the outer boundary of the hollow of the elbow, and conceals the radial extensors of the carpus, and, in the upper two-thirds of the forearm, the radial artery and nerve.

The **extensor carpi radialis longior** (m. ext. carp. rad. longus) **arises** by fleshy fibres from the lower third of the external supracondyloid ridge of the humerus on its anterior aspect, from the front of the external intermuscular septum, and from the common tendon of origin of succeeding muscles, which is attached to an impression on the antero-external surface of the external condyle (Figs. 257, and 258, p. 335). It ends in a tendon in the lower half of the forearm, which passes beneath the posterior annular ligament, to be **inserted** into the back of the base of the second metacarpal bone on its radial side (Fig. 269, p. 348).

The upper part of the muscle is concealed by the brachio-radialis, and the lower part is crossed by the extensors of the thumb. It covers the supinator radii brevis and extensor carpi radialis brevior above, and the back of the radius and the carpus below.

The **extensor carpi radialis brevior** (m. ext. carp. rad. brevis) **arises** from the common tendon, from the external lateral ligament of the elbow, from the fascia over it, and from intermuscular septa on each side. It passes down the back of the forearm and under the posterior annular ligament in close relation to the previous muscle, to be **inserted** by a tendon into the back of the base of the third metacarpal bone below the styloid process on its radial side. It usually has an additional insertion into the back of the base of the second metacarpal bone (Fig. 269, p. 348). A bursa is placed beneath the two radial extensor tendons close to their insertion.

Partially concealed by the extensor carpi radialis longior and the extensor muscles of the thumb, and having the extensor communis digitorum on its inner side, the muscle covers the supinator brevis, the lower part of the radius, and the back of the carpus.

The **extensor communis digitorum arises** from the common tendon, from the external condyle, from the fascia over it, and from intermuscular septa on each side. Extending down the back of the forearm it ends above the wrist in four tendons, of which the outermost often has a separate fleshy belly. After passing beneath the posterior annular ligament in a compartment along with the extensor indicis, the tendons separate on the back of the hand, where the three innermost tendons are joined together by two obliquely-placed bands. One passes downwards and outwards, and connects together the third and second tendons; the other is a broader

and shorter band, which passes also downwards and outwards, and joins the fo to the third tendon. In some cases (Fig. 257) a third band is present, which pa downwards and inwards from the first to the second tendon; and frequently tendon for the little finger is joined to the tendon for the ring finger, and separ from it only a short distance above the lower end of the metacarpal bone.

The tendons are **inserted** in the following manner: On the finger each ten spreads out so as to form a membranous expansion over the knuckle and on back of the first phalanx. The border of the tendon is indefinite over the me carpo-phalangeal articulation, of which it forms the posterior ligament. On back of the first phalanx the tendon receives laterally the insertions of the intero and lumbrical muscles. At the lower end of the first phalanx the tendon sp into ill-defined median and lateral slips, proceeding over the back of the f inter-phalangeal articulation, of which they form the posterior ligament. T median slip is inserted into the back of the base of the second phalanx, while t two lateral pieces become united to form a membranous tendon on the back the second phalanx, which, after passing over the second inter-phalangeal articul tion, is inserted into the base of the terminal phalanx.

The extensor communis digitorum is superficial in its whole length, and lies the upper part of the forearm between the radial extensors of the carpus external and the extensor minimi digiti internally. It conceals the supinator brevis a other deep muscles of the forearm, as well as the posterior interosseous vessels a nerves. The extensors of the thumb become superficial along its outer border the lower third of the forearm.

The **extensor minimi digiti** (m. extensor digiti quinti proprius) has an ori similar to and closely connected with that of the preceding muscle, from t common tendon, the fascia over it, and lateral intermuscular septa. Passing do the back of the forearm as a narrow fleshy slip, between the extensor commu digitorum and the extensor carpi ulnaris, it ends in a tendon which occupies groove between the radius and ulna in a special compartment of the poster annular ligament. On the back of the hand the tendon, usually split into two pa lies internal to the tendons of the extensor communis digitorum, and is fina **inserted** into the expansion of the extensor tendon on the dorsum of the fi phalanx of the little finger.

The **extensor carpi ulnaris** has a double **origin**: (1) from the common tend from the external condyle of the humerus, from the fascia over it, and from t intermuscular septa; and (2) through the medium of the deep fascia, from t posterior border of the ulna in its middle two-fourths. The muscle ends in tendon in the lower third of the forearm, which occupies a groove on the back the ulna in a special compartment of the posterior annular ligament, and is inser into the ulnar side of the base of the fifth metacarpal bone (Fig. 269, p. 348).

The muscle is superficially placed between the extensor minimi digiti and anconeus, external to the posterior border of the ulna. It conceals the supina radii brevis and the posterior interosseous vessels and nerve above, and in the lo two-thirds of the forearm it lies upon the posterior surface of the ulna.

The **anconeus** is a small triangular muscle **arising** by a separate tendon fi the lower part of the back of the external condyle of the humerus (Fig. 2 p. 335), and from the posterior ligament of the elbow-joint. Spreading out c the ulna, it is **inserted** by fleshy fibres into a triangular surface on the outer s of the olecranon process and back of the ulna, as low down as the oblique (Fig. 271, p. 351). It is also inserted into the fascia which covers it.

It is covered by the thickened fascia of the forearm giving insertion to triceps muscle. It conceals the back of the elbow-joint and part of the origi the supinator brevis muscle.

The **epitrochleo-anconeus** is an occasional small muscle **arising** from the back of the inte condyle of the humerus, and **inserted** into the inner side of the olecranon process. It covers ulnar nerve in its passage to the forearm.

Deep Muscles.

The **deep muscles** on the back of the forearm comprise five muscles, of wh

inator radii brevis, extends between the ulna and radius; the others s of the thumb and forefinger: the extensor ossis metacarpi pollicis, vis and extensor longus pollicis, and extensor indicis.

inator radii brevis (m. supinator) muscle has a complex **origin.** It hy and tendinous fibres: (1) from the external condyle of the humerus; external lateral and orbicular ligaments of the elbow-joint; (3) from ar surface on the shaft of the ulna just below the lesser sigmoid cavity; a the fascia over this origin the ads outwards and enveloping the of the radius, and into the anterior rfaces of the bone, ds as the bicipital far upwards as nd as far down- oblique line and a of the pronator The insertion of n some cases en- r a variable dis- o the posterior he shaft of the the origin of the is metacarpi pol- he neck and the of the posterior he shaft are left cular attachment p. 351, and 264,

then continued along the back of the first metacarpal bone, and the meta
phalangeal articulation, to be **inserted** into the back of the base of the first p
of the thumb. Before reaching its insertion the tendon helps to form the c

the metacarpo-phalangeal joint. In the forearm the muscle is deeply placed ıeath the superficial extensors, and is separated from the extensor longus pollicis the posterior interosseous nerve.

The extensor longus pollicis (extensor secundi internodii pollicis) **arises** from ı intermediate impression occupying the outer part of the posterior or extensor :face of the ulna in its middle third, and from the interosseous membrane, below ı extensor ossis metacarpi pollicis (Fig. 271, p. 351). Its tendon grooves the :k of the radius, and occupies a special compartment beneath the posterior nular ligament. Extending obliquely across the back of the hand, it is **inserted** o the dorsal surface of the base of the second phalanx of the thumb.

The muscle is deeply placed beneath the superficial extensors of the forearm, l lies between the extensor brevis pollicis and the extensor indicis. It separates ı posterior interosseous artery from the nerve, the latter passing beneath it. On ı back of the hand the tendon crosses the radial artery, and helps to form the ısule of the first metacarpo-phalangeal articulation.

At the wrist the tendons of the muscles of the thumb, the extensor ossis meta-pi pollicis and extensor brevis pollicis externally, and the extensor longus llicis internally, bound a hollow (the "anatomical snuff-box") best seen in tension and abduction of the thumb, which corresponds to the position of the lial artery as it winds round the wrist to reach the palm of the hand.

The extensor indicis (m. extensor indicis proprius) **arises** by fleshy fibres below ı extensor longus pollicis from the lowest impression on the back of the ulna, tending down from the middle of the shaft to within two inches of its lower end, l sometimes also from the interosseous membrane (Fig. 271, p. 351). Its tendon ses through a compartment of the posterior annular ligament along with the ıdons of the extensor communis digitorum, and is **inserted** into the forefinger ning the membranous expansion of the tendon of the extensor communis gitorum on the dorsum of the first phalanx.

Lying deeply in the forearm, the muscle is placed internal to the extensor ıgus pollicis, and covers the posterior interosseous nerve. On the back of the nd its tendon lies on the inner side of the tendon of the common extensor stined for the forefinger.

NERVE-SUPPLY.

Four nerves are engaged in supplying the muscles of the forearm and hand—the median and ıar on the front, the musculo-spiral and posterior interosseous nerves on the back of the ıh.

Action of the Muscles of the Forearm and Hand.

The muscles of the forearm and hand are concerned in the movements of the elbow, wrist, fingers.

In the majority of cases the muscles act upon more than one joint.

1. Action on the Elbow-Joint.—It has been shown already that flexion and extens of the elbow are assisted by certain of these muscles. The **flexor muscles** are the pron radii teres, and the flexor muscles of the wrist and fingers. In the position of pronation, movement of flexion is aided by the brachio-radialis and extensors of the wrist and fingers. T **extensors** are the supinator brevis and anconeus, and the extensor muscles of the wrist and fing

2. Pronation and supination of the hand are performed by special muscles, aided by mus which act also upon other joints. The brachio-radialis assists in flexion and pronation on the hand, and in extension and supination on the other hand. In the supine position it assi pronation, and in the prone position it assists supination, in each case bringing the hand i the position intermediate between pronation and supination.

Pronation.	Supination.
Pronator radii teres	Supinator radii brevis
Pronator quadratus	Biceps
Brachio-radialis	Brachio-radialis
Flexor carpi radialis	Extensors of thumb and fingers
Weight of the limb	Weight of the limb

3. Action on the Wrist-Joint.—The movements at the wrist-joint are flexion and extensio abduction and adduction. Flexion and adduction are much more extensive movements th extension and abduction, on account of the form of the wrist-joint. The following muscles pr duce these movements:—

Flexion.	Extension.	Adduction.	Abduction.
Flexor carpi radialis	Extensors of the wrist	Flexor carpi ulnaris	Flexor carpi radialis
Palmaris longus	Extensors of thumb and fingers	Extensor carpi ulnaris	Extensors of wrist
Flexor carpi ulnaris			Extensors of thumb
Long flexors of thumb and fingers			

4. Movements of the Fingers.—Two separate series of movements occur in relation to t articulations of the fingers: flexion and extension (at the metacarpo-phalangeal and int phalangeal joints), and abduction and adduction (only at the metacarpo-phalangeal joints). T movements and the muscles concerned are given in the following tables:—

Flexion.	Extension.
Flexor sublimis digitorum	Extensor communis digitorum
Flexor profundus digitorum	Extensor indicis
Lumbricales (*acting on the metacarpo-*)	Extensor minimi digiti
Interossei (*phalangeal articulations*)	Lumbricales (*acting on the inter-phal-*)
Flexor brevis minimi digiti	Interossei (*angeal articulations*)

Abduction.	Adduction.
Lumbricales Flexor brevis and Opponens minimi digiti (from the inner side of the hand)	
Dorsal interossei (from the middle line of the middle finger)	Palmar interossei (to the middle line of the middle finger)

Flexion is more powerful and complete than extension of the fingers. The flexor profundus gitorum alone acts on the terminal phalanges; the flexor sublimis and flexor profundus together ex the proximal inter-phalangeal joint; and flexion of the metacarpo-phalangeal articulation is fected by these muscles, assisted by the interossei, lumbricales, and flexor brevis minimi digiti. xtension of the phalanges is effected by the united action of the extensors of the digits, the terossei and lumbricales; extension of the fingers at the metacarpo-phalangeal joints is produced ely by the long extensor muscles. *Separate extension of the index finger* only is possible; the ree inner fingers can only be flexed and extended together, on account of the connecting bands ining the extensor tendons together on the back of the hand.

5. **Movements of the Thumb.**—The movements of which the thumb is capable are flexion d extension (occurring at the carpo-metacarpal, metacarpo-phalangeal, and inter-phalangeal ints); abduction and adduction, together with circumduction (occurring at the carpo-metacarpal int).

The muscles and their respective actions are given in the following table:—

Flexion.	Extension.
Opponens pollicis (carpo-metacarpal joint)	Extensor ossis metacarpi pollicis (carpo-metacarpal joint)
Flexor brevis Adductors Abductor (carpo-metacarpal and metacarpo-phalangeal joint)	Extensor brevis pollicis (carpo-metacarpal and metacarpo-phalangeal joint)
Flexor longus pollicis (all joints)	Extensor longus pollicis (all joints)

Adduction.	Abduction.
Adductors of the thumb Flexor brevis Opponens pollicis First dorsal interosseous	Abductor pollicis Extensors of the thumb

Circumduction—a combination of the above muscles.

The characteristic features of the movements of the upper limb are their range and finement. The hand, in addition to its intrinsic powers, can be moved through a ide range and in several planes by the muscles acting on the wrist and radio-ulnar ints; this range is increased by the fore and aft movements at the elbow-joint, and the tensive movements of which the shoulder and clavicular joints are capable. The sult is that the hand can be brought into a position to cover and guard any portion the body. The precision and refinement of movement is made possible by the co-dinate movements of the various muscles acting upon the several joints, so that tions can be performed (as raising the food to the mouth) in which all the articulations of e limb are brought into play; while others (such as writing) are possible by movements the joints of the wrist and fingers along with fixation of the elbow-joint.

THE LOWER LIMB.

FASCIÆ AND MUSCLES OF THE THIGH AND BUTTOCK.

FASCIÆ.

The **superficial fascia** of the thigh and buttock is continuous above with the cia of the abdomen and back, internally with that of the perineum, and below h that of the leg. It presents noticeable features in the buttock and groin.

In the buttock the superficial fascia is of considerable thickness, and is us loaded with fat, whereby it assists in forming the contour of the buttock and fold of the nates.

In the groin it is divisible into *two layers*: a **superficial fatty layer,** contin with a similar layer on the front of the abdominal wall above, and over perineum internally, and a **deeper membranous layer**, which is attached abo the inner half of Poupart's ligament, and to the deep fascia of the thigh just b the outer half of that ligament. Internally it is attached to the pubic arch, below the level of Scarpa's triangle it blends inseparably with the superficial layer. The se tion of these layers of the s ficial fascia i casioned by presence bet them of the fe and inguinal phatic gland internal saph vein and its taries, and small arteries attachment o deeper layer fascia to the arch and Pou ligament cut the superf tissues of the from the peri and the an abdominal and prevents passage dow thigh of fluid collected in the perineum or beneath the fascia of the an abdominal wall.

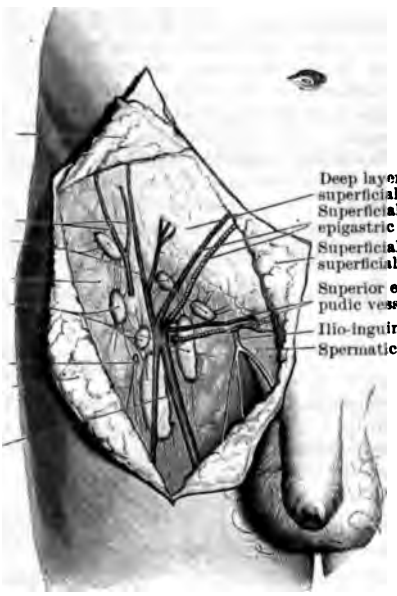

FIG. 273.—THE GROIN. STRUCTURES BETWEEN THE LAYERS OF THE SUPERFICIAL FASCIA.

The **deep fascia** or **fascia lata** forms a tubular investment for the muscle vessels of the thigh and buttock. It is firmly attached above to the iliac cres great sacro-sciatic ligament, the ischium, the pubic arch, the pubic symphysi crest, and Poupart's ligament. Below, in relation to the knee, it is contin with the deep fascia of the leg, gains attachment to the patella, the tuberosit the tibia and the head of the fibula, and forms the lateral ligaments of the pa

On the front of the thigh the deep fascia is thick and strong. It is pi by numerous openings for vessels and nerves, the most important of whi the **saphenous opening** for the internal saphenous vein. A femoral hernia through this opening to reach the front aspect of the anterior abdominal wal is an oval opening of variable size situated just below the inner half of Pou ligament, and immediately in front of the femoral vessels. It is cover the superficial fascia, and by a special layer of fascia, the **cribriform fas** thin perforated lamina, attached to the margins of the opening. The outer of the opening is formed by the margin of the *iliac portion* of the fascia which is attached above to the iliac crest and Poupart's ligament; the edge is formed by the *pubic portion* of the fascia lata, which is continued up behind the femoral sheath, over the adductor longus and pectineus musc the ilio-pectineal line and the capsule of the hip-joint. These two layers fascia lata are continuous at the lower concave margin of the saphenous op forming its **inferior cornu**. As they pass upwards towards the pelvis they c different planes, the iliac portion being in front of the femoral sheath, whi pubic portion of the fascia is behind it. The **superior cornu** of the saphenous op

l in front of the sheath, is derived solely from the iliac portion of the fascia lata. ms a strong triangular band of fascia attached above to the inner half of art's ligament, and is known as the **falciform ligament**. It has an important in directing the course of a femoral hernia upwards on to the abdominal

ternally in relation to the adductor muscles of the thigh the fascia lata ies much thinner. *At the knee* it is associated with the tendons of the vasti es, and forms the **lateral ligaments of the patella**, attached to the borders of atella and to the tuberosities of the tibia. *Externally* it gives rise to the

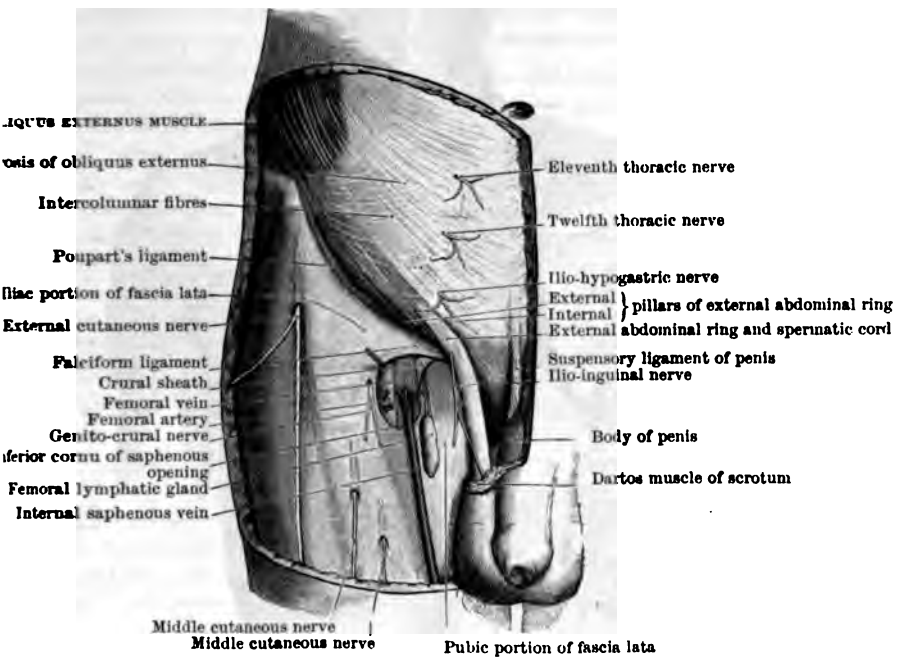

FIG. 274.—THE GROIN—THE STRUCTURES SEEN ON REMOVAL OF THE SUPERFICIAL FASCIA.

ibial band—a broad thick layer of fascia which is attached above to the iliac , and receives the insertions of two muscles in the upper part of the thigh—tensor fasciæ femoris, and part of the gluteus maximus; it is attached below ıe capsule of the knee-joint and the outer tuberosity of the tibia. The fascia ath the tensor fasciæ femoris muscle, continued upwards from the ilio-tibial l, sends a strong band inwards which joins the origin of the rectus femoris and apsule of the hip-joint.

On either side of the thigh above the knee an intermuscular septum is formed; **external intermuscular septum** extends inwards from the ilio-tibial band to the rnal supra-condyloid ridge and linea aspera of the femur, and gives attachment ıe vastus externus and crureus in front, and the short head of the biceps behind. **internal intermuscular septum** is more complex. It is represented by a layer of a which forms separate envelopes for the gracilis and sartorius muscles, and ıe upper and middle thirds of the thigh encloses the adductor muscles. In the lle third of the thigh the fascia is specially thickened by transverse fibres ecting together the adductor muscles and the vastus internus. This sheet of a forms a special aponeurosis beneath the sartorius, which roofs over the ral artery in Hunter's canal. In the lower third of the thigh the intermuscular ım is closely associated with, and is to a large extent represented by, the on of the adductor magnus muscle.

The **fascia lata of the buttock** is thick anteriorly where it covers and gives origin ıe gluteus medius, thinner posteriorly over the gluteus maximus, at the upper er of which it splits to enclose the muscle. It is greatly thickened over the

region of the great trochanter, where it forms the insertion of the **greater pa** the same muscle.

On the **back of the thigh** and over the **popliteal space** the fascia is strengthe by transverse fibres derived from the hamstring muscles. The **popliteal f**

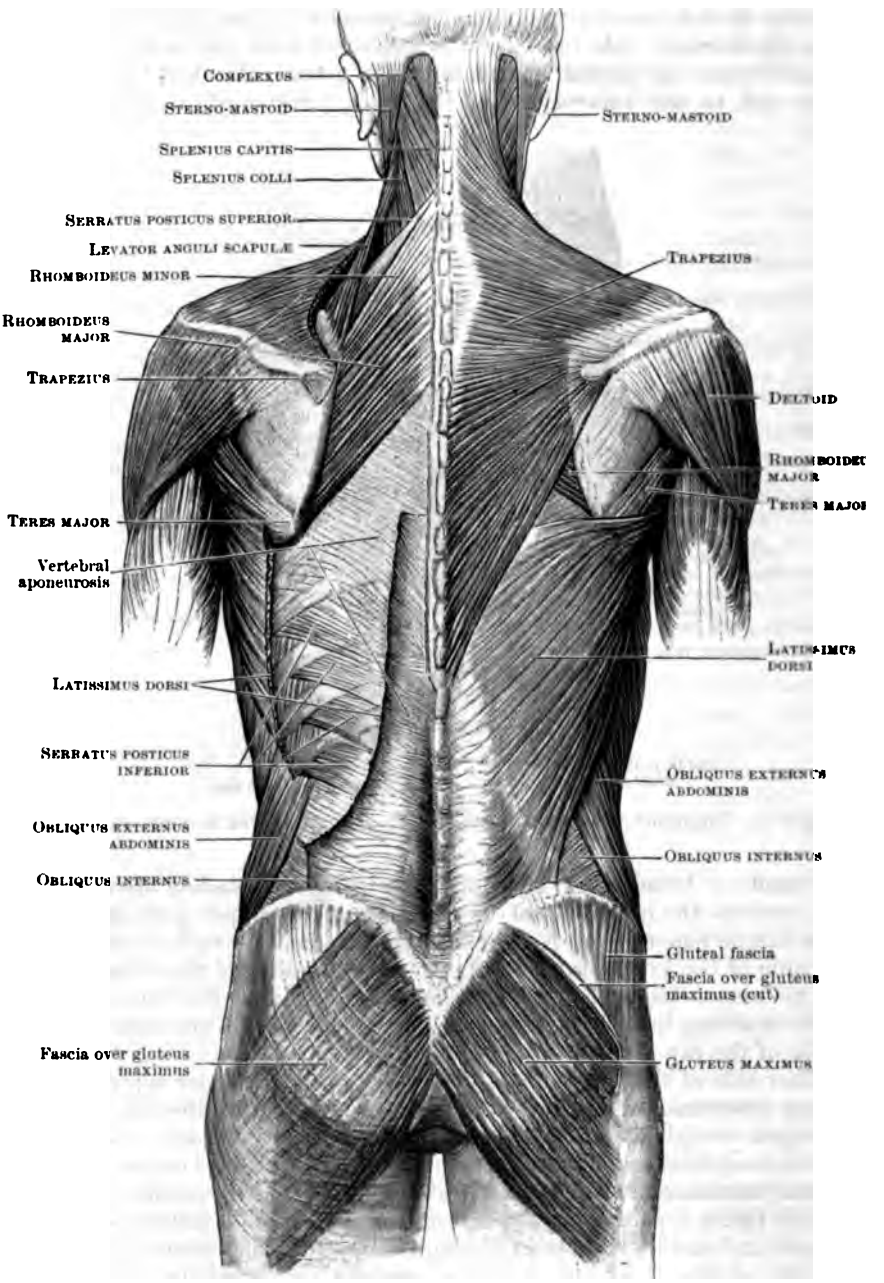

Fig. 275.—Superficial Muscles of the Back.

forming the roof of the popliteal space is specially thick, and is usually pie by the external saphenous vein.

A **femoral hernia** appears in the thigh through the saphenous opening, there passing upwards over Poupart's ligament to the anterior abdominal wall.

Femoral Sheath.—This is a conical membranous investment for the fen vessels, prolonged into Scarpa's triangle beneath Poupart's ligament, and

ius above with the internal fascial lining of the abdominal wall, formed by fascia transversalis in front and the fascia iliaca behind. The sheath is ed into three compartments—an external space for the artery, an inter- ate space for the vein, and an internal channel containing lymphatics, and d the **crural canal**. The wall of this is known as the **crural sheath**. This is the passage through which a femoral hernia enters the thigh. Its upper is the **crural ring**, placed behind Poupart's ligament in front of the origin of ectineus muscle from the pubis; it is bounded internally by Gimbernat's ent, and externally by the femoral vein. In front of it the fascia trans- lis forming the sheath is thickened to form the **deep crural arch**. The part of art's ligament in front of the ring is called the **superficial crural arch**. The epigastric artery separates the crural ring from the internal abdominal ring. crural canal ordinarily contains fat which is continuous above with the extra- oneal tissue. The crural ring is filled by a plug of fat or a lymphatic gland, ituting the **crural septum**.

he crural canal ends behind the saphenous opening, covered by the cribriform ; the falciform ligament crosses over it and conceals its upper portion. The e of a femoral hernia is determined by this band of the fascia lata. The hernia nds through the crural ring, pushing the crural septum before it; it traverses rural canal, and is directed forwards through the saphenous opening. The ior part of the hernia being pressed upon and retarded by the crural arches by the falciform ligament, the posterior part pushes onwards, hooks round the form ligament, and is directed upwards over Poupart's ligament. The cover- of a femoral hernia, in addition to peritoneum and extra-peritoneal tissue al septum), are crural sheath, cribriform fascia, superficial fascia, and skin.

THE MUSCLES ON THE FRONT OF THE THIGH.

The muscles on the front of the thigh include the sartorius, quadriceps extensor, psoas, and pectineus muscles.

The **sartorius**, a long strap-like muscle stretching obliquely across the thigh, es by short tendinous fibres from the anterior superior spine of the ilium and of the notch below it (Fig. 285, p. 369). It passes down the thigh to the r side of the knee, where it is **inserted** by aponeurotic fibres into the inner ace of the shaft of the tibia just below the inner tuberosity, and by its borders fascial expansions which join the capsule of the knee-joint and the fascia of the leg (Fig. 279, p. 363). An expansion from the upper part of the don of insertion is attached along an oblique line, which is directed downwards backwards, above the attachment of the gracilis, to the internal lateral ligament he knee-joint, with which it is connected.

The sartorius is superficial in its whole extent. It is so twisted on itself that he upper third of its length its superficial surface looks forwards, in the lower d inwards, at the side of the knee. It passes diagonally down the thigh, separat- the quadriceps extensor externally from the adductor muscles internally. Its r third forms the outer boundary of Scarpa's triangle: its middle third forms roof of Hunter's canal; and its lower third, in contact with the inner side of the e, is separated from the tendon of the gracilis muscle by the long saphenous ve and a branch of the anastomotic artery. A bursa lies beneath the tendon at insertion. The sartorius conceals in its upper third the external circumflex els and branches of the anterior crural nerve, and it covers the femoral vessels Hunter's canal.

The **quadriceps extensor** (m. quadriceps femoris) lies between the sartorius he one hand and the tensor fascia femoris and ilio-tibial band on the other; composed of four muscles—the rectus femoris, vastus externus, crureus, and us internus.

The **rectus femoris** has a double tendinous **origin**. (1) The *straight head* s from the anterior inferior spine of the ilium (Fig. 282, p. 366); (2) the *ted head* springs from a rough groove on the dorsum ilii just above the est part of the acetabulum (Fig. 285, p. 369). A bursa lies beneath this

head of origin. The two heads, bound together and connected to the cap the hip-joint by a band of fascia derived from the under surface of the fasciæ femoris (ilio-tibial band), give rise to a single tendon which exten

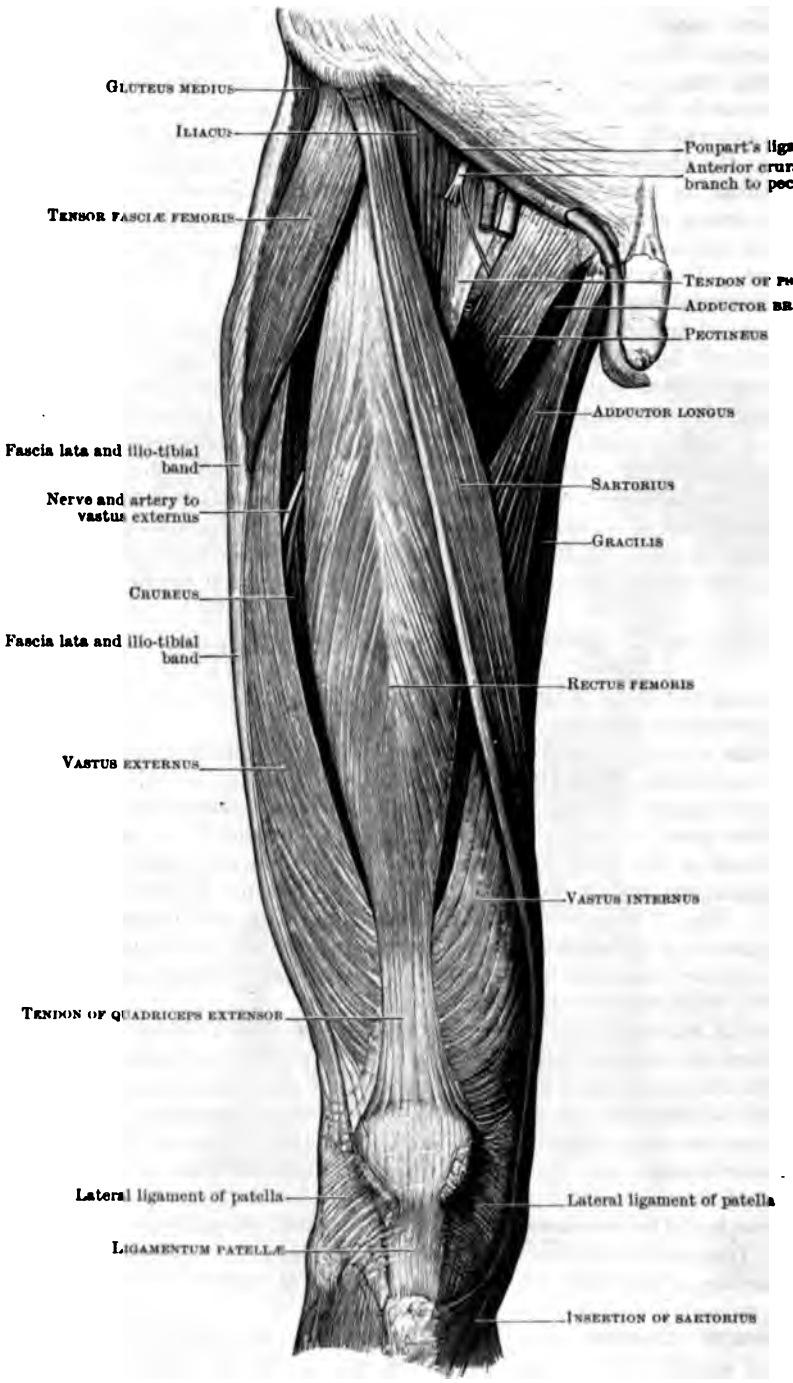

Fig. 276.—The Muscles on the Front of the Thigh.

some distance on the front of the muscle, and from which the muscular fibres The muscular fibres springing from this tendon, and also from a median tendon, present a bipennate arrangement, and end below in a broad tendon passes upwards for some distance along the posterior surface of the muscle.

tendon gradually narrows towards the knee, and spreading out again, is **inserted** into the upper border of the patella. It receives laterally parts of the insertions of the vasti muscles, and on its deep surface is joined by the tendinous insertion of the crureus.

The rectus femoris is superficial except at its origin, which is covered by the glutei, tensor fasciæ femoris, and sartorius muscles. On its inner side lie the iliacus, sartorius, and vastus internus; on its outer side are the tensor fasciæ femoris and vastus externus. It conceals the crureus muscle and branches of the external circumflex artery and anterior crural nerve. A bursa, which communicates with the synovial membrane of the knee-joint, lies beneath its tendon in front of the lower end of the shaft of the femur.

The **vastus externus** (m. vastus lateralis) has an **origin**, partly fleshy, partly membranous, (1) (slightly) from the capsule of the hip-joint, (2) from the tubercle of the femur, (3) from a concave surface on the front of the shaft of the bone internal to the great trochanter, (4) from the lower border of the great trochanter, (5) from the outer margin of the gluteal ridge of the femur and the tendon of the gluteus maximus, (6) from the upper half of the linea aspera, and (7) from the fascia lata and external intermuscular septum (Fig. 277, p. 361).

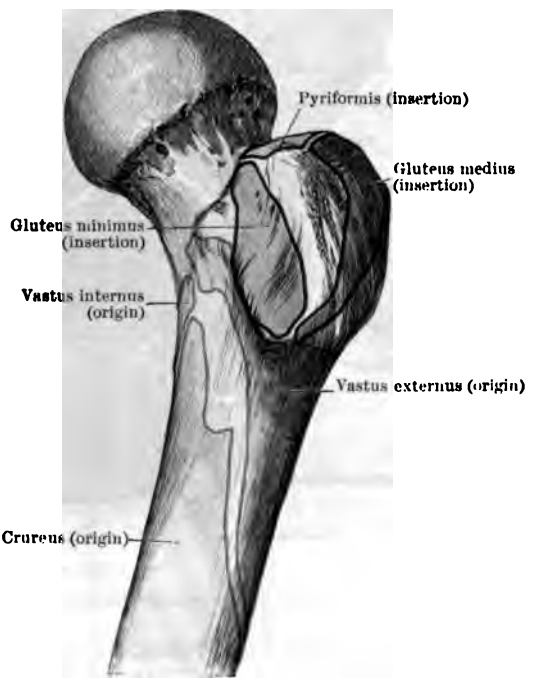

FIG. 277.—MUSCLE-ATTACHMENTS TO THE ANTERIOR SURFACE OF THE UPPER PART OF THE FEMUR.

It forms a thick, broad muscle directed downwards and forwards, and is **inserted** by a broad membranous tendon into (1) the outer border of the tendon of the rectus femoris, (2) the upper and outer border of the patella, and (3) the capsule of the knee-joint, and the external lateral ligament of the patella. The vastus externus is covered superficially by the fascia lata and the ilio-tibial band. A bursa intervenes between it and the membranous insertion of the gluteus maximus: at its inner border is the rectus femoris; and under cover of it, on a deeper plane, is the crureus, which is also to a large extent concealed by the muscle. Between the vastus externus and crureus is the descending branch of the external circumflex artery.

The **vastus internus** (m. vastus medialis) is larger than the vastus externus and has a more extensive **origin**, from (1) the shaft of the femur—from the lower two-thirds or more of the spiral line, the linea aspera, and the upper two-thirds of the line leading from the linea aspera to the internal condyle of the femur; (2) the membranous expansion of the fascia lata which lies beneath the sartorius and forms the roof of Hunter's canal; and (3) the internal intermuscular septum and the tendon of the adductor magnus (Figs. 277, p. 361, and 281, p. 365).

From its origin the muscle is directed downwards and outwards towards the knee; it is **inserted** by a strong aponeurotic tendon into (1) the inner border of the rectus tendon; (2) the upper and inner border of the patella; and (3) the capsule of the knee-joint and the internal lateral ligament of the patella. The vastus internus is superficial except at its origin, which is concealed by the sartorius muscle and femoral vessels. Along its outer side are the rectus and crureus; the muscle conceals the inner side of the shaft of the femur and the crureus, with which it is closely incorporated in its lower two-thirds.

The **crureus muscle** (m. vastus intermedius) **arises** by fleshy fibres (1) from the

upper two-thirds of the shaft of the femur on the anterior and external surfa
(2) from the lower half of the outer lip of the linea aspera and the upper p
of the line leading therefrom to the external condyle, as well as (3) from
corresponding portion of the external intermuscular septum (Fig. 277, p. 361).

For the most part deeply placed, the muscle is directed downwards to
insertion into the deep surface of the tendons of the rectus and vasti muscles
means of fibres which join a membranous expansion on its surface.

The crureus is concealed by the rectus and vasti muscles, and externally,
the lower half of the thigh, by the ilio-tibial band. It is closely adherent to th
vastus externus muscle in the middle third of the thigh; it is inseparable fr
the vastus internus below the upper third. Beneath the crureus is the femu

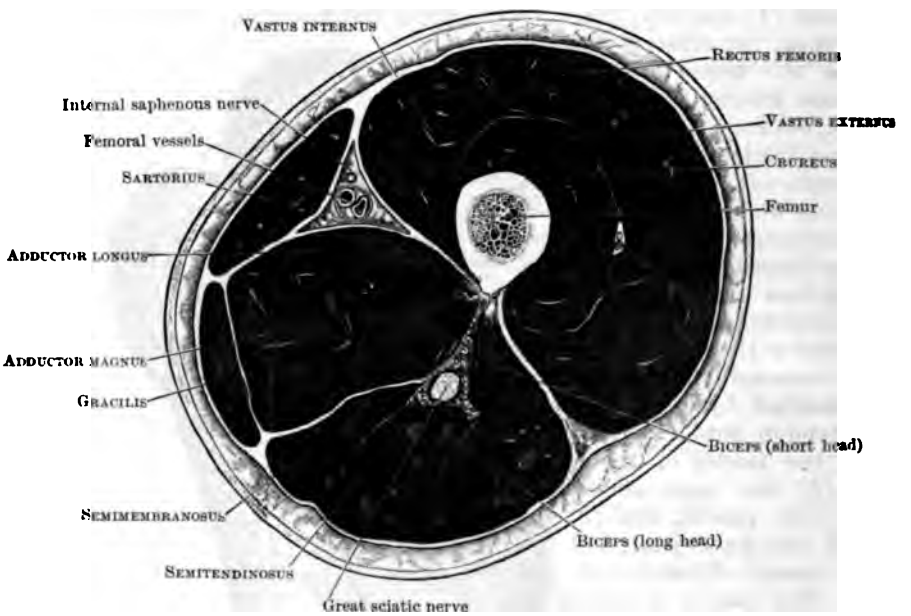

Fig. 278.—Transverse Section of the Thigh (Hunter's Canal).

and in the lower third of the thigh it conceals the subcrureus muscle, a bursa, and the upward prolongation of the synovial membrane of the knee-joint.

The **subcrureus** consists of a number of separate bundles of muscular fibres **arising** beneath the crureus from the lower fourth of the front of the femur, and **inserted** into the synovial membrane of the knee-joint beneath the tendon of the rectus femoris.

The four elements composing the quadriceps extensor muscle have been traced in their convergence to the patella and the lateral ligaments of the patella. Their ultimate **insertion** is into the tibia (Fig. 279, p. 363), by means of the **ligamentum patellæ** and the **lateral ligaments of the patella.** The patella, indeed, is in one sense a sesamoid bone formed in the tendon of the muscle, the ligamentum patellæ being the real tendon of insertion, and the lateral ligaments fascial expansions from its borders. The insertion of the muscle forms the front of the capsule of the knee-joint.

The **ilio-psoas muscle** is a compound muscle, consisting of one or sometimes two elements,—**psoas (magnus and parvus)**, connecting the femur and pelvic girdle to the axial skeleton; and another element, the **iliacus**, extending between the innominate bone and the femur. The muscles chiefly occupy the posterior wall of the abdomen and false pelvis, their insertions only appearing in the thigh below Poupart's ligament.

The **psoas magnus** (m. psoas major) is a large pyriform muscle, which has an extensive **origin** by fleshy fibres from the vertebral column in the lumbar region. It arises (1) from the intervertebral discs above each lumbar vertebra, and from the

argins of the vertebræ—from the lower border of the 12th thoracic
er border of the 5th lumbar vertebra; (2) it arises also from four
arches which pass over the sides of the bodies of the first four
ebræ; and (3) it has an additional origin posteriorly from the transverse
all the lumbar vertebræ. The fibres form a fusiform muscle directed
over the pelvic brim and beneath Poupart's ligament, ending in a
ch is **inserted** into the apex of the lesser trochanter of the femur (Fig.
).

as parvus (m. psoas minor) is often absent (40 per cent). It **arises** by
s from the intervertebral disc between the last thoracic and first lumbar
nd from the contiguous margins of these vertebræ. The muscle is
osed to the anterior surface of the psoas magnus. It forms a slender
, and is **inserted** by a narrow tendon into the middle of the ilio-pectineal
e ilio-pectineal eminence, its margins blending with the fascia covering
agnus.

acus muscle arises by fleshy fibres, mainly from a horseshoe-shaped
nd the margin of the iliac fossa; it has additional origins also from
the sacrum, the anterior sacro-iliac, lumbo-sacral, and ilio-lumbar
nd outside the pelvis, from the upper part of the ilio-femoral band.
shaped muscle, its fibres passing downwards over the hip-joint towards
trochanter of the femur. It is **inserted** by fleshy fibres (1) into the
of the tendon of the psoas magnus; (2) into the concave anterior and
ces of the small trochanter; and (3) into the shaft of the femur below
rochanter for about an inch (Fig. 281, p. 365); and (4) by its most
res into the capsule of the hip-joint. These fibres are often separate,
iliacus minor, or **ilio-capsularis.**

scle occupies the false pelvis and Scarpa's triangle. It forms the back

wall of the false pelvis and is covered anteriorly by the iliac fascia. It is in contact with the cæcum on the right side and the iliac colon on the left si The psoas muscle lies along its inner border, with the anterior crural nerve in interval between them. After passing beneath Poupart's ligament, and over capsule of the hip-joint, the muscle occupies the outer part of the floor of Scar triangle, internal to the sartorius and rectus femoris muscles.

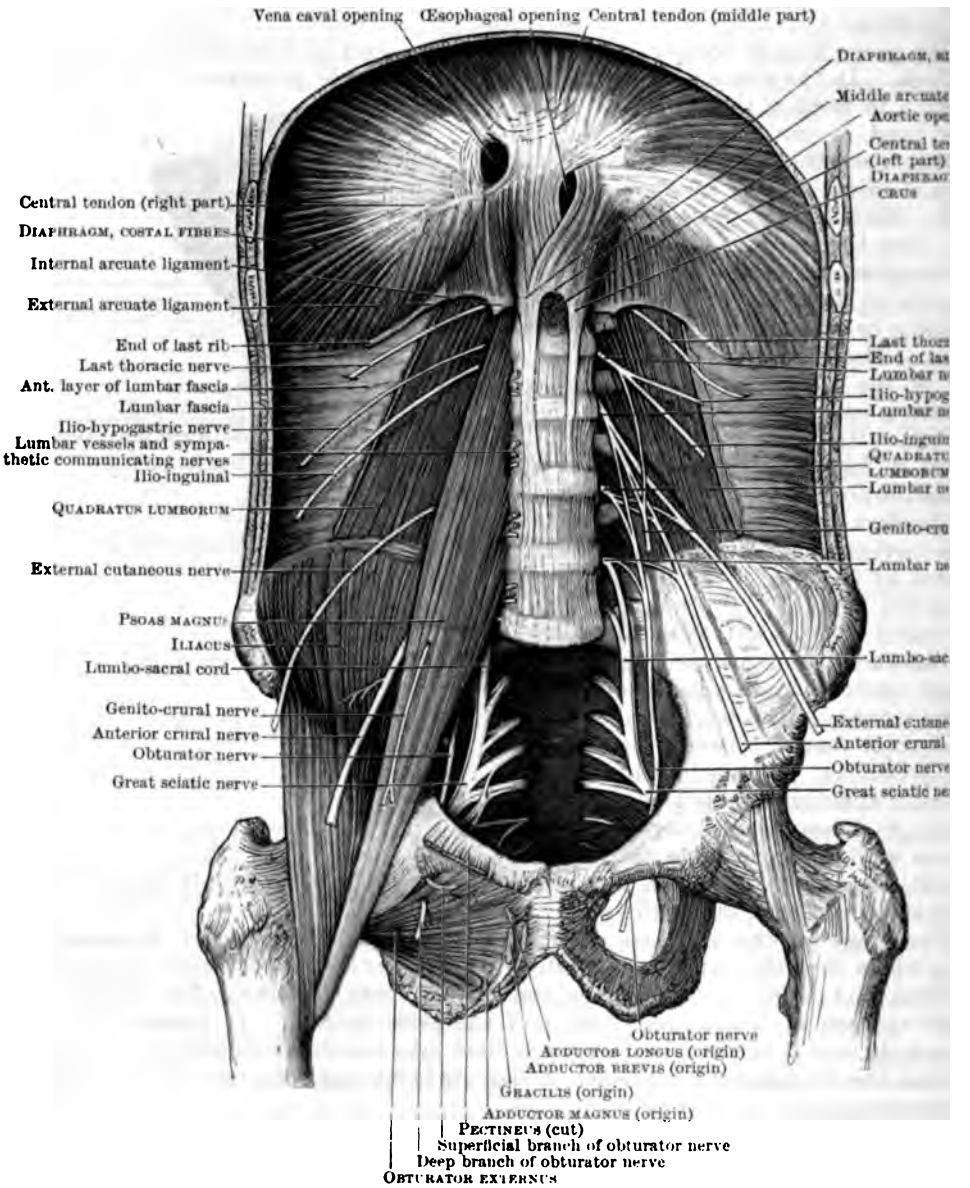

Fig. 280.—View of the Posterior Abdominal Wall, to show the Muscles and the Nerves the Lumbo-Sacral Plexus.

The **pectineus** muscle **arises** by fleshy fibres from the sharp anterior por of the ilio-pectineal line of the pubis, and from the triangular surface of pubic bone in front of this (Fig. 282, p. 366). It also arises from the fem surface of Gimbernat's ligament, and from the pubic portion of the fascia lata w covers it. Forming a broad muscular band, it is directed obliquely downw backwards, and outwards, to be **inserted** by a thin flat tendon about two in in length into the upper half of the pectineal line leading from the back of

all trochanter of the femur towards the linea aspera; its lower attachment ing placed in front of the ertion of the adductor brevis uscle (Fig. 281, p. 365).

The pectineus forms a part the floor of Scarpa's triangle. overed by the pubic portion of e fascia lata, it is partially ncealed by the femoral vessels d the insertion of the ilio-soas. It lies in front of the ubic bone, the obturator ex-rnus and adductor brevis uscles, and the superficial part the obturator nerve. Its ter border is separated from e psoas by the internal cir-mflex vessels. Its inner border in contact above with the dductor longus, but is separated om it below by the deep moral vessels. The muscle ay be occasionally divided nto inner and outer parts, the ormer innervated by the ob-turator, the latter by the anterior rural nerve.

FIG. 281.—MUSCLE-ATTACHMENTS TO THE POSTERIOR ASPECT OF THE UPPER PART OF THE FEMUR.

THE MUSCLES ON THE INNER SIDE OF THE THIGH.

The muscles on the inner side of the thigh include the adductors of the femur—the adductor longus, adductor brevis, and adductor magnus; the gracilis, and the obturator externus.

The **gracilis muscle** is a long flat band placed on the inner side of the thigh and knee. It **arises** by a thin aponeurotic tendon from the lower half of the edge of the symphysis pubis, and for a similar distance from the border of the adjoining part of the pubic arch (Fig. 282, p. 366). Its flattened fleshy belly passes down on the inner side of the thigh to the knee, where it ends in a tendon, which expands to be **inserted** into the inner side of the shaft of the tibia just below the inner tuberosity, behind the sartorius and above and in front of the semitendinosus (Fig. 279, p. 363). It is separated from the sartorius tendon by a bursa, and beneath its tendon is another bursa common to it and the semitendinosus.

The gracilis is superficial in its whole extent, except at its insertion which is concealed by the insertion of the sartorius muscle. Its deep surface covers the borders of the adductor longus and adductor magnus muscles, as well as the superficial part of the obturator nerve. At the inner side of the knee it lies between the sartorius and semitendinosus.

The **adductor longus** is a triangular muscle **arising** by a rounded tendon from the anterior surface of the body of the pubis in the angle between the crest and symphysis (Fig. 282, p. 366). Extending downwards and outwards, it is **inserted** into the middle two-fourths of the inner lip of the linea aspera in front of the adductor magnus. Lying in the same plane as the pectineus, the adductor longus is in contact with that muscle near its origin, but is separated from it below by an interval through which the deep femoral vessels pass. Its inner border is in contact with the gracilis and sartorius muscles. Its anterior surface forms part of the floor of Scarpa's triangle above, part of the floor of Hunter's canal below. It is covered near its insertion by the sartorius and the femoral vessels, and it is connected to

the origin of the vastus internus by an aponeurotic expansion of **fascia bene** the sartorius, forming the roof of Hunter's canal. Its posterior **surface is** relation with the adductor brevis and the adductor magnus **muscles, the d** femoral vessels, and the superficial part of the obturator nerve. **The addu** longus may be double, or more or less fused with the pectineus.

The **adductor brevis** is a large muscle which **arises** by fleshy **and sh** tendinous fibres from an elongated oval surface on the front of **the body** upper part of the descending ramus of the pubis, surrounded by the **other mus** of this group (Fig. 282, p. 366). Directed downwards and outwards, **the mu** expands, to be **inserted** by a short aponeurotic tendon, behind the **insertion of t** pectineus, into the lower two-thirds of the line leading from the small **trochanter**

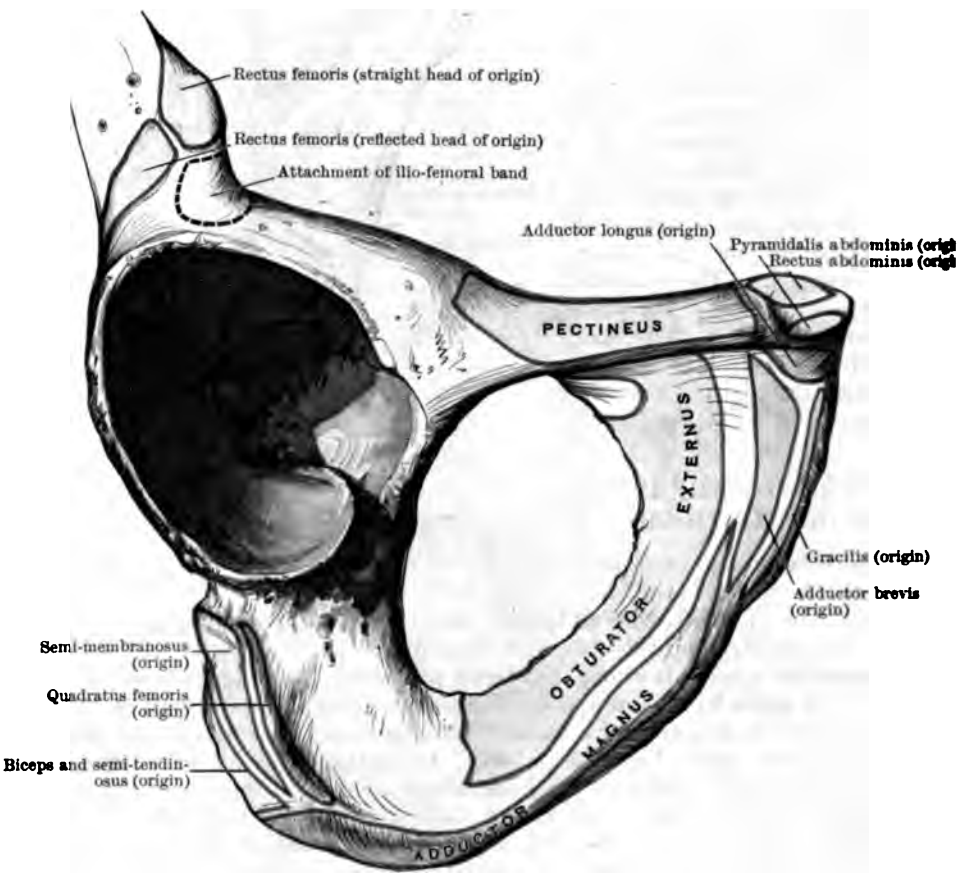

FIG. 282.—MUSCLE-ATTACHMENTS TO THE OUTER SURFACE OF THE PUBIS AND ISCHIUM.

the femur to the linea aspera, and to the upper fourth of the linea aspera itse (Fig. 286, p. 370).

The adductor brevis is the central muscle of the adductor group. It is almo wholly concealed by the pectineus and adductor longus. It rests upon th adductor magnus; at its upper border is the obturator externus, separated fro it by the internal circumflex vessels; at its lower border is the adductor longu separated by the deep femoral vessels. It separates the superficial and deep par of the obturator nerve in their course down the thigh.

The **adductor magnus**, the largest of the adductor group, is a roughly tr angular muscle **arising** mainly by fleshy fibres by a curved origin from the low part of the outer border and a large portion of the adjoining inferior surface of th ischial tuberosity, from the edge of the ischial ramus, and from the anterior surfa of the descending ramus of the pubis, its most anterior fibres arising between th obturator externus and adductor brevis (Figs. 282, p. 366, and 285, p. 369

upper fibres are directed horizontally outwards from the pubis towards the upper part of the femur; the lowest fibres are directed downwards from the ischial tuberosity to the internal condyle of the femur; while the intermediate fibres radiate obliquely outwards and downwards. The muscle is **inserted** by tendinous fibres (1) into the space below the insertion of the quadratus femoris, above the linea aspera; (2) into the whole length of the linea aspera; (3) into the internal supracondyloid ridge of the femur; (4) into the adductor tubercle on the internal condyle of the femur; and (5) into the internal intermuscular septum (Fig. 286, p. 370). The part of the muscle attached to the space above the linea aspera is often separated from the rest as the **adductor minimus**. The attachment of the muscle into the supracondyloid ridge is interrupted for the passage of the

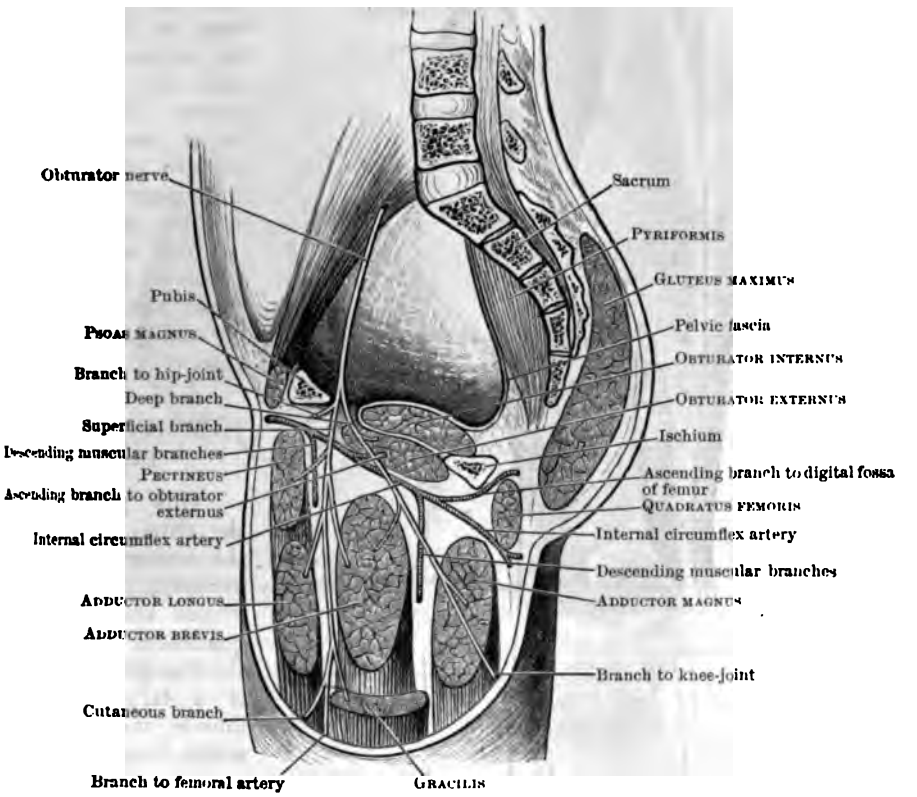

Fig. 283.—Scheme of the Course and Distribution of the Obturator Nerve.

femoral vessels to the popliteal space. The attachment to the internal condyle is by means of a strong tendon which receives the fibres arising from the ischium (the part of the muscle associated with the hamstring group). This tendon is closely connected with the internal lateral ligament of the knee-joint.

The adductor magnus intervenes between the other adductor muscles in front and the hamstring muscles behind. It is concealed anteriorly by the pectineus, adductor brevis, adductor longus, and sartorius. The deep femoral artery lies on it above. It forms the floor of Hunter's canal below, where the femoral vessels lie upon it. The hamstring muscles and great sciatic nerve are behind the adductor magnus; the obturator externus and quadratus femoris are at its upper border; and along its inner border are the gracilis and sartorius muscles.

The **obturator externus** is placed deeply under cover of the previous muscles. It is a fan-shaped muscle lying horizontally in the angle between the hip bone and the neck of the femur. It **arises** from the outer surface of the pubis and ischium, which form the inferior half of the margin of the thyroid foramen, and from the corresponding portion of the outer surface of the obturator membrane (Figs. 282, p. 366, and 285, p. 369). Its fibres converge towards the great trochanter, and

end in a stout tendon which, after passing below and behind the hip-joint, is i into the digital f the great trochante 286, p. 370, and 289, The inferior surf the muscle is in with the pectine ductor brevis, an ductor magnus n separated from th the internal circ vessels. The super face is in relati the obturator me and the neck femur. The tend below and behin capsule of the hi and near its in appears in the (under cover o gluteus maximus tween the inferior lus and quadratus muscles.

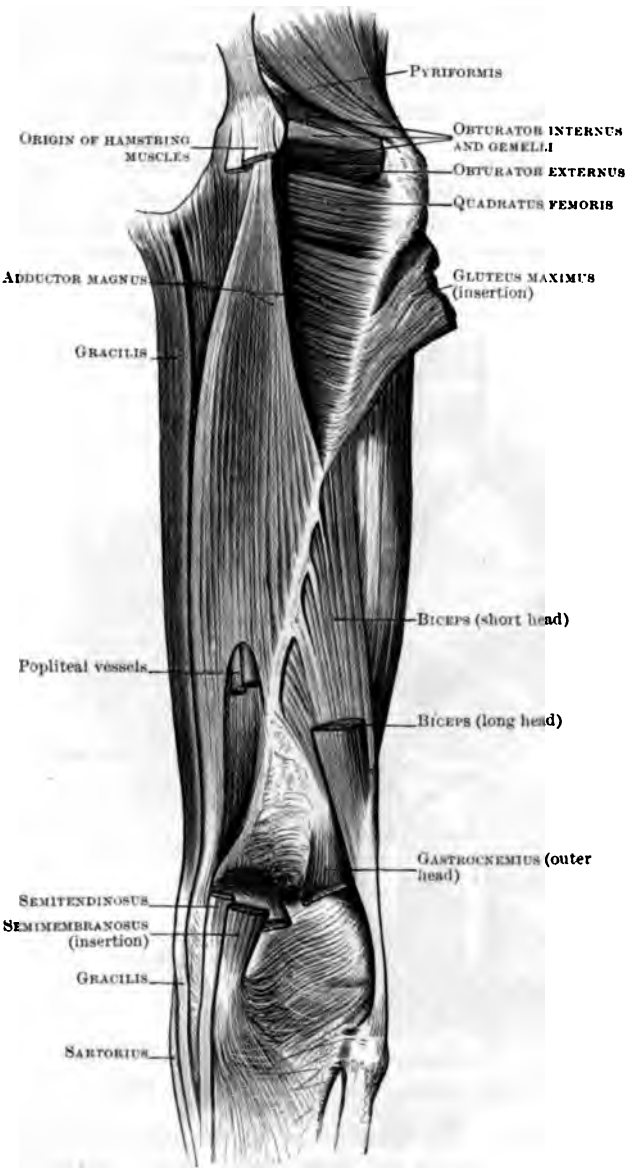

Fig. 284.—The Posterior Surface of the Thigh (superficial muscles removed).

THE MUSCLES O BUTTOCK.

This group i the three glutei the tensor fasciæ pyriformis, obtura ternus and gemel quadratus femoris.

The **gluteus ma** is a large quadr muscle, with a cre **origin**, from (1) a po the area on the dor above the superior line (Fig. 285, p. 36 the tendon of the spinæ; (3) the p surface of the sacr coccyx (Fig. 3 396); and (4) the posterior surface of the great sacro-sciatic ligament fibres which form its upper and outer border take origin directly fr fascia lata which envelopes the muscle. The muscle forms a large mass, whose fibres are directed obliquely outwards over the buttock, i by the fascia lata, and are **inserted** by short tendinous fibres, partly into th lata over the great trochanter of the femur (joining the ilio-tibial ban partly into the gluteal ridge (Fig. 286, p. 370). The fascia lata recei insertion of the whole of the superficial fibres of the muscle and the upp of the deep fibres. The lower half of the deep portion of the muscle is inse the most part into the gluteal ridge; but the lowest fibres of all are insert fascia lata, and are thereby connected with the external intermuscular sept the origin of the short head of the biceps.

The gluteus maximus is the coarsest and heaviest muscle in the body.

ight it helps to form the fold of the nates. It is superficial in its whole extent. e gluteus medius is visible at its upper border, covered by the fascia lata; at its ver border the hamstring muscles and great sciatic nerve appear on their way wn the thigh. The muscle conceals the bones from which it arises, along with e great sciatic ligament, the ischial tuberosity, and the great trochanter of the nur. It also conceals the gluteus medius and pyriformis, with a branch of the iteal artery between them; the obturator internus and gemelli, with the sciatic ssels and nerves, the pudic vessels and nerve, and the muscular branches of the ral plexus above them, and the obturator externus and a branch of the internal cumflex artery below them; the quadratus femoris and upper part of the ductor magnus muscles, with the internal circumflex vessels between them. It vers the origins of the hamstring muscles, and by its insertion into the fascia lata,

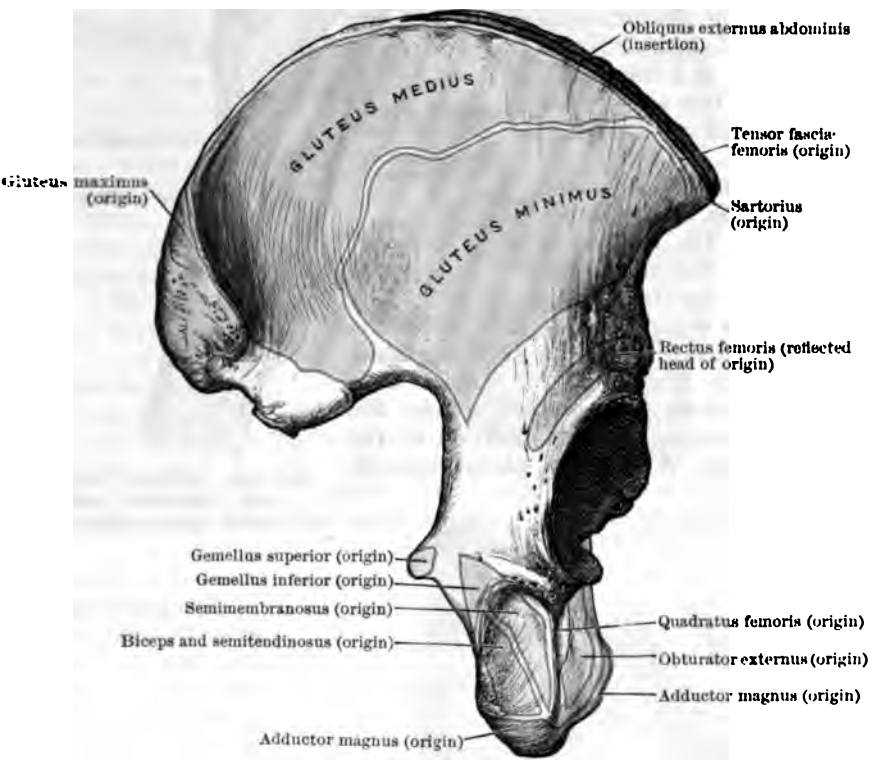

FIG. 285.—MUSCLE-ATTACHMENTS TO THE DORSUM ILII AND TUBER ISCHII.

the vastus externus. The first perforating artery pierces the attachment of the muscle to the gluteal ridge. Three bursæ are beneath it: one (not always present) over the tuberosity of the ischium, a second over the outer side of the great trochanter, and a third over the vastus externus. The fibres of the gluteus maximus arising from the coccyx may form a separate muscle (**agitator caudæ**).

The **tensor fasciæ femoris** (m. tensor fasciæ latæ), lying on the same plane as he gluteus maximus, **arises** from the iliac crest and the dorsum ilii just external to he anterior superior spine, and from the fascia covering its outer surface (Fig. 85, p. 369). Invested like the gluteus maximus by the fascia lata, it is **inserted** bout the level of the great trochanter of the femur into the fascia, which forms the **lio-tibial band** (p. 357).

The tensor fasciæ femoris muscle is superficially placed, and is enclosed in a trong investment of the fascia lata, the deeper layer of which is prolonged up to join he tendon of the rectus femoris and the capsule of the hip-joint. The muscle is laced along the anterior borders of the gluteus medius and gluteus minimus, and onceals branches of the gluteal and external circumflex vessels and the termination f the superior gluteal nerve. The sartorius muscle is adjacent to it anteriorly at

its origin, and is separated from it below by the rectus femoris.

The **gluteus medius arises** by fleshy and tendinous fibres (1) from the dorsum ilii, between the iliac crest and the superior curved line above and the middle curved line below (Fig. 285, p. 369), and (2) from the strong fascia lata covering its surface anteriorly. It is a fan-shaped muscle, its fibres converging to the great trochanter, to be **inserted** by a strong, short tendon into the postero-superior angle of the trochanter, and into a well-marked diagonal line on its outer surface (Figs. 286, p. 370, 277, p. 361, and 289, p. 371).

The muscle is covered along its anterior border by the tensor fasciæ femoris. Its surface is covered over by the fascia lata and the gluteus maximus. Its inferior border is separated from the pyriformis muscle by the superficial branch of the gluteal artery. Its deep surface is in contact with the gluteus minimus, the gluteal vessels, the superior gluteal nerve, and the insertion of the pyriformis muscle. A bursa is placed beneath the tendon at its ins

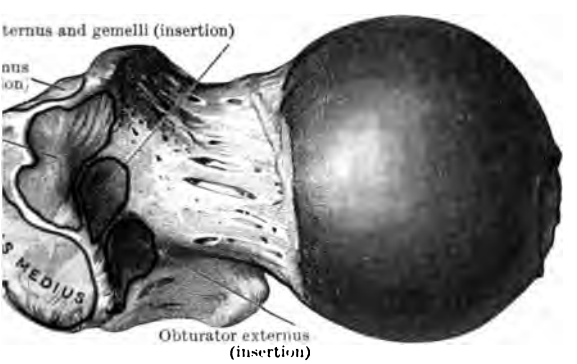
obturator internus (Figs. 286, p. 370, 277, p. 361, and 289, p. 371).

riformis, besides appearing in the buttock, lines the posterior wall of the the pelvis it lies behind the rectum, covered by a thin layer of the lvic fascia. In the buttock it is covered by the gluteus maximus, and at its insertion by the gluteus medius, and it lies upon the ilium and the capsule of the hip-joint. At its upper border are the gluteus medius and gluteus minimus, separated by the superior gluteal nerve and the gluteal artery; its lower border is separated from the gemelli and obturator internus by an interval in which the sciatic and pudic l the nerves of the sacral plexus appear. The anterior fibres of the y be separated.



uscle-Attachments to the Upper Aspect of the Great Trochanter of the Femur.

turator internus arises by fleshy fibres on the pelvic aspect of the hip om the whole of the margin of the thyroid foramen (except the obturator a portion posteriorly opposite the small sciatic notch); (2) from the the obturator membrane; (3) from the whole of the pelvic surface of

the hip bone behind and above the thyroid foramen; and (4) slightly fro parietal pelvic fascia covering it internally. It is a fan-shaped muscle, a fibres converging to the lesser sacro-sciatic foramen, give rise to several te which hook round the margin of the foramen (a bursa intervening), and traversing the buttock, unite together to be **inserted** into a facet on the surface of the great trochanter of the femur above the digital fossa (Figs. 2 370, and 289, p. 371).

In the pelvis the muscle occupies the lateral wall, covered by the pa (obturator) layer of pelvic fascia, which separates it from the pelvic cavity and the ischio-rectal fossa below. It is separated from the contents of the above by the peritoneum and extra-peritoneal fat, below by the fat in the rectal fossa. The internal pudic vessels and nerve cross it in the outer wall fossa in a special sheath of the fascia. In the buttock the tendon is embra the gemelli muscles which are attached to its upper and lower margins. The is crossed by the sciatic vessels and nerves, and lies against the upper and bac of the capsule of the hip-joint.

The **gemelli muscles** form accessory portions of the obturator internus. are two in number, **superior** and **inferior**, and are wholly composed of fleshy fi

The **superior gemellus arises** from the gluteal surface of the ischial spin from the upper part of the margin of the lesser sciatic notch (Fig. 285, p. It is **inserted** into the upper margin and superficial surface of the tendon obturator internus muscle.

The **gemellus inferior arises** from the upper part of the gluteal surface ischial tuberosity and the lower part of the margin of the lesser sciatic (Fig. 285, p. 369). It is **inserted** into the lower margin and superficial of the tendon of the obturator internus.

The **quadratus femoris arises** from the outer margin of the ischial tube (Figs. 282, p. 366, and 285, p. 369), and is **inserted** into the quadrate tu and quadrate line of the femur (Fig. 286, p. 370). The muscle is placed b the gluteus maximus, and is crossed by the sciatic vessels and nerves. Its is concealed by the hamstring muscles. Its deep surface is in contact wit obturator externus muscle and the small trochanter of the femur, a bursa vening. Its upper border is separated from the inferior gemellus by an in containing the tendon of the obturator externus and the ascending branch internal circumflex artery. Its lower border is separated from the upper m of the adductor magnus by the internal circumflex vessels. The muscle infrequently fused with the adductor magnus.

THE MUSCLES ON THE BACK OF THE THIGH.

The Hamstring Muscles.

The muscles comprised in this series include the biceps, semitendinosu semimembranosus. A part of the adductor magnus, already described, also b morphologically to this group.

The **biceps flexor cruris** (m. biceps femoris) has a double **origin**. (1) *It head* arises by means of a tendon, in common with the semitendinosus, fro lower and inner facet upon the tuberosity of the ischium (Figs. 282, p. 36 285, p. 369) and from the great sacro-sciatic ligament. This head, united distance of two to three inches with the semitendinosus, forms a separate mass, which extends to the lower third of the thigh, to end in a tendon join the short head of the muscle. (2) *The short head* arises separately by flesh tendinous fibres (1) from the whole length of the outer lip of the linea aspe the upper two-thirds of the external supra-condyloid ridge of the femur, a from the external intermuscular septum for a corresponding extent. The limit of its origin is sometimes blended with the insertion of the lowest fi the gluteus maximus. The fibres of the short head, directed downwards, joi tendon of the long head, and the muscle is **inserted** (1) into the head

fibula by a strong tendon, which is split into two parts by the long external lateral ligament of the knee-joint; (2) by a slip attached to the outer tuberosity of the tibia; and (3) along its posterior border by a fascial expansion which connects the tendon with the popliteal fascia.

The long head of the biceps is concealed at its origin by the gluteus maximus muscle. In the lower two-thirds of the thigh it is superficially placed, with the semitendinosus and semimembranosus on its inner side. It conceals the great sciatic nerve, the origins of the semimembranosus and quadratus femoris, the adductor magnus, and the short head of the muscle. The united heads assist in

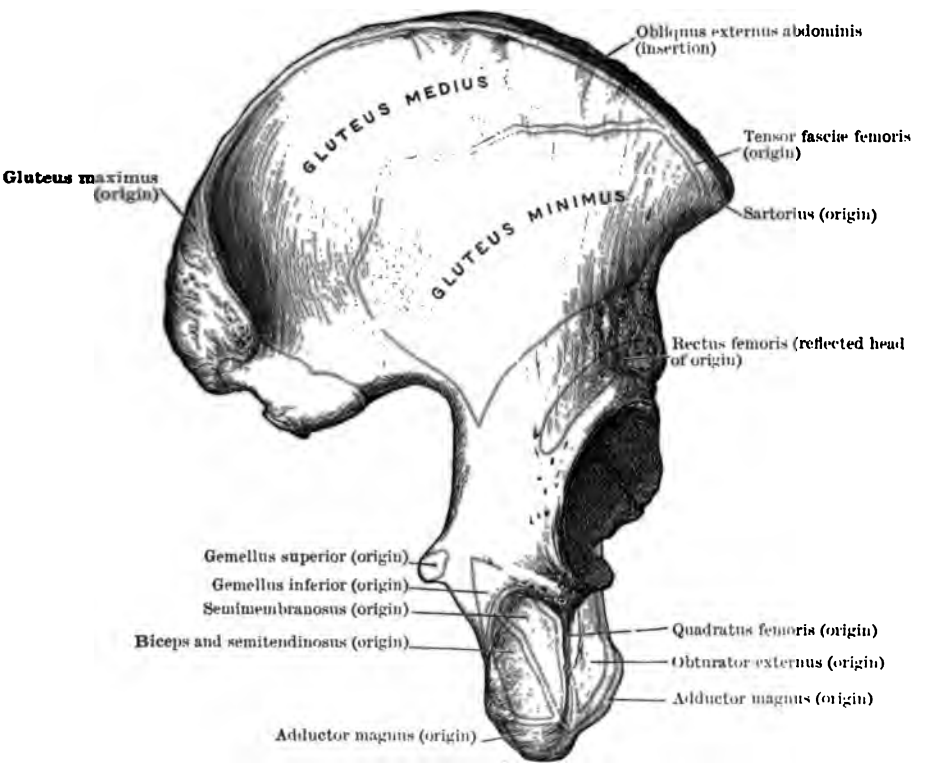


FIG. 290.—MUSCLE-ATTACHMENTS TO THE DORSUM ILII AND TUBER ISCHII.

forming the outer boundary of the popliteal space, and partially conceal the outer head of the gastrocnemius.

The short head may be absent: there may be an additional origin from the ischium or femur; and the long head may send a slip to the gastrocnemius or tendo Achillis (**tensor fasciæ suralis**).

The **semitendinosus arises**, in common with the long head of the biceps, from the lower and inner facet upon the ischial tuberosity (Fig. 285, p. 369). Separating from the common tendon after a course of two or three inches, the muscle forms a long, narrow band which becomes tendinous in the middle third of the thigh. Passing over the inner side of the knee it spreads out and becomes membranous, and is **inserted** (1) into the inner side of the shaft of the tibia just below the internal tuberosity, below the gracilis and behind the sartorius (Fig. 292, p. 374), and (2) into the fascia lata of the leg. A bursa separates it from the sartorius in front, and another, common to it and the gracilis, lies beneath its insertion.

The origin of the muscle is concealed by the gluteus maximus. In the back of the thigh it is superficial to the semimembranosus; and at the inner side of the knee the tendon lies behind that of the gracilis, and also behind the sartorius. It forms one of the inner boundaries of the popliteal space. The belly of the muscle is marked by an oblique septal *tendinous intersection* about its middle.

The **semimembranosus arises** by a tendon from the upper and outer fa the ischial tuberosity (Figs. 282, p. 366, and 285, p. 369). In the upper of the thigh the tendon gives to a rounded fleshy belly, v becoming tendinous at the b the knee, is **inserted** mainly the horizontal groove on the of the inner tuberosity o tibia, and into a triangular below the hinder end of the g and above the insertion o popliteus (Figs. 292, p. 37- 299, p. 383). A bursa lies b the tendon at its insertion. three *additional membrano sertions*: (1) a fascial band e downwards and inwards to jo posterior border of the in lateral ligament of the knee (2) another fascial band e downwards and outwards, the fascia covering the po

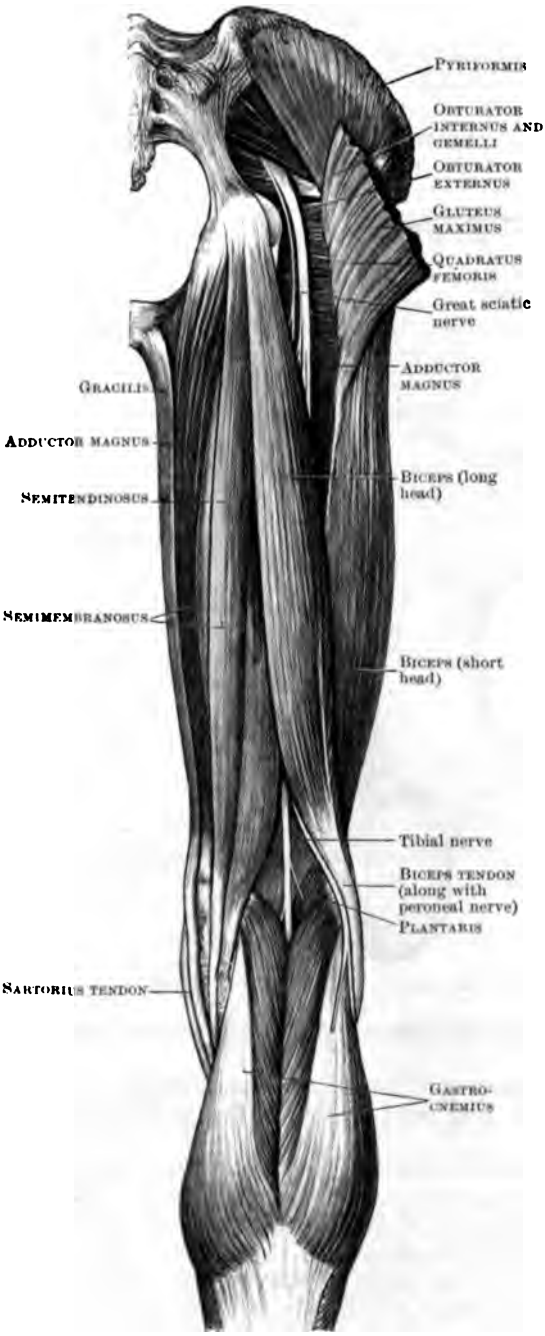

Fig. 291.—The Muscles on the Back of the Thigh.

muscle (popliteus fascia), and is attached to the oblique line of the tibia (3) a third strong band extends upwards and outwards to the back of the ex condyle of the femur, forming the posterior ligament of the knee-joint.

The tendon of origin of the semimembranosus is concealed by the g maximus, and immediately beyond the ischium it is grooved by the common of the long head of the biceps and semitendinosus. In the back of the thig

ed by the semitendinosus, and lies upon the adductor magnus and great ic nerve. It forms part of the inner boundary of the popliteal space, and als the popliteal vessels. Its tendon passes over the inner head of the ocnemius on its way to its insertion.

Nerve-Supply of the Muscles of the Thigh and Buttock.

2. Movements of the Pelvis on the Thigh.—It is to be noted that the several mo tabulated above refer to the movements of the femur at the hip-joint. The contractio same groups of muscles produces similar movements of the pelvis on the femur, exemp the various changes in the attitude of the pelvis in relation to the thigh and the v column, which occur in locomotion.

3. Movements at the Knee-Joint.—The movements at the knee-joint are mainly and extension. Flexion is much more powerful than extension. There is also a limited of rotation of the tibia. The movements are produced by certain of the muscles describe associated with certain of the muscles of the leg.

THE FASCIÆ AND MUSCLES OF THE LEG AND FOOT.

FASCIÆ.

The **superficial fascia** of the leg presents no special features except sole, where it is greatly thickened by pads of fat, particularly under the tub of the os calcis, and under the balls of the toes. It is closely adherent plantar fascia, especially at the roots of the toes.

The **deep fascia** has numerous important attachments about the Posteriorly it forms the popliteal fascia, and is joined by expansions fr tendons of the sartorius, gracilis, semitendinosus, and biceps muscles. In f the knee it is attached to the patella, the ligamentum patellæ, and the tub

bia; laterally it is connected to the tuberosities of the tibia and the head of ɔula, and forms the **lateral patellar ligaments**, broad fascial bands which pass ely from the sides of the patella to the tuberosities of the tibia, and are joined res of the vasti muscles. Passing down the leg, the fascia blends over the surface of the tibia with the periosteum of the bone. It extends round ıter side of the leg from the anterior to the internal border of the tibia, ıg together and giving origin to the muscles, and gaining an attachment to wer part of the shaft of the fibula. **Two septa** pass from its deep surface; ɛptum, attached to the anterior border of the fibula, encloses the musculo- ɛous nerve, and separates the extensor from the peronei muscles. The other n is attached to the posterior border of the fibula, and separates the peronei the flexor muscles. From the last-named septum another extends across the ɔf the leg, forms a partition between the superficial and deep flexor muscles, ncloses the posterior tibial vessels and nerves. It gives rise to a subordinate n attached to the vertical line of the tibia and the oblique line of the fibula, separate the lis posticus e from the s of the toes her side.

t the ankle eep fascia is gthened by onal trans- fibres; it is hed to the oli and the os , and gives ɔ the **annular nts.**

he **internal lar ligament** hes between nternal mal- ıs and the osity of the lcis. While ɔontinuous at

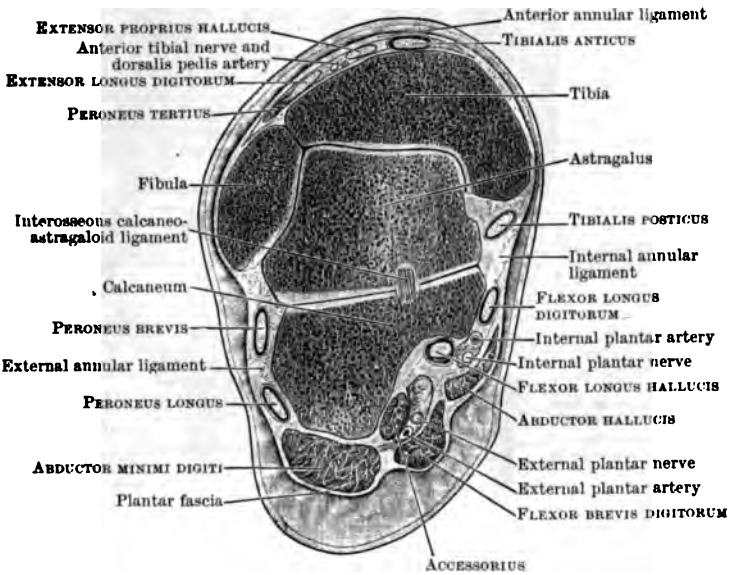

Fig. 293.—Coronal Section through the left Ankle-Joint, Astragalus, and Calcaneum.

ɔper border with the general investment of the deep fascia of the leg, it is y formed by the septal layer covering the deep muscles on the back of the It sometimes gives insertion to the plantaris muscle. It is continuous below the plantar fascia, and gives origin to the abductor hallucis muscle. It is ɛd by the calcanean vessels and nerve. Along with the posterior tibial vessels ıerve, the tendons of the tibialis posticus, flexor longus digitorum, and flexor s hallucis, pass beneath it, each enclosed in a separate synovial sheath.

he **external annular ligament**, much smaller, is a thickened band of the fascia stretching between the external malleolus and the os calcis. It binds the tendons of the peronei, which occupy a space beneath the ligament, lined single synovial membrane.

he **anterior annular ligament** is in two parts. An **upper band**, broad and ined at its upper and lower borders, stretches across the front of the ankle ɛen the two malleoli. This band binds down to the lower end of the tibia ɛndons of the tibialis anticus and extensor muscles of the toes. One synovial h is found beneath it, surrounding the tendon of the tibialis anticus.

n the dorsum of the foot, where the general covering of deep fascia is much er, a special well-defined band stretches over the extensor tendons. This **band** of the anterior annular ligament (fundiform or lambdoid ligament) has achment externally to the outer border of the greater process of the os calcis. ides into two bands as it passes inwards over the dorsum of the foot—an

upper part, which joins the upper ligament and is attached to the internal malleol and a *lower part*, which passes across the dorsum of the foot, and joins the fascia the sole at its inner border. Beneath this ligament are three special compartme with separate synovial sacs, one for the tibialis anticus tendon, a second for t of the extensor proprius hallucis, and a third for the extensor longus digitor and peroneus tertius tendons. There are occasionally other additional bands the deep fascia passing like the straps of a sandal across the dorsum of the foot.

The **plantar fascia** is of great importance. In the centre of the sole it form a thick triangular band, attached posteriorly to the tuberosity of the os calcis. I spreads out anteriorly and separates into *five slips*, which are directed forwards t the bases of the toes. These slips as they separate are joined together by ill-defin bands of transverse fibres, which constitute the **superficial transverse metatars ligament**. The slip for each toe joins the tissue of the web of the toe and i continuous with the digit sheath. It splits to form band of fibres directed forwar on each side of the toe to attached to the sides of t metatarso-phalangeal articul tion and the base of the fir phalanx.

Calcaneo-metatarsal ligament

FIG. 294.—THE PLANTAR FASCIA AND PLANTAR CUTANEOUS NERVES.

This central portion of t plantar fascia assists in pr serving the arch of the foot, b drawing the toes and the calcis together.

On each side it is continuo with a much thinner lay which covers the lateral muscl of the sole, and joins the fasc of the dorsum of the foot each border. It also gives ri to intermuscular septa, whic pass upwards on each side the flexor brevis digitoru enclosing that muscle in separate sheath, and givi investments on either side the abductor muscles of t great and little toes. At t outer border of the foot the **calcaneo-metatarsal ligament**, a thickened band of t fascia, connects the tuberosity of the os calcis with the base of the fifth metatar bone.

The **digital sheaths**, though smaller, are the same in arrangement as those the fingers. **Vaginal ligaments** are present in relation to the first and sec phalanges.

THE MUSCLES OF THE LEG AND FOOT.

The muscles of the leg and foot are divisible into three series: (1) the exten muscles on the front of the leg and dorsum of the foot; (2) the peronei on outer side of the leg; and (3) the flexor muscles on the back of the leg and in sole of the foot.

THE MUSCLES ON THE FRONT OF THE LEG AND DORSUM OF THE FOOT.

The muscles on the front of the leg and dorsum of the foot include two grou (1) on the front of the leg, the tibialis anticus, long extensors of the toes peroneus tertius; and (2) on the dorsum of the foot, the extensor brevis digitor

The **tibialis anticus** (m. tibialis anterior) **arises** by fleshy fibres from the ou

ity and the upper two-thirds of the outer surface of the shaft of the tibia, ıe interosseous membrane, from the fascia over it, and from an inter- ır septum externally. The muscle ends in a strong tendon which passes e dorsum of the foot, to be **inserted** into a facet on the anterior and inferior the inner surface of the internal cuneiform and the adjacent inner side of : of the first metatarsal bone (Fig. 295, p. 379).
muscle is superficially placed along the outer side and front of the tibia,

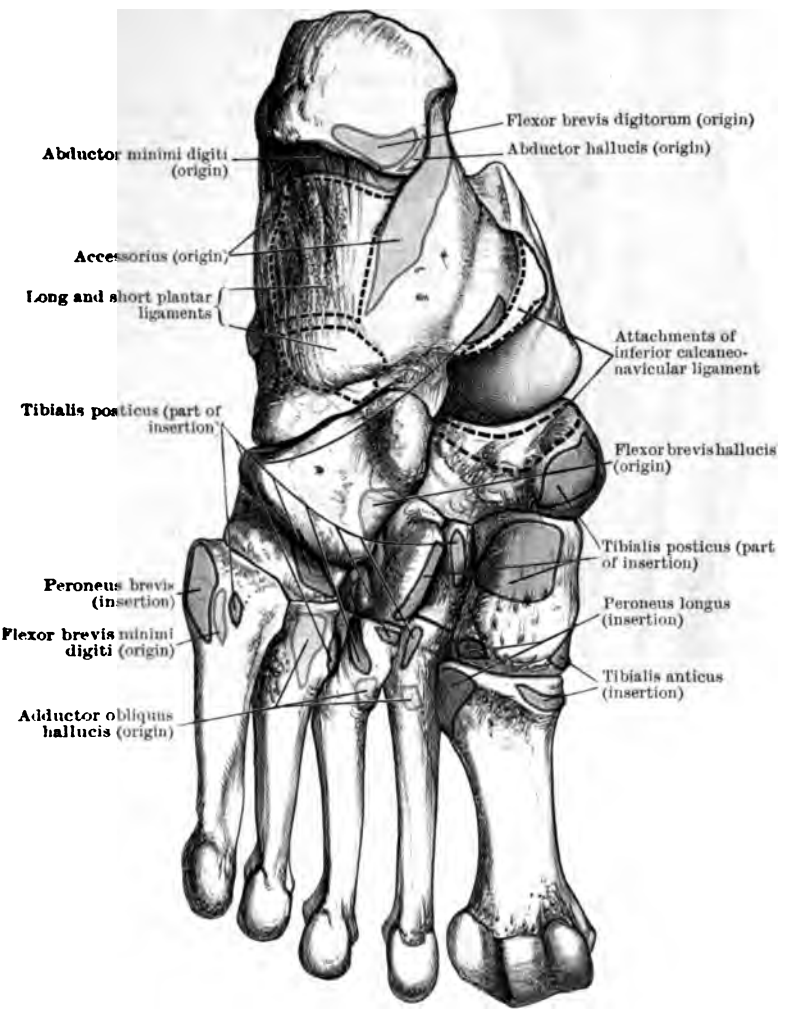

FIG. 295.—MUSCLE-ATTACHMENTS TO TARSUS AND METATARSUS (Plantar Aspect).

l to the long extensors of the toes and the anterior tibial vessels and nerve. don occupies special compartments beneath both upper and lower parts of erior annular ligament, enclosed in a separate, single, synovial sac.

tibio-fascialis anticus is a separated portion of the muscle occasionally present, inserted fascia on the dorsum of the foot.

extensor longus digitorum arises by fleshy fibres from the outer side of ternal tuberosity of the tibia, from the upper two-thirds or more of the r surface of the shaft of the fibula, from the fascia over it, and from inter- ar septa on either side. It gives rise to a tendon which passes beneath the r annular ligament, and in front of the ankle subdivides into four tendons, l into the four outer toes, exactly in the same way as the corresponding ; in the hand (see p. 347). They form membranous expansions on the

dorsum of the first phalanx, joined by the tendons of the extensor brevis digi lumbricales, and interossei, which separate into one central and two latera attached respectively to the middle and terminal phalanges.

The muscle is superficial, and is placed external to the tibialis anticu extensor proprius hallucis, and internal to the peronei muscles. The mu cutaneous nerve is on its outer side. I ceals the anterior tibial vessels and The tendon occupies a separate compar along with the peroneus tertius benea lower part of the anterior annular lig invested by a special synovial membran

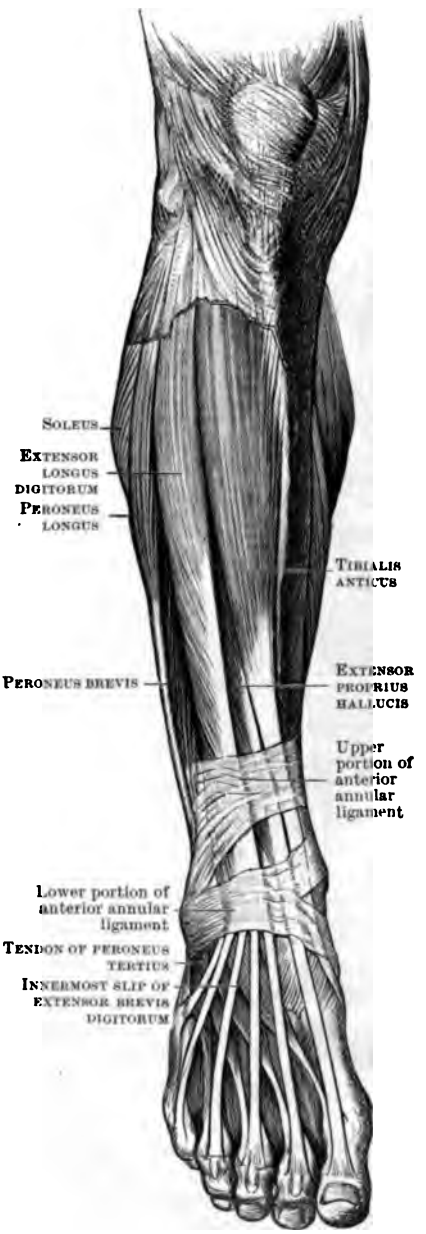

Fig. 296.—Muscles of the Front of the Right Leg and Dorsum of the Foot.

The **peroneus tertius** is a sep portion of the extensor longus digi It is an essentially human muscle. It (inseparably from the extensor longu torum) from the lower part of the a surface of the fibula, from the inter membrane, and from the intermuscular s external to it. The tendon of the mu **inserted** into the dorsal aspect of the the fifth metatarsal bone. It accom the extensor longus digitorum beneat anterior annular ligament, and lies e to the tendons of that muscle on the d of the foot.

The **extensor proprius hallucis** (m. extensor hallucis longus) **arises** by fibres from the front of the fibula middle three-fifths, internal to the ori the extensor longus digitorum, and corresponding extent from the inter membrane. Its tendon passes over the of the foot, to be **inserted** into the the terminal phalanx of the great to the leg the muscle is deeply placed b the tibialis anticus and extensor longu torum. It conceals the anterior tibial and nerve, and crosses the termination anterior tibial artery in front of the joint. It is invested by a special s sac as it lies beneath the lower part anterior annular ligament. On the dor the foot the tendon is placed on the inn of the dorsalis pedis artery.

The **extensor longus primi interno extensor ossis metatarsi hallucis** are o separate slips of this muscle inserted into t of the great toe.

The **extensor brevis digitorum** a the dorsum of the foot by short ter and fleshy fibres from a special impres the upper surface of the greater process os calcis, and from the deep surface of the lower band of the anterior ligament.

It usually gives rise to four fleshy bellies, from which narrow tendc directed forwards and inwards, to be **inserted** into the four inner toes. Th outer tendons join those of the long extensor muscle to form the memb expansions on the dorsum of the toes. The *innermost tendon* is inserted sep into the base of the first phalanx of the great toe.

The muscle is covered by the lower band of the anterior annular ligament, and the tendons of the extensor longus digitorum and peroneus tertius; the slip of the muscle passing to the great toe crosses over the dorsalis pedis artery.

The Muscles on the Outer Side of the Leg.

The muscles on the outer side of the leg comprise the peronei—longus and brevis.

The **peroneus longus arises** by fleshy fibres from the head and the upper two-thirds of the outer surface of the shaft of the fibula, from intermuscular septa on either side, and from the fascia over it. It forms a stout tendon, which hooks round the external malleolus, crosses the outer side of the os calcis, and passing through the groove on the cuboid bone, is directed across the sole of the foot to be **inserted** into the outer sides of the internal cuneiform and the base of the first metatarsal bones (Fig. 295, p. 379). The muscle is placed superficially in the leg, and is separated by intermuscular septa from the extensor longus digitorum and peroneus brevis in front, and the soleus and flexor longus hallucis behind. It partially conceals the peroneus brevis, along with which it passes beneath the external annular ligament, invested by a common synovial sheath. As it enters the sole of the foot a *fibro-cartilage* is formed in the tendon, which plays over a smooth tubercle on the cuboid bone, a bursa intervening. In its passage across the foot the tendon is enclosed in a fibrous sheath reinforced from the inferior calcaneo-cuboid ligaments and the tibialis posticus tendon, and is concealed by the first three layers of the muscles of the sole.

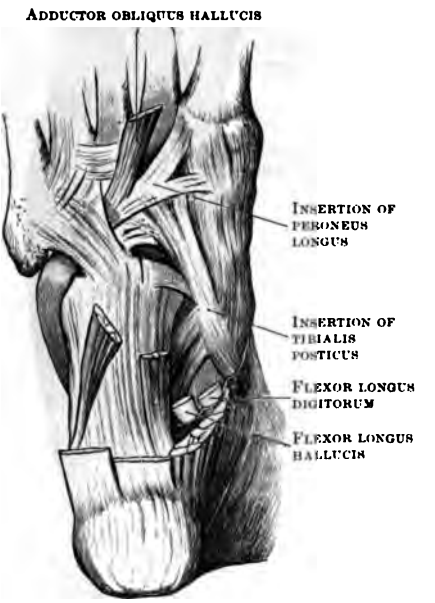

Fig. 297.—The Insertions of the Peroneus Longus and Tibialis Posticus Muscles in the Sole of the Right Foot.

The **peroneus brevis arises** by fleshy fibres from the lower two-thirds of the outer surface of the shaft of the fibula, and from an intermuscular septum along its anterior border. The tendon passes over the back of the external malleolus and the outer side of the os calcis, to be **inserted** into the tubercle and dorsal surface of the base of the fifth metatarsal bone. In the leg the peroneus brevis lies behind the extensor longus digitorum and peroneus tertius, and in front of the peroneus longus, which partially overlaps it. Its tendon lies directly behind the external malleolus beneath the external annular ligament, invested by a synovial sheath common to it and the peroneus longus.

The peroneus longus and brevis may be fused together, or additional slips may be present, as **peroneus accessorius, peroneus quinti digiti, peroneo-calcaneus externus,** and **peroneo-cuboideus.**

The Muscles on the Back of the Leg.

The muscles on the back of the leg are divisible into two layers: (1) a **superficial set,** consisting of the gastrocnemius and soleus (the so-called triceps muscle of the leg), and the plantaris; and (2) a **deep set,** consisting of the popliteus, flexor longus digitorum, tibialis posticus, and flexor longus hallucis.

The **gastrocnemius arises** by *two heads,* inner and outer, by means of strong tendons which are prolonged over the surface of the muscle. The outer head arises by an impression on the upper and posterior part of the outer surface of the external condyle, and from the lower end of the external supra-condyloid ridge; while the inner head arises from a prominent rough mark on the popliteal space of the femur above the internal condyle and from the surface between that and the

adductor tubercle. Each head has an additional origin from the back o capsule of the knee-joint. A bursa lies beneath each tendon of origin. Each belly of the muscle is **inserted** into a broad membranous tendon, prolonged up on its deep surface for some distance. The inner head is the larger.

The **tendo Achillis** is formed by the union of the two membranous inse of the bellies of the gastrocnemius. Prolonged upwards beneath the se bellies, the tendon forms a broad membranous band connecting together the parts of the two bellies. Narr gradually, and becoming thick the lower half of the leg, the t is finally **inserted** into the interm surface on the posterior aspect os calcis. A bursa lies beneat tendon at its insertion. The Achillis also affords insertion soleus and (sometimes) the pla muscles.

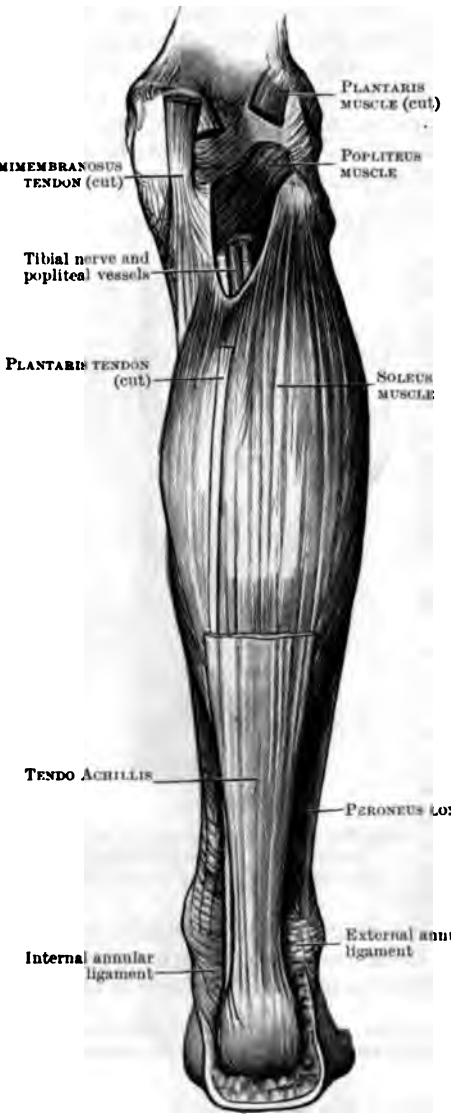

Fig. 298.—The Soleus Muscle.

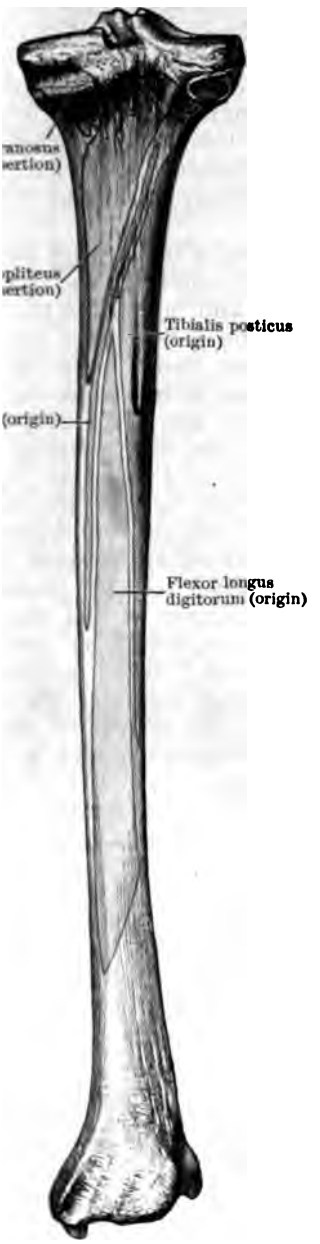
The gastrocnemius is supe except at its origin. The inner is concealed by the semitend and semimembranosus muscle partially covers the popliteal and the tibial nerve in the lowe of their course. It forms part inner boundary of the popliteal The outer head is concealed pa by the biceps tendon and the pe nerve, and covers the plantaris n the popliteal vessels, and the nerve. It forms part of the boundary of the popliteal space. two bellies are for the most pa close contact, the external sapl vein occupying the interval be them. The tendo Achillis i lower half of the leg partially co the soleus and the deeper m The plantaris tendon lies alo inner border.

The **plantaris arises** by fibres from the external supr dyloid ridge of the femur for ab inch at its lower end, from the ad part of the popliteal space of the and from the posterior ligament knee-joint. It forms a narrow slip which ends in a tendon ext down the back of the leg, to be in into the inner side of the tub of the os calcis, or the tendo A or the internal annular ligament. The tendon of the muscle is capable c siderable lateral extension. The plantaris lies between the outer head gastrocnemius and the soleus, and crosses the popliteal vessels and the nerve. In the lower half of the leg its tendon lies along the inner border tendo Achillis. The muscle is not always present.

The **soleus** has a triple **origin** by means of short tendinous and fleshy (1) from the posterior surface of the head and the shaft of the fibula in its third; (2) from a fibrous arch stretching over the popliteal vessels and tibial between the tibia and fibula; and (3) from the oblique line and middle th

r border of the tibia (Fig. 299, p. 383). From this origin the upper r fibres are directed downwards to join a tendon placed on the superficial f the muscle, which is inserted into the tendo Achillis; the lower fibres ·ted directly into the tendo Achillis to within one or two inches of the os calcis.

The muscle is concealed by the gastrocnemius, plantaris, and tendo Achillis in nearly its whole extent. It is partially superficial on each side of the gastrocnemius



.—Muscle-Attachments to the rior Surface of the Tibia.

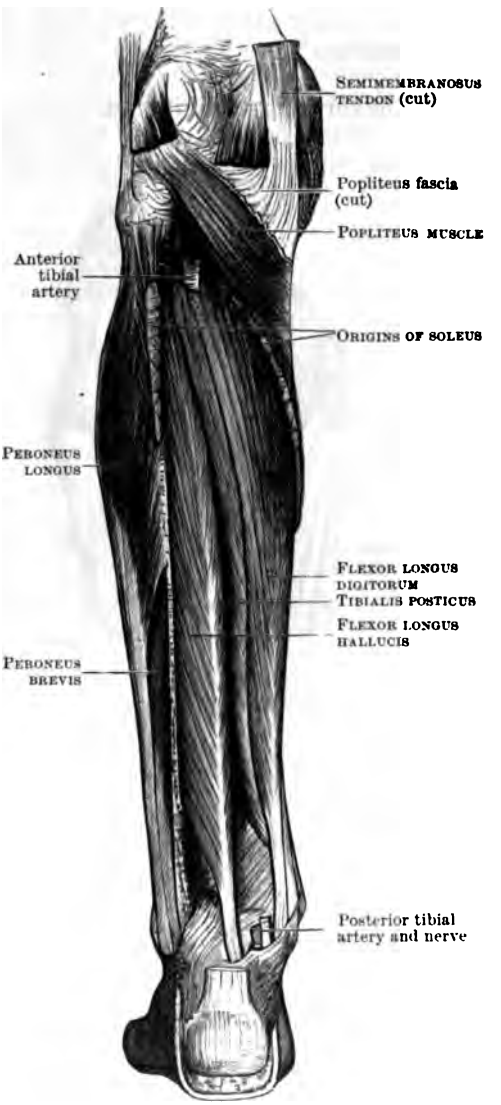


Fig. 300.—The Deep Muscles on the Back of the Left Leg.

do Achillis. The muscle covers the tibialis posticus and the flexor muscles oes as well as the posterior tibial vessels and nerve.

deep muscles of the back of the leg comprise the popliteus, the long flexors oes, and the tibialis posticus.

popliteus is deeply placed behind the knee. It arises by a stout tendon rough impression in front of a groove on the outer aspect of the external

condyle of the femur. This tendon passes between the external semilunar ca and the capsule of the knee-joint, and pierces the posterior ligament, from it takes an additional fleshy origin. A bursa is placed beneath the tendon, communicates usually with the synovial cavity of the knee-joint. The mu **inserted** by fleshy fibres (1) into a triangular surface on the back of the tibia the oblique line (except a small area below the fibular facet) (Fig. 299, p. 38 (2) into the fascia over it (the popliteus fascia, derived from the tendon of the membranosus muscle). The popliteus is covered at its origin by the capsule knee-joint. Posteriorly it is concealed by the gastrocnemius and plantaris m and by the popliteal vessels and the tibial nerve. Its lower border corresp the point of bifurcation of the popliteal artery and the origin of the soleus n

The **popliteus minor** is a small occasional muscle attached to the popliteal space of th and the posterior ligament of the knee-joint.

The **flexor longus digitorum** occupies both the back of the leg and the the foot. Its **origin** is by fleshy fibres from the posterior surface of the shaft tibia in its middle three-fifths, below the oblique line, and internal to the line and the origin of the posticus, from the fascia and from an intermuscular on each side (Fig. 299, p Its tendon, after passing b the internal annular lig enters the sole of the fo divides into four subordina dons, which are **inserted** in four outer toes in precise same manner as the flexo fundus digitorum is inser the hand. Each tendon the digital sheath of the tc forates the tendon of the brevis digitorum, and is ir into the base of the te phalanx. **Ligamenta acc** (**longa** and **brevia**) are pres in the hand. Associated this muscle in the sole of tl are the lumbricales and sorius muscles.

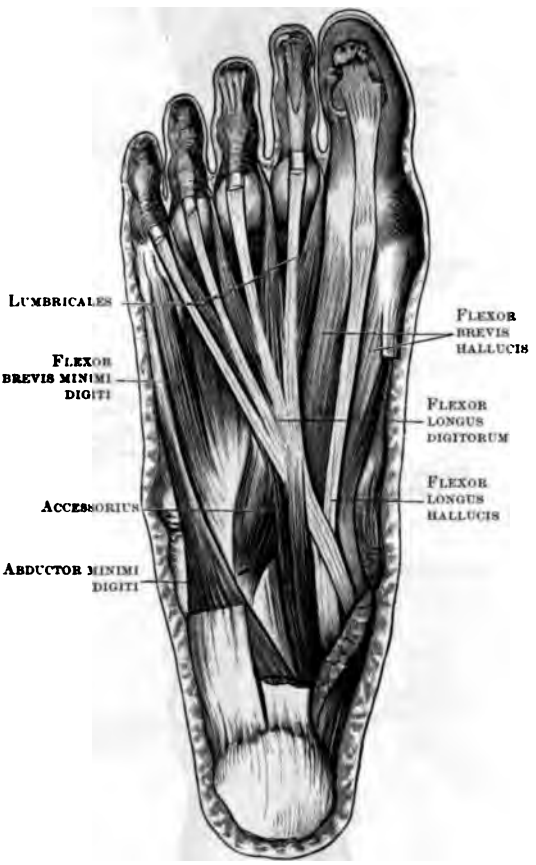

FIG. 301.—THE MUSCLES OF THE RIGHT FOOT (after removal of the first layer).

The **lumbricales** are fou muscles **arising** in associatio the tendons of the flexor pro digitorum in the sole. Th *muscle* arises by a single origi the tibial side of the ten the flexor longus digitoru the second toe; the *other* arise by two heads fro adjacent sides of all four te Each muscle is **inserted** in dorsal expansion of the extensor tendon, the metatarso-phalangeal capsul the base of the first phalanx, precisely as in the case of the lumbrical n of the hand. Each muscle passes forwards on the tibial side of the corresp toe, superficial to the transverse metatarsal ligament.

The **flexor accessorius muscle** (m. quadratus plantæ) **arises** by two hea the outer tendinous head springs from the outer border of the inferior sur the os calcis and from the outer border of the long plantar ligament; (2) the head, which is fleshy, arises from the concave inner surface of the os calcis whole extent, and from the inner border of the long plantar ligament (Fi

379). The long plantar ligament separates the two origins. The two heads ite to form a flattened band, which is **inserted** into the upper aspect of the ıdons of the flexor longus digitorum, and usually into those destined for the :ond, third, and fourth toes.

In the leg the flexor longus digitorum lies at first internal to the tibialis sticus, and is partially concealed by the soleus and tendo Achillis. Its tendon ɔsses over the tibialis posticus above the ankle-joint, passes beneath the internal nular ligament, invested by a special synovial sheath, and below the ligament ɔsses the plantar or superficial surface of the tendon of the flexor longus hallucis. ı it passes over this tendon it receives from it a special band of fibres, usually sociated with the tendons for the second and third toes.

In the sole of the foot the tendons of the flexor longus digitorum, along with the mbricales and accessorius, and the flexor longus hallucis muscles, constitute the cond layer of muscles of the sole. They are placed between the abductors of the eat and little toes and the flexor brevis digitorum on the one hand, and the flexor evis and adductors of the great toe on the other.

The flexor longus hallucis arises by fleshy fibres on the back of the leg from e lower two-thirds of the posterior surface of the shaft of the fibula, from the scia over it, and from intermuscular septa on either side. Its tendon passes neath the internal annular ligament enclosed in a special synovial sheath, and ter grooving the back of the lower end of the tibia, the astragalus, and the under rface of the sustentaculum tali of the os calcis, it is directed forwards in the le of the foot, to be **inserted** into the base of the terminal phalanx of the great toe.

The muscle is partially concealed in the leg by the soleus and tendo Achillis. ; lies at its origin between the tibialis posticus and the peronei muscles, separated om the former by the peroneal artery. In the foot, concealed by the abductor allucis, it crosses over the deep aspect of the tendon of the flexor longus digitorum,) which it is connected by a strong fibrous band destined for the tendons for the cond and third toes. At the root of the great toe the tendon occupies the ıterval between the insertions of the flexor brevis hallucis.

The **tibialis posticus muscle** (m. tibialis posterior) has a fourfold fleshy **origin** ı the leg. It arises (1) from the upper four-fifths of the shaft of the fibula etween the oblique line and the interosseous border; (2) from the lower part of he outer tuberosity of the tibia and from the upper two-thirds of the shaft of the one below the oblique line and between the vertical line and the interosseous order (Fig. 299, p. 383); (3) from the interosseous membrane; and (4) from the ascia over it and the septa on either side. The muscle gives rise to a strong endon which passes beneath the internal annular ligament, invested by a special ynovial sheath, and grooves the back of the internal malleolus, on its way to the nner border of the foot. The tendon then spreads out and is **inserted** by three ands into (1) the tubercle of the navicular bone and the plantar surfaces of the nternal and middle cuneiform bones, (2) the plantar aspects of the second, hird, fourth, and sometimes the fifth metatarsal bones, the middle and external uneiform bones, and the groove on the cuboid, and (3) by a recurrent slip ıto the inner border of the sustentaculum tali of the os calcis from which a .brous expansion passes outwards to join the inner border of the short plantar igament (Fig. 302, p. 386).

In the leg the tibialis posticus is concealed, as it lies on the interosseous membrane between the tibia and fibula, by the superficial muscles and the posterior ibial vessels and nerve. It lies between the flexor longus hallucis and flexor ɔngus digitorum, and is crossed by the tendon of the latter muscle just above the nkle. Just below the knee between its tibial and fibular origins is an angular pace through which the anterior tibial vessels pass. In the foot its tendon is overed by the long flexor tendons and by the short flexor muscles of the great toe. :he tendon is in contact with the inferior calcaneo-navicular ligament in the nterval between the sustentaculum tali and the navicular bone.

The **peroneo-calcaneus** muscle, when present, **arises** from the fibula, and is **inserted** into the s calcis.

The Muscles in the Sole of the Foot.

The muscles in the sole of the foot are divisible into four layers placed be the plantar fascia.

First layer: Abductor hallucis, flexor brevis digitorum, abductor minimi di

Second layer: Lumbricales and accessorius, together with the tendons of flexor longus hallucis and flexor longus digitorum.

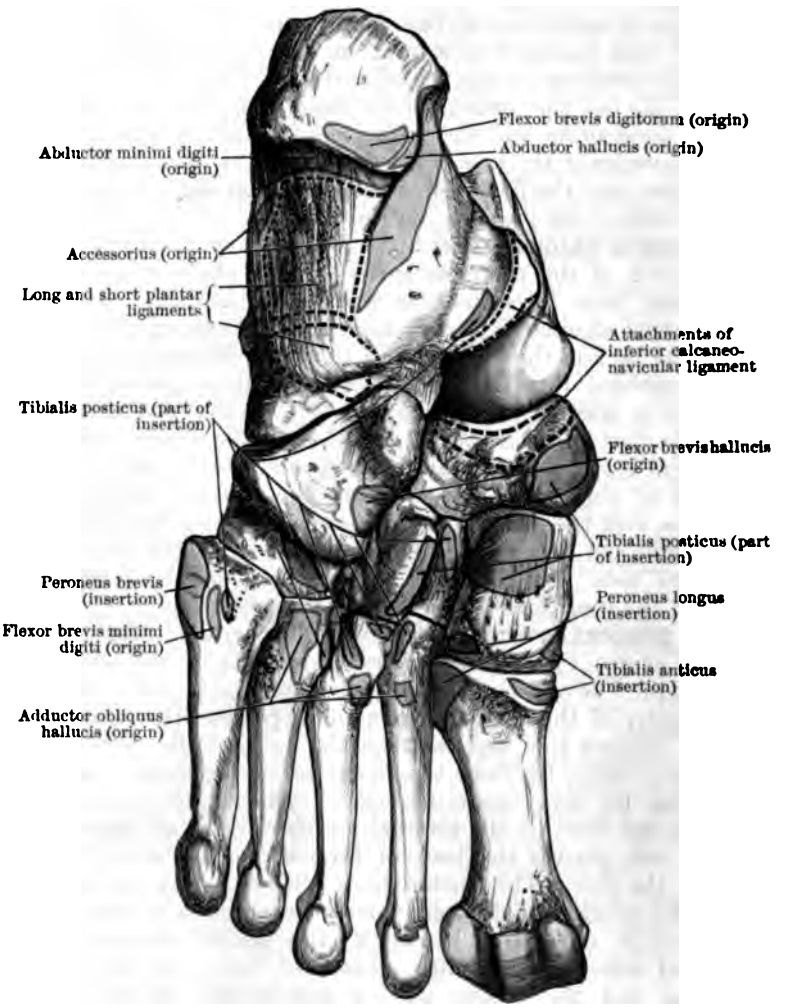

Fig. 302.—Muscle-Attachments to Tarsus and Metatarsus (Plantar Aspect).

Third layer: Flexor brevis hallucis, adductors of the great toe, and flexor brevis minimi digiti.

Fourth layer: Interossei (plantar and dorsal).

The **abductor hallucis** has a double **origin**, (1) by a short tendon from the inner side of the greater tubercle on the tuberosity of the os calcis (Fig. 302, p. 386), and (2) by fleshy fibres from the internal annular ligament, the plantar fascia which covers it, and the intermuscular septum between it and the flexor brevis digitorum. Lying superficially along the inner border of the sole, its tendon is **inserted**, along with part of the flexor brevis hallucis, into the inner side of the posterior end of the first phalanx of the great toe. The muscle lies beneath the plantar fascia, internal to the flexor brevis digitorum, and conceals the plantar vessels and nerves, and near its origin the long flexor tendons.

The **flexor brevis digitorum** has likewise a double **origin**: (1) by a short

om the fore-part of the greater
f the tuberosity of the os calcis
, p. 386), and (2) by fleshy
m the thick central part of the
ascia which covers it, and from

—THE MUSCLES OF THE RIGHT FOOT (after removal of the second layer).

fascia and the calcaneo-metatarsal ligament, and from the intermuscular septum between it and the flexor brevis digitorum. Its tendon lies along the fifth metatarsal bone, and is **inserted** by a tendon into the outer side of the posterior end of the first phalanx of the little toe. The outermost fibres usually obtain an additional insertion into the outer side of the plantar surface of the fifth metatarsal bone. It lies on the outer side of the flexor brevis digitorum, and partially conceals the flexor brevis minimi digiti.

The tendons of the long flexors of the toes, the **lumbricales** and **accessorius muscles**, constituting the **second layer of muscles**, have already been described. Lying beneath the abductor hallucis and the flexor brevis digitorum, and separated from them by the

plantar vessels and nerves, they occupy the hollow of the tarsus and the between the first and fifth metatarsal bones; their deep surfaces are in c with the adductors of the great toe and the interossei muscles.

The **flexor brevis hallucis** arises by tendinous fibres (1) from the inner the under surface of the cuboid bone (Fig. 302, p. 386), and (2) from the t of the tibialis posticus. Directed forwards over the first metatarsal bon muscle separates into two parts, between which is the tendon of the flexor l hallucis. Each portion gives rise to a tendon which is **inserted** into the sponding side of the base of the first phalanx of the great toe; in each t under the metatarso-phalangeal articulation, a sesamoid bone is developed. inner tendon is united with the insertion of the abductor, the outer tendo the insertions of the adductor muscles of the great toe.

The **adductor obliquus hallucis** arises by fleshy and short tendinous fibres (1 the sheath of the peroneus longus, and (2) from the plantar surfaces of the po extremities of the second, third, and fourth metatarsal bones (Fig. 302, p. Occupying the hollow of the foot, on a deeper plane than the long flexor t and lumbricales, and separated from the interossei by the plantar arch, it is on the outer side flexor brevis hallu is directed obliqu wards and forwa be **inserted** on the side of the base first phalanx of th toe between and with the flexor bre adductor transv hallucis. The forms one side of angular space in t through which t ternal plantar and nerve pass.

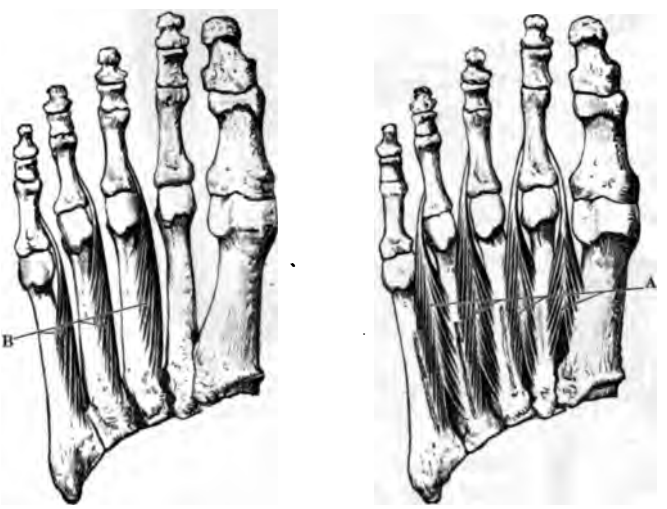

FIG. 305.—INTEROSSEOUS MUSCLES OF THE FOOT.

A, Dorsal muscles (plantar aspect); B, Plantar muscles of the right foot.

The **adductor versus hallucis** from (1) the caps the outer four met phalangeal articu and (2) the tra metatarsal ligament. Directed transversely inwards, under cover of the tendons and lumbricales, the muscle is **inserted**, along with the ad obliquus (from which it is separated by an angular interval), into the side of the base of the first phalanx of the great toe.

The **flexor brevis minimi digiti** (m. flexor brevis digiti quinti) from (1) the sheath of the peroneus longus, and (2) the base of th metatarsal bone (Fig. 302, p. 386). Partially concealed by the abductor digiti, the muscle passes along the fifth metatarsal bone, to be **inserted**, in c with that muscle, into the outer side of the base of the first phalanx of the lit

The **interossei muscles** of the foot resemble those of the hand except respect. In the hand the line of action of the muscles is the middle line middle finger. In the foot the *second toe* is the digit round which the musc grouped, and their attachments and their actions differ accordingly.

There are four dorsal and three plantar muscles, which occupy together t interosseous spaces, and project into the hollow of the foot.

The **four dorsal muscles**, one in each interosseous space, **arise** by two hea from the shafts of the metatarsal bones. Each gives rise to a tendon, whic passing dorsal to the transverse metatarsal ligament, is **inserted** on the dorsum foot into the side of the first phalanx, the metatarso-phalangeal capsule, a dorsal expansion of the extensor tendon. The *first* and *second muscles* are i

the second toe on the tibial and fibular sides respectively. The *third* and *th muscles* are inserted into the third and fourth toes on their fibular sides. The **three plantar muscles** occupy the three outer interosseous spaces. Each s by a single head from the tibial side of the third, fourth, and fifth metatarsal es respectively. Each ends in a tendon which passes dorsal to the transverse atarsal ligament, and is **inserted**, in the same manner as the dorsal muscles, into third, fourth, and fifth toes on their tibial side.

ACTION OF THE MUSCLES OF THE LEG AND FOOT.

The muscles of the leg and foot act chiefly in the movements of the ankle-joint (assisted by ements of the inter-tarsal joints); of the metatarso-phalangeal joints (assisted by movements he tarso-metatarsal and inter-metatarsal joints); and of the inter-phalangeal joints of the ral toes.

I. **Tibio-Fibular Articulations.**—The upper tibio-fibular articulation is only capable of it gliding movement, occasioned by the action of the biceps and popliteus and the muscles ng from the fibula.

II. **Movements at the Ankle-Joint.**—The movements at the ankle-joint are movements of on and extension of the foot on the leg, along with inversion and eversion (only during nsion). These movements are produced at the ankle, aided by movements in the inter-tarsal ts, and are occasioned by the following muscles:—

a. Flexion.	Extension.	*b.* Inversion.	Eversion.
bialis anticus	Gastrocnemius	Tibialis anticus	Peroneus tertius
tensor communis digitorum	Plantaris		Peroneus longus
tensor proprius hallucis	Soleus	Tibialis posticus	Peroneus brevis
roneus tertius	Tibialis posticus		
	Peroneus longus		
	Peroneus brevis		
	Flexor longus digitorum		
	Flexor longus hallucis		

III. Movements of the Toes.—*A.* **At the Metatarso-Phalangeal Joints** (assisted by mo ments at the tarso-metatarsal and inter-metatarsal joints).—These movements are flexion a extension, abduction and adduction (in a line corresponding to the axis of the second toe).

a. **Flexion.**	**Extension.**
Flexor longus digitorum Accessorius Lumbricales Flexor longus hallucis Flexor brevis hallucis Flexor brevis digitorum Flexor brevis minimi digiti Interossei	Extensor longus digitorum Extensor brevis digitorum Extensor proprius hallucis

b. **Abduction.**	**Adduction.**
(*From and to the middle line of the second toe.*)	
Abductor hallucis Dorsal interossei Abductor minimi digiti	Adductores hallucis Plantar interossei

B. **At the inter-phalangeal joints** the movements are limited to flexion and extension.

Flexion.	**Extension.**	
Flexor brevis digitorum (*acting on the first joint*)	Extensor longus digitorum	(*acting on bo joints*)
Flexor longus digitorum (*acting on both joints*)	Extensor brevis digitorum	
Flexor longus hallucis (*acting on the hallux*)	Interossei Lumbricales Extensor proprius hallucis	

Movements of the Lower Limb generally.

The characteristic features of the lower limb are stability and strength, and its muscles joints are both subservient to the functions of transmission of weight and of locomotion. In standing position the centre of gravity of the trunk falls between the heads of the fem and is located about the middle of the body of the last lumbar vertebra. It is transmi through the bones of the lower limb to the arch of the foot, where the astragalus distribute backwards through the os calcis to the heel, and forwards through the tarsus and metatarsu the balls of the toes.

Locomotion.—The three chief means of progression are walking, running, and leaping. **walking**, the body and its centre of gravity are inclined forwards, the trunk oscillates from to side as it is supported alternately by each foot, the arms swing alternately with the corresp ing leg, and one foot is always on the ground. The act of progression is performed by the aided in two ways by gravity. The movements of the leg are as follows: At the beginnin a step, one leg, so to speak, "shoves off;" the heel is raised and the limb is extended. By action of the muscles flexing the hip and knee-joint, and extending the ankle-joint and toes, limb is raised from the ground sufficiently to clear it, and passes forwards by the actio gravity, aided by the force given to the movement by the extensor muscles. After passing line of the centre of gravity the flexion of the joints ceases, the muscles relax, and the gradually returns to the ground. The other limb then passes through the same cycle, the we of the body now resting on the limb which is in contact with the ground. As the foot rea the ground it, as it were, rolls over it; the heel touches it first, then the sole, and lastly, as foot leaves the ground again, only the toes. In **running**, the previous events are all exagger The time of the event is diminished, while the force and distance are increased. Both feet a the ground at one time; the action of flexors and extensors alternately is much more powerf that on the one hand the knees are drawn upwards to a greater extent in the forward moven and not the whole foot, but only the toes reach the ground in the extension of the limb. attempt is made to bring the foot to the ground in front of the line of the centre of gravity. the same time the trunk is sloped forwards much more than in walking. In **leaping**, the ac of the limbs are still more exaggerated. The movements of flexion of the limb are still marked, and the foot reaches the ground still farther in front of the line of the centre of gra

AXIAL MUSCLES.

THE FASCIÆ AND MUSCLES OF THE BACK.

THE FASCIÆ OF THE BACK.

The general fascial investments of the back have been described along with the erficial muscles associated with the shoulder-girdle (p. 318). The latissimus si muscle has been described as arising in large part from the **vertebral apo-rosis.** This is a strong fibrous lamina which conceals the erector spinæ muscle. the loin it extends from the spines of the lumbar vertebræ outwards to the erval between the last rib and the iliac crest, where it is concerned in forming **lumbar fascia.** Below the loin the vertebral aponeurosis is attached to the iliac st, and more internally blends with the subjacent tendinous origin of the erector næ. The fascia ı be followed wards over the ctor spinæ in region of the ɔrax, where it is tached exter-lly to the ribs d is continuous th the inter-stal aponeur-s. In the lower rt of the thorax is replaced by ıscular slips— serratus posti-inferior; in upper part of e thorax it ses beneath the ratus posticus perior and nds with the ep cervical cia.

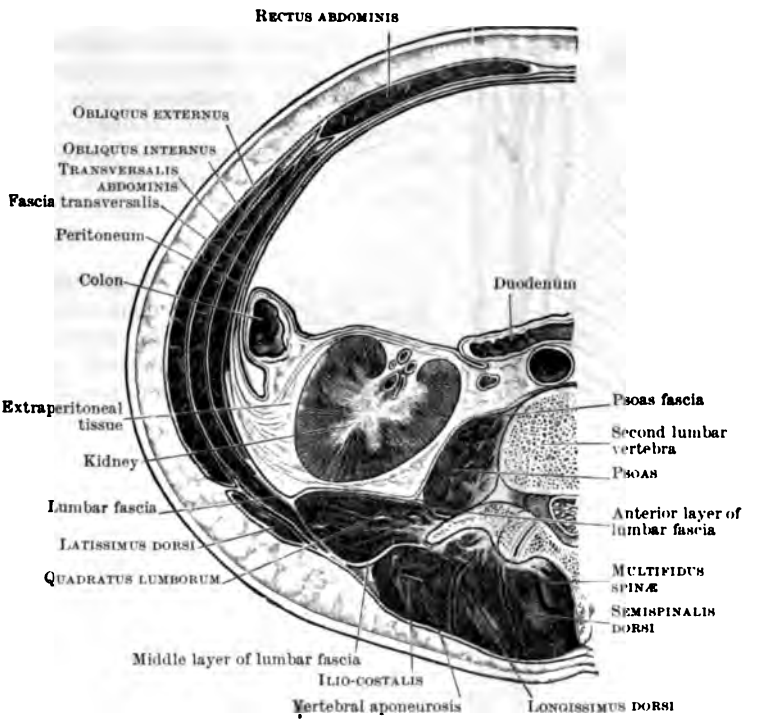

Fig. 306.—Transverse Section through the Abdomen, opposite the Second Lumbar Vertebra.

The **lumbar cia** is a narrow ımentous band ich connects last rib to the iliac crest between the muscles of the back on the one hand and se of the abdominal wall on the other. It is formed by the union of three fascial ıta, called respectively the **vertebral aponeurosis** or posterior layer, just described; middle, and the anterior layers. The **middle layer** is a fascia which stretches wards from the ends of the transverse processes of the lumbar vertebræ, between erector spinæ behind and the quadratus lumborum muscle in front. The **anterior er** is attached to the lumbar vertebræ near the bases of their transverse processes. covers the front of the quadratus lumborum muscle, and separates it from the as. The **psoas fascia** is continuous at the outer border of the psoas muscle with anterior layer of the lumbar fascia. At the outer borders of the quadratus ıborum and erector spinæ muscles the three layers are blended together to form lumbar fascia, which in turn gives partial origin to the obliquus internus and ınsversalis abdominis muscles.

THE MUSCLES OF THE BACK.

The muscles of the back are arranged in four series according to their at ments: (1) vertebro-scapular and vertebro-humeral, (2) vertebro-costal vertebro-cranial, and (4) vertebral. They are in irregular strata, the superficial muscles having the widely spread attachments.

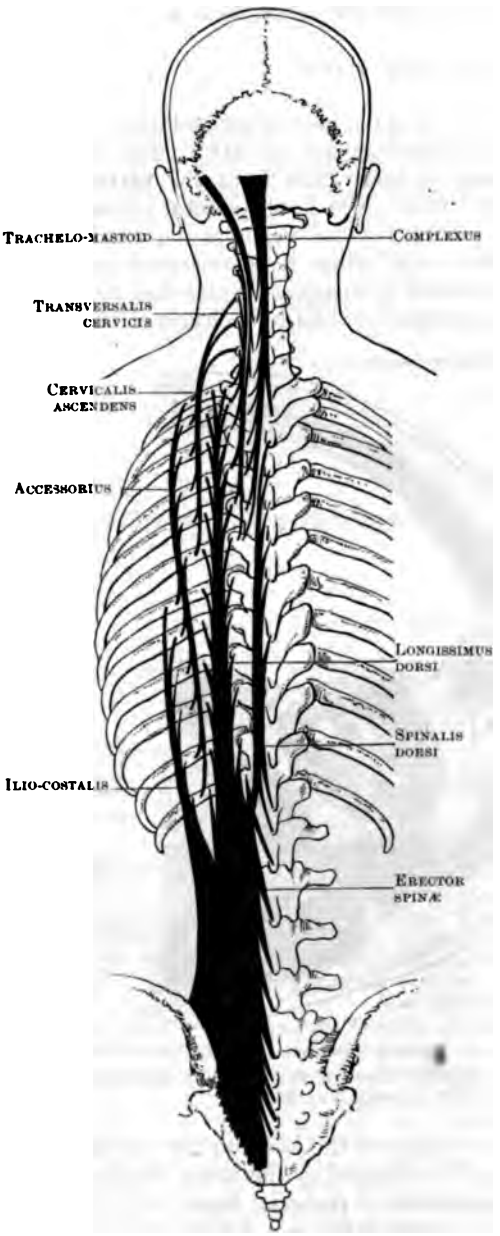

FIG. 307.—SCHEMATIC REPRESENTATION OF THE PARTS OF THE ERECTOR SPINÆ MUSCLE.

The first series of muscles of back, connecting the axial skelet the upper limb, have already described. They are arranged in layers: (1) trapezius and latiss dorsi superficially; (2) levator a scapulæ, and rhomboidei, beneath trapezius.

The remaining muscles are al entirely axial, and may be div according to position, into four gr (1) serrati postici, superior and inf splenius capitis and splenius colli erector spinæ and complexus; (3) t verso-spinales (semispinalis and m fidus spinæ); and (4) the small muscles (rotatores, interspinales, i transversales, and suboccipital mus

FIRST GROUP.

The **serratus posticus sup** has a membranous **origin** from the mentum nuchæ and the spines o last cervical and upper three or thoracic vertebræ. It is directe liquely downwards and outwards, **inserted** by separate slips into the se third, fourth, and fifth ribs. The m is concealed by the vertebro-sca muscles, and crosses obliquely splenius, erector spinæ, and compl It lies superficial to the vert aponeurosis.

The **serratus posticus inferio** a membranous **origin** through medium of the vertebral aponeu from the last two thoracic and firs lumbar spinous processes. It form muscular bands which pass a horizontally outwards to an **ins** into the last four ribs. The mus slips overlap one another from upwards. The muscle is on the plane as the vertebral aponeurosis is concealed by the latissimus dor

The **splenius muscle** is a broad, flattened band which occupies the back neck and the upper part of the thoracic region. It **arises** from the ligamentum n (from the level of the fourth cervical vertebra downwards) and from the sp processes of the last cervical and higher (four to six) thoracic vertebræ. Its extend upwards and outwards into the neck, separating in their course in upper and a lower part. The upper part forms the **splenius capitis**, whi **inserted** into the mastoid process and the outer part of the superior curved li

occipital bone (Fig. 312, p. 397). The lower part forms the **splenius colli cervicis**, which is **inserted** into the posterior tubercles of the transverse processes the upper three or four cervical vertebræ, behind the origin of the levator guli scapulæ. The muscle is partially concealed by the trapezius and sterno-astoid, and appears between them in the floor of the posterior triangle of the ck (splenius capitis). It is covered by the rhomboid muscles, levator anguli apulæ, and serratus posticus superior. It conceals the transversalis cervicis, achelo-mastoid, and complexus muscles.

Second Group.

The erector spinæ (m. sacro-spinalis) possesses vertebral, vertebro-cranial, and rtebro-costal attachments. It consists of an elongated mass composed of separated ps extending from the sacrum to the skull. Simple at its origin, it becomes ore and more complex as it is traced upwards towards the head. It **arises** (1) by eshy fibres from the iliac crest; (2) from the posterior sacro-iliac ligament; and) by tendinous fibres continuous with the former from the iliac crest, the back of e sacrum, and the spines of the upper sacral and all the lumbar vertebræ. Its ores extend upwards through the loin, enclosed between the posterior and middle yers of the lumbar fascia, and separate into two columns—an outer portion erived from the external fleshy origin, the **ilio-costalis**, and an inner portion comrising the remaining larger part of the muscle, the **longissimus dorsi**.

The **ilio-costalis** (m. ilio-costalis lumborum) is **inserted** by six slender slips into he lower six ribs.

Internal to the insertion of each is the origin of a slip of the **accessorius muscle**

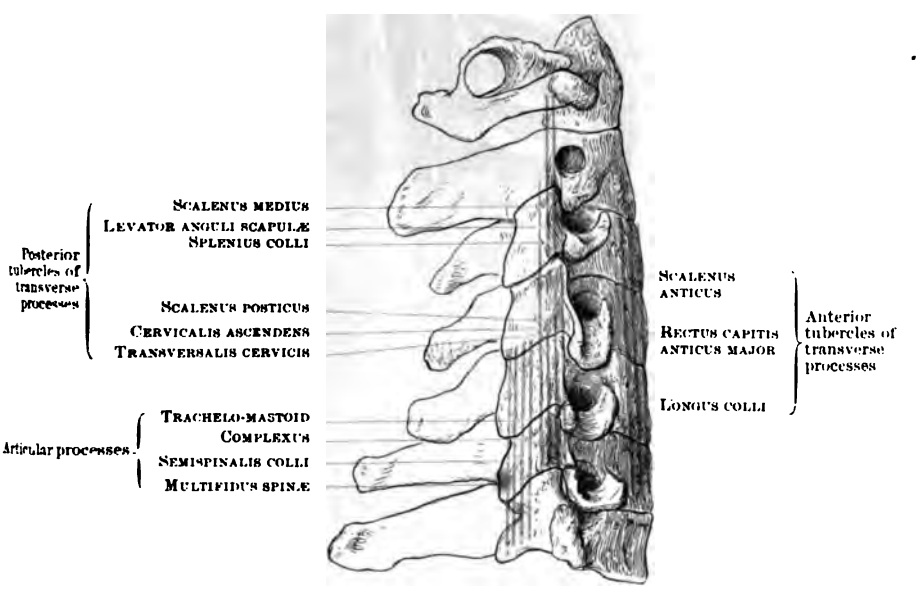

Fig. 308.—Scheme of Muscular-Attachments to the Transverse Processes of the Cervical Vertebræ.

m. ilio-costalis dorsi), which, **arising** from the lower six ribs internal to the ilio-ostalis, is **inserted** in line with it by similar slips into the upper six ribs.

The **cervicalis ascendens** (m. ilio-costalis cervicis) **arises** in the same way by ix slips from the upper six ribs, internal to the insertions of the accessorius. It orms a narrow band, which, extending into the neck, is **inserted** into the posterior ubercles of the transverse processes of the fourth, fifth, and sixth cervical vertebræ, ehind the scalenus posticus. The ilio-costalis, accessorius, and cervicalis ascendens orm together a continuous muscular column, and constitute the outermost group the component elements of the erector spinæ.

The longissimus dorsi is the largest element in the erector spinæ muscle.

With its cervical prolongations—the transversalis cervicis and trachelo-mast it forms the middle column of the erector spinæ. Mostly tendinous on the su at its origin, it becomes fleshy in the upper part of the loin. It is thickest i loin, and becomes thinner as it passes upwards in the back between the co formed by the ilio-costalis, etc., externally, and the spinalis dorsi internally is **inserted** by two series of slips, inner and outer, externally into nearly al

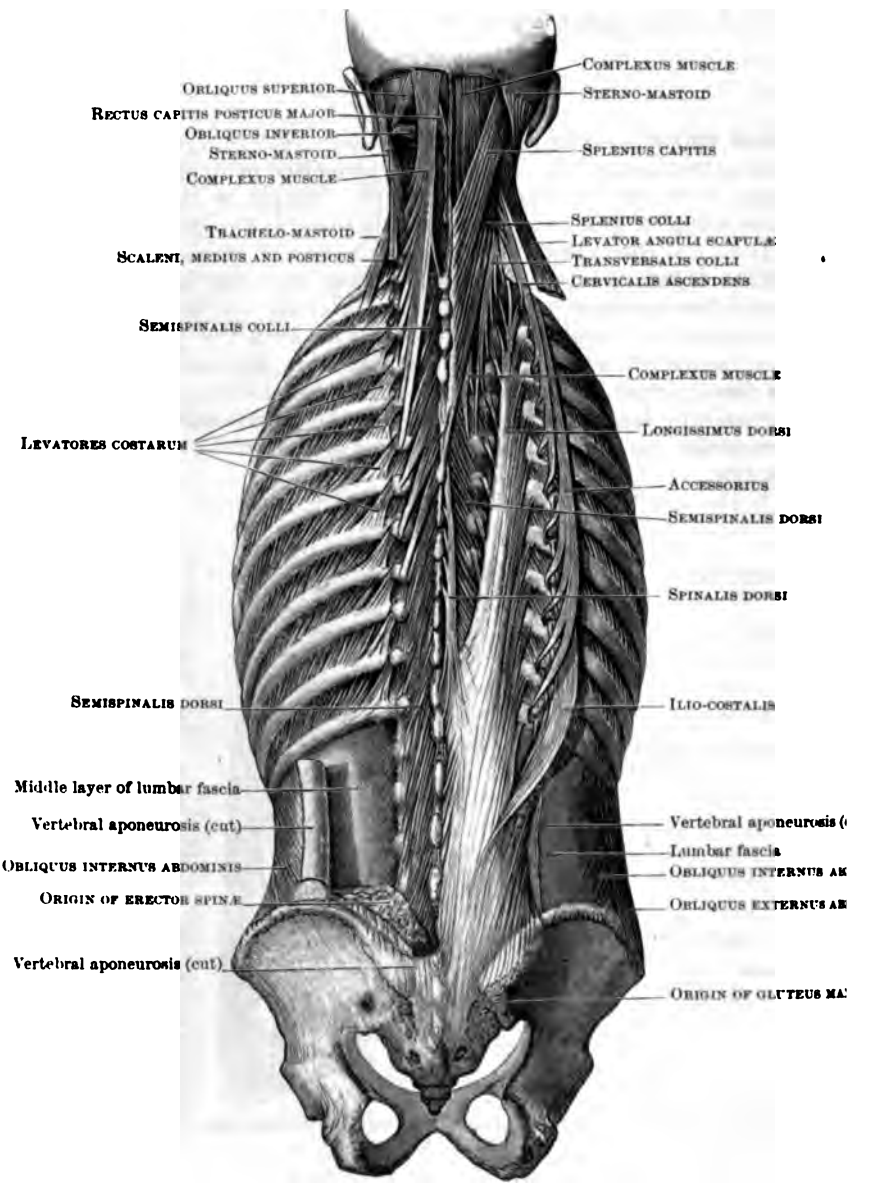

Fig. 309.—Deeper Muscles of the Back.

ribs, and internally into the transverse processes of the thoracic and the acc processes of the upper lumbar vertebræ. It is prolonged upwards into the by its association with the common origin of two muscles, the transversalis c and the trachelo-mastoid.

The **transversalis cervicis** (m. longissimus cervicis) has an **origin** fro transverse processes of the upper six thoracic vertebræ, internal to the inse of the longissimus dorsi. Extending upwards into the neck, it is **inserted** in

tubercles of the transverse processes of the second, third, fourth, fifth, h cervical vertebræ. It lies in the neck, underneath the cervicalis ascendens nius colli muscles.

trachelo-mastoid (m. longissimus capitis) **arises**, partly by an origin to it and the previous muscle, from the transverse processes of the upper ıcic vertebræ, and partly by an additional origin from the articular pro- f the lower four cervical vertebræ. Separating from the transversalis the muscle ascends through the neck as a narrow band which is **inserted** mastoid process beneath the splenius capitis muscle. In the neck the s placed between the splenius capitis and complexus.

spinalis dorsi forms the innermost column of the erector spinæ. It the thoracic portion of the back, and **arises** by tendinous fibres from the o thoracic and upper two lumbar spinous processes, and also directly from on of the longissimus dorsi. It is a narrow muscle which, lying close to ıcic spinous processes internal to the longissimus dorsi and complexus, is into the upper (four to eight) thoracic spines. This muscle is not prolonged neck. It partially covers the semispinalis, dorsi, and colli.

erector spinæ muscle is bound down by the vertebral aponeurosis, and ıled by the more superficial muscles (sterno-mastoid, trapezius, levator :apulæ, rhomboids, splenius, serrati postici). It covers the ribs posteriorly, ially conceals the semispinales and complexus muscles.

complexus muscle (m. semispinalis capitis) closely resembles in position :hments the trachelo-mastoid. It takes **origin** by tendinous slips from the ;e processes of the upper six thoracic and the articular processes of the ur cervical vertebræ, internal to the transversalis cervicis and trachelo-

It has an additional origin also from the spinous process of the last vertebra. It forms a broad muscular sheet which extends upwards in the be **inserted** by fleshy and short tendinous fibres into the inner impression the superior and inferior curved lines of the occipital bone (Fig. 312,

The inner portion of the muscle is separate, and forms the **biventer** consisting of two fleshy bellies with an intervening tendon, placed vertically :t with the ligamentum nuchæ. The insertion of the muscle is crossed by pital artery. The complexus is covered mainly by the splenius and ·mastoid muscles. It conceals the semispinalis colli and the muscles of ccipital triangle, along with the accompanying vessels and nerves.

Third Group.

group comprises the semispinales and multifidus spinæ.

e muscles are only incompletely separate from one another. The semi- dorsi, and colli, form a superficial stratum, the multifidus spinæ being more aced. The more superficial muscles have the longer fibres; the fibres of the ıs spinæ pass over fewer vertebræ. Both muscles extend obliquely upwards ısverse to spinous processes.

semispinalis muscle extends from the loin to the axis vertebra. Its e artificially separated into an inferior part, the **semispinalis dorsi**, and r part, the **semispinalis colli**.

semispinalis dorsi arises from the transverse processes of the lower six vertebræ. It is **inserted** into the spinous processes of the last two cervical four thoracic vertebræ.

semispinalis colli or **cervicis arises** from the transverse processes of the thoracic vertebræ and the articular processes of the lower four cervical

It is **inserted** into the spines of the cervical vertebræ from the second to

The semispinalis muscle occupies the vertebral furrow, and is concealed ector spinæ and complexus; it covers the multifidus spinæ muscle. It is me plane as the muscles of the suboccipital triangle.

nultifidus spinæ differs from the previous muscle in extending from the o the axis, and in the shortness of its fasciculi, which pass over fewer to reach their insertion. It **arises** from the sacrum, from the posterior

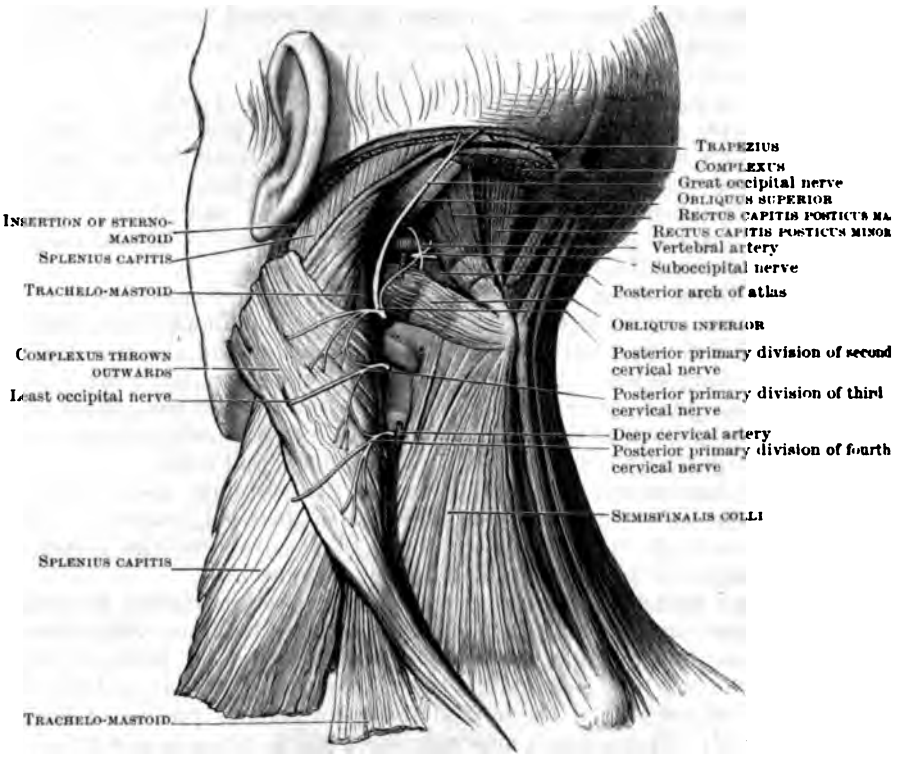

Fig. 310.—The Suboccipital Triangle.

sacro-iliac ligament (Fig. 311, p. 396), from the mammillary processes of

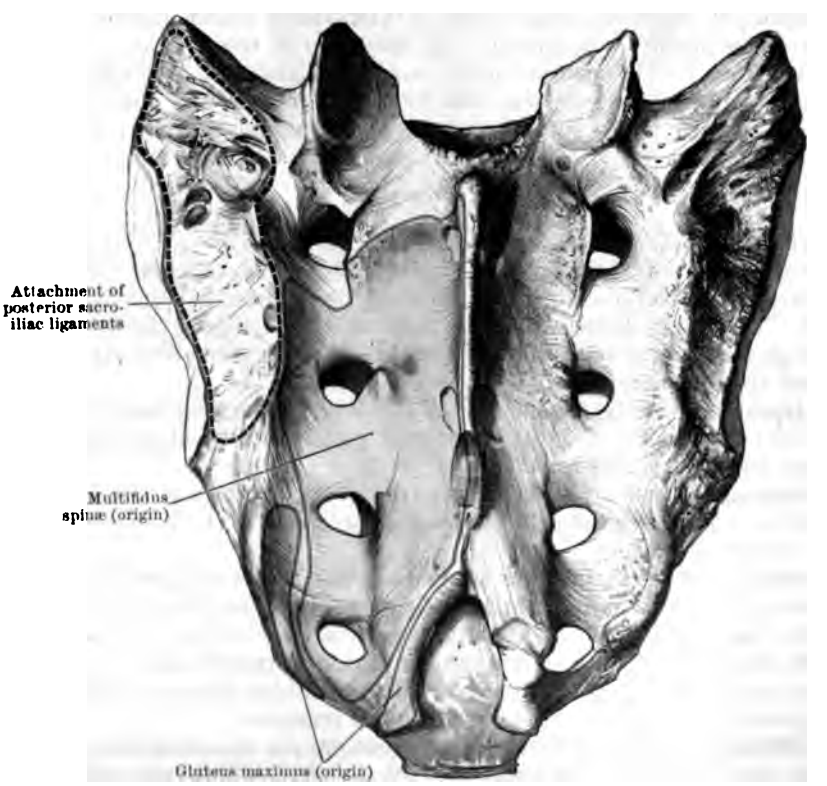

Fig. 311.—Muscle-Attachments to the Sacrum (Posterior Aspect).

ıbar vertebræ, from the transverse processes of the thoracic vertebræ, and from articular processes of the lower four cervical vertebræ. It is **inserted** into the nes of the vertebræ up to and including the axis. Lying in contact with the tebral laminæ, the muscle is covered in the back and neck by the semispinalis, l in the loin by the erector spinæ muscle.

Fourth Group.

This group includes several sets of small muscles, which are vertebro-cranial or er-vertebral in their attachments.

The muscles bounding the **suboccipital triangle** are four in number—obliquus erior, obliquus superior, rectus capitis posticus major, and rectus capitis posticus nor.

These muscles are concealed by the complexus and splenius capitis; they enclose triangular space (the suboccipital triangle) in which the vertebral artery, posterior primary division of the suboccipital nerve, and the posterior arch of

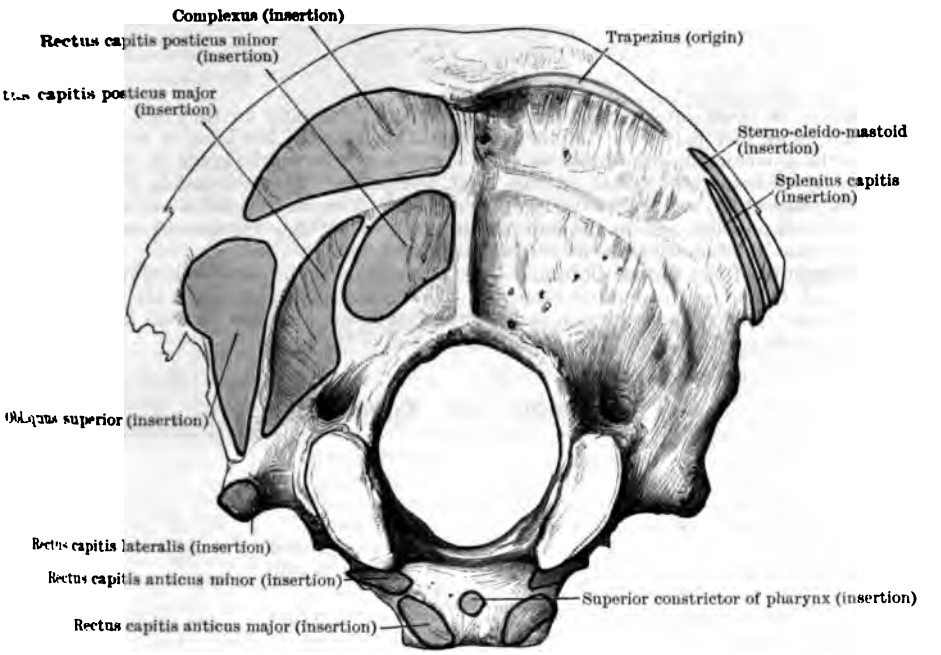

Fig. 312.—Muscle-Attachments to Occipital Bone (Inferior Surface).

the atlas are contained. The obliquus inferior is separated from the semispinalis muscle by the great occipital (second cervical) nerve.

The **obliquus inferior arises** from the spine of the axis, and is **inserted** into the transverse process of the atlas.

The **obliquus superior arises** from the transverse process of the atlas, and is **inserted** into the occipital bone beneath and external to the complexus and above the inferior curved line (Fig. 312, p. 397).

The **rectus capitis posticus major arises** from the spine of the axis, and is **inserted** into the occipital bone beneath the obliquus superior and complexus, and below the inferior curved line (Fig. 312, p. 397).

The **rectus capitis posticus minor arises** beneath the previous muscle from the spine of the atlas, and is **inserted** into the occipital bone below the inferior curved line internal to and beneath the rectus capitis posticus major (Fig. 312, p. 397).

The **rotatores dorsi** are eleven pairs of small muscles occupying the vertebral groove in the thoracic region, beneath the transverso-spinales, of which they form the deepest fibres. Each consists of a small slip **arising** from the transverse process, and **inserted** into the lamina of the vertebra directly above.

The **inter-spinales** are bands of muscular fibres connecting together the s processes of the vertebræ.

The **inter-transversales** are slender slips extending between the trai processes. They are double in the neck, the anterior divisions of the spinal passing between them.

The **rectus capitis lateralis**, extending from the transverse process of th to the jugular process of the occipital bone (Fig. 312, p. 397), is homologou the posterior of the two inter-transverse muscles. In the loin the inter-transv muscles are usually double, but they are often absent, or are replaced by mem

Nerve-Supply.

With the exception of the vertebro-scapular and vertebro-humeral muscles (tr latissimus dorsi, levator anguli scapulæ, rhomboidei, p. 318), the muscles of the back supplied by the *posterior primary divisions* of the spinal nerves. In the upper part of th the muscles are supplied mainly by the external branches; in the lower part chiefly internal branches of the nerves. In the cervical and sacral regions a limited plexiform a ment of the nerves occurs (*posterior cervical* and *posterior sacral plexuses*).

Actions.

The action of these muscles is extremely complex. Not only do they act on the column, ribs, head, and pelvis, in conjunction with other muscles, but some of them act relation to the movements of the limbs as well. In this section will be given an analysis movements in relation to the spinal column, head, and pelvis. The movements of the li of the ribs (respiration) are dealt with in other sections. The chief muscles are engaged serving the erect position, and in the movements of the trunk they are assisted in large by muscles whose chief movements are referred to elsewhere.

1. **Movements of the Spinal Column.**—The movements of the vertebral column are extension, and lateral movement or rotation. These movements occur in all regions thorax, and loin; flexion and extension and lateral movement are most limited in the r the thorax; while rotation is most limited in the region of the loin.

a. **Flexion** and **Extension.**

Longus colli	Serrati postici
Rectus capitis anticus major	Splenius capitis
Scaleni antici (together)	Splenius colli
Psoas magnus and parvus	Erector spinæ
Levator ani	Semispinalis dorsi
Ischio-coccygeus	Semispinalis colli
	Complexus
Sphincter ani externus	Multifidus spinæ
Rectus abdominis	Interspinales
Pyramidalis abdominis	
Obliquus externus abdominis	Intercostal muscles
Obliquus internus „	Diaphragm

E FASCIÆ AND MUSCLES OF THE HEAD AND NECK.

FASCIÆ.

uperficial fascia of the head and neck possesses certain features of special Over the scalp it is closely adherent to the skin and subjacent epicranial is, and contains the superficial vessels and nerves. Beneath the skin of s it is loose and thin and contains no fat. Over the face and at the e neck it is separated from the deep fascia by the facial muscles and ma myoides. In the hollow between the buccinator and the masseter nuous with a pad of fat (*suctorial pad*) occupying the interval between cles.

The **extrinsic muscles of the ear** are three in number: retrahens, att and attrahens aurem.

The **retrahens aurem** (m. auricularis posterior) is a narrow fleshy slip arises from the surface of the mastoid process and is inserted into the deep su of the pinna. It bridges across the groove between the mastoid process an pinna, and conceals the posterior auricular vessels and nerve.

The **attollens aurem** (m. auricularis superior) is a small fan-shaped m which arises from the temporal fascia, and descends to be inserted into the t the root of the pinna.

The **attrahens aurem** (m. auricularis anterior) is a similar small muscle, p in front of the attollens, and stretching obliquely between the temporal fasci the top of the root of the pinna.

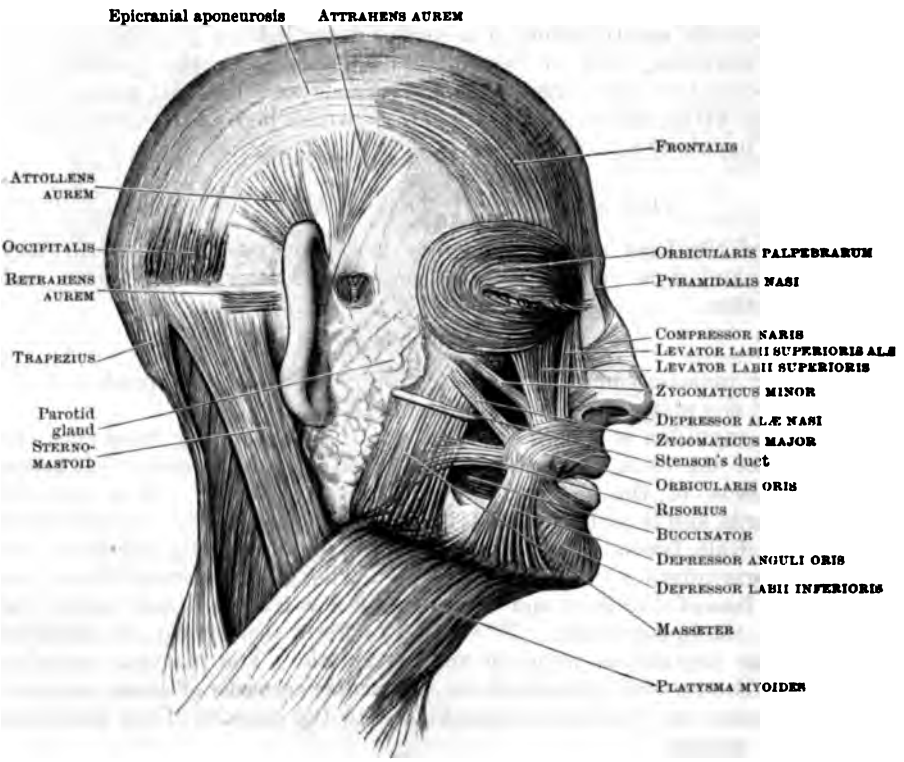

FIG. 314.—THE MUSCLES OF THE FACE AND SCALP (muscles of expression).

These two muscles conceal branches of the temporal vessels as they lie temporal fascia.

The ear muscles are rudimentary and usually functionless.

THE MUSCLES OF THE FACE.

The facial muscles are divided into three groups, associated with the s apertures of the eye, nose, and mouth.

1. The **muscles of the eyelids** include four muscles: the levator pal superioris (described with the orbital muscles), orbicularis palpebrarum, tensor and corrugator supercilii.

The **orbicularis palpebrarum** (m. orbicularis oculi) is a transversely sphincter muscle surrounding and occupying the eyelids. It is divisible in *external portion* (pars orbitalis) composed of coarse fibres, spreading on to the for temple, and cheek, and an *internal portion* (pars palpebralis), composed o fibres, situated beneath the skin of the eyelids. At the inner canthus of t the muscle (by its palpebral fibres) gains an attachment to the tarsal lig

l **the borders** of the naso-lachrymal groove. Its fibres enclose the lachrymal **and the canaliculi.** The posterior fibres, extending between the posterior edge **the naso-lachrymal** groove and the tarsal ligaments behind the lachrymal sac, **ıstitute the tensor tarsi muscle.** The fibres of the muscle which extend along the **ırgins of the lids constitute a separate ciliary bundle.**

Externally the orbicularis palpebrarum has no bony attachment; so that when **contracts and closes** the eyelids, both lids at the same time tend to be drawn **wards towards** the inner canthus of the eye.

The corrugator supercilii arises from the nasal eminence, and passing horizon**lly outwards, blends** with the upper fibres of the orbicularis palpebrarum on its **ıder surface.** The contraction of this muscle throws the skin of the forehead into **rtical folds,** while at the same time drawing the inner half of the eyebrow upwards, **produces** concentric curved folds on each side of the middle line of the forehead.

2. The **muscles of the nose** comprise five small muscles proper to the nose, and **e common** to the nose and upper lip: the pyramidalis nasi, compressor naris. **latores naris** (anterior and posterior), depressor alæ nasi, and levator labii **perioris alæque nasi.** They are all small and feeble.

The **pyramidalis nasi arises** from the occipito-frontalis muscle and the skin **er the glabella;** it is **inserted** into a membrane stretching over the nose, which **so** gives attachment to the compressor naris.

The **compressor naris** (m. nasalis) **arises** by a narrow origin from the superior **ıxilla,** under cover of the levator labii superioris alæque nasi. It passes forwards **er the bridge** of the nose, and ends in a membranous **insertion** common to it and **e** previous muscle.

The **dilatores naris** are feeble muscular slips placed on the outer side of the **ırgin** of the nostril, one anteriorly, the other posteriorly.

The **depressor alæ nasi** is a small muscle **arising** from the upper part of the **:isor fossa** of the maxilla; it divides into two parts as it passes upwards and **wards,** and is **inserted** into the ala and the septum of the nose (depressor septi).

The **levator labii inferioris alæque nasi** is a narrow band **arising** from the root **the nasal process** of the maxilla. It descends alongside the nose, and is **inserted** **rtly** into the ala of the nose and partly into the orbicularis oris muscle.

3. The **muscles of the mouth** comprise eleven muscles, of which all but one, **ıe** orbicularis oris, are bilaterally placed. The muscles are: levator labii superioris **aeque** nasi, levator labii superioris, levator anguli oris, zygomatici (major and **inor**), risorius, orbicularis oris, depressor anguli oris, depressor labii inferioris, **vator** menti, and buccinator.

The **orbicularis oris** is the sphincter muscle surrounding the lips. It is con**nuous** with the other muscles converging to the mouth. It lies between the skin **nd** mucous membrane of the mouth, and is limited above by the nose, below by **he** junction of lower lip and chin. Its mesial fibres are attached above to the **eptum** of the nose (naso-labial band) and to the incisor fossa (superior incisive **undle**); below they are attached to the lower jaw on each side of the symphysis **inferior** incisive bundle). These bundles radiate outwards to join the rest of the **nuscle,** which is joined at its margin by the levators and depressors of the lower **ip** and angle of the mouth, and by the buccinator muscle. The *lower fibres* of the **nuscle** are continued laterally into the buccinator and levator anguli oris; its *pper fibres* are continued into the buccinator and depressor anguli oris.

The **levator labii superioris alæque nasi** has already been described.

The **levator labii superioris arises** from the superior maxilla just above the **nfra-orbital** foramen. It passes almost vertically downwards to join the orbi**ularis** oris and the skin of the upper lip between the attachments of the levator **abii superioris** alæque nasi and the levator anguli oris. It conceals the infra**rbital** vessels and nerve.

The levator anguli oris arises from the canine fossa of the upper jaw below the **nfra-orbital foramen** and under cover of the foregoing muscle. It is directed **outwards and downwards,** to be **inserted** into the orbicularis oris and the skin at **he angle of the mouth.**

The **zygomatici (major and minor)** are more superficial than the prec muscle.

The **zygomaticus minor** is the anterior muscle. It **arises** from the malar and is often continuous with the most peripheral fibres of the **orbicularis p** brarum. It is directed obliquely downwards and forwards over the **levator a** oris, to be **inserted**, along with the levator labii superioris, into the **orbicularis** The **zygomaticus major** is a narrow muscular band which **arises** from the r portion of the zygomatic arch. It passes to the angle of the mouth, to be ins partly into the skin, partly into the orbicularis oris.

The **risorius** is a thin flat muscle which forms in part a continuation o platysma myoides on the face, in part a separate muscle, with an **origin** fron masseteric fascia. It passes transversely forwards, to be **inserted** at the ang the mouth into the orbicularis oris and skin.

The **depressor anguli oris arises** from the external oblique line of the lowe and from the platysma myoides (Fig. 319, p. 407). It is triangular in for fibres converging to the angle of the mouth, where they are **inserted** int orbicularis oris and the skin. Some of the fibres reach the upper lip throug orbicularis muscle.

The **depressor labii inferioris arises** from the outer surface of the lowe beneath and internal to the depressor anguli oris (Fig. 319, p. 407). It is qu lateral in form, and is directed upwards, to be **inserted** into the orbicularis ori the skin of the lower lip. Its external fibres conceal the mental foramen, an overlapped by the depressor anguli oris. Its internal fibres join with those o opposite muscle.

The **levator menti** is a small muscle which **arises** from the incisor fossa o lower jaw (Fig. 319, p. 407), and passing forwards, is **inserted** into the sk the chin.

The **buccinator muscle** forms the lateral wall of the mouth, and is in posteriorly with the constrictor muscles of the pharynx. It **arises** (1) fron alveolar arches of the upper and lower jaws (Fig. 319, p. 407), and between attachments, from the pterygo-mandibular ligament. Its fibres are dir forwards to the angle of the mouth, where they blend with the correspo (upper and lower) portions of the orbicularis oris muscle. The *middle fibres* muscle decussate at the angle of the mouth, so as to pass, the lower set t upper lip, the upper set to the lower lip. The buccinator is covered on its surface by the mucous membrane of the mouth. Superficially it is conceale the muscles above mentioned, which converge to the angle of the mouth; separated from the masseter by the *suctorial pad of fat*; it is pierced by the of the parotid gland, and by branches of the long buccal nerve.

Nerve-Supply.

The facial and scalp muscles are all innervated by the **facial nerve**. The *posterior au branch* supplies the retrahens aurem and occipitalis; the branches forming the *pes an* supply the frontalis, attollens, and attrahens aurem, the several muscles associated wi apertures of the eye, nose, and mouth (including the buccinator), and the platysma myoide

Actions.

The almost infinite variety of facial expression is produced partly by the action o muscles, partly by their inactivity, or by the action of antagonising muscles (antithesis). one hand joy is, for example, betrayed by the action of one set of muscles, while grief is panied by the contraction of another (opposing) set. Determination or eagerness is accom by a fixed expression due to a combination of muscles acting together; despair, on the hand, is expressed by a relaxation of muscular action. For a philosophical account of the of the facial muscles, the student should consult Darwin's *Expression of the Emotions in M Animals*, and Duchenne's *Mechanisme de la Physiologie humaine*.

The **platysma myoides** retracts and depresses the angle of the mouth, and depresses th jaw. The **occipito-frontalis**, by its anterior belly, raises the eyebrows; both bellies together tighten the skin of the scalp; acting along with the orbicularis palpebrarum, it the scalp backwards and forwards. The **corrugator supercilii** draws inwards the e and vertically wrinkles the skin of the forehead. The **pyramidalis nasi** draws downwa skin between the eyebrows, as in frowning. The upper eyelid is raised by the **levator pa superioris**. The closure of the lids is effected by the **orbicularis palpebrarum**, whose fibr

ıe **lowering** of the eyebrows, in the protection of the eyeball, and, by pressure on nal **gland**, in the secretion of tears. The **tensor tarsi**, acting along with the orbicularis m, **compresses** the lachrymal sac and aids in the passage of its contents into the nasal e **muscles of the ear** and **nose** have quite rudimentary actions expressed by their f the muscles of the mouth, the **orbicularis oris** has a complex action, depending on the ɔntraction of its component parts. It causes compression and closure of the lips in ,ys, tightening the lips over the teeth, contracting them as in osculation, or causing protrusion of one or the other. The **accessory muscles** of the **lips** draw them upwards i, levator anguli oris, levator labii superioris alæque nasi, levator labii superioris), zygomaticus major, risorius, platysma, depressor anguli oris, buccinator), and down- ressor anguli oris, depressor labii inferioris, platysma). The **levator menti** elevates the : chin and protrudes the lower lip. The **buccinator** retracts the angles of the mouth, ɜ cheeks, and brings them in contact with the teeth.

The Fascia and Muscles of the Orbit.

eyeball with its muscles, vessels, and nerves, is lodged in a mass of soft ling fat which entirely fills up the cavity of the orbit. Surrounding rior part of the eye- ıe **capsule of Tenon**, ɔnstitutes a large space or synovial relation to the eye- ıteriorly the capsule ntact with the con- ɜ, and intervenes the latter and the ; posteriorly it is by and prolonged e optic nerve. It is membrane connected lobe of the eye by ɔolar tissue. It is ɔy the tendons of the uscles, along which it sends prolongations continuous with the muscular sheaths.

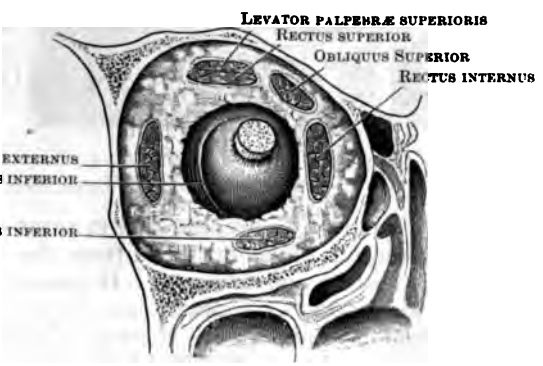

Fig. 315.—Transverse Vertical Section through the Orbit behind the Eyeball to show the Arrangement of Muscles.

316.—The Muscles of the Orbit (from above).

The **muscles of the orbit** are seven in number: one, the levator palpebræ superioris, belongs to the upper eyelid; the other six are muscles of the eyeball.

The **levator palpebræ superioris** lies immediately beneath the orbital periosteum and covers the superior rectus muscle. It has a narrow **origin** above that muscle from the margin of the optic foramen. It expands as it passes forwards, to end, in relation to the upper lid, in a membranous expansion which is **inserted** in a fourfold manner: (1) slightly into the orbicularis palpebrarum and skin of the upper lid, (2) mainly into the upper border of the tarsal cartilage, (3) slightly into the conjunctiva, and (4) by its edges into the upper border of the margin of the orbital opening.

The **recti muscles** are four in number—**superior**, **inferior**, **internal**, and **external**. They all **arise** from a membranous ring surrounding the optic foramen, which is separable into two *superior common tendon*, giving origin to the superior and internal

recti and the upper head of the external rectus; and an *inferior common ten* giving origin to the internal and inferior recti and the lower head of the exte rectus. The two origins of the external rectus muscle are separated by the pas into the orbit of the oculo-motor, nasal, and abducent nerves. Forming flatte bands which traverse the fat of the orbit around the optic nerve and eyeball, four muscles in tendons wh pierce the cap of Tenon, and inserted into sclerotic about 6 millimetres (th to four lines) beh the margin of cornea. The erior and infe recti are inserte the vertical p slightly interna the axis of the ball; the exte and internal rec the transverse p

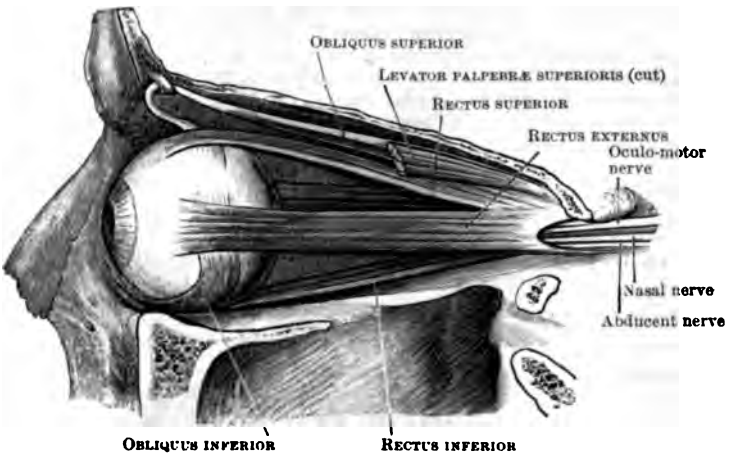

Fig. 317.—The Muscles of the Orbit (from without).

of the eyeball; and all are attached in front of the equator of the eyeball.

The **obliquus superior arises** from the margin of the optic foramen betw the recti superior and internus. It passes forwards as a narrow muscular b internal to the rectus superior, and at the anterior margin of the orbit forn narrow tendon which passes through a special fibrous pulley (trochlea) atta to the roof of the orbit. Its direction is then altered, and passing outw

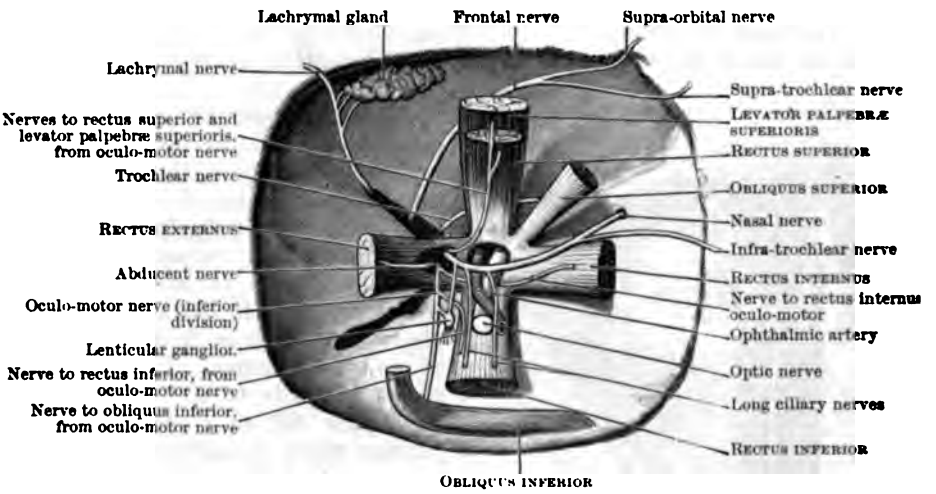

Fig. 318.—Schematic Representation of the Nerves which traverse the Cavity of the Or

between the tendon of the superior rectus and the eyeball, it is **inserted** into sclerotic between the superior and external recti, midway between the margi the cornea and the entrance of the optic nerve.

The **obliquus inferior arises** from the inner side of the floor of the orbit behind its anterior margin, and external to the naso-lachrymal groove. It fo a slender rounded slip, which curls round the inferior rectus tendon, and pa between the external rectus and the eyeball, to be **inserted** into the scler between the superior and external recti, and farther back than the supe oblique muscle.

Müller's muscle is a rudimentary bundle of non-striated muscular fibres bridging acros

o-maxillary fissure and infra-orbital groove. It is supplied by fibres from the sympathetic, ıay have a slight influence in the protrusion of the eyeball.

Nerve-Supply.

ıe muscles of the orbital cavity are supplied by the third, fourth, and sixth cranial nerves. fourth nerve (trochlearis) supplies the obliquus superior; the sixth (abducens) supplies the ı externus; the third nerve (motor oculi) supplies the others—levator palpebræ superioris, superior, inferior and internus, and obliquus inferior.

Actions.

ıe **levator palpebræ superioris** elevates the upper eyelid and antagonises the orbicularis brarum muscle. The six muscles inserted into the eyeball serve to move the longitudinal f the eyeball upwards, downwards, inwards, and outwards, besides causing a rotation of the ll on its own axis. The following table expresses the action of individual muscles. It must membered that, while similar movements occur simultaneously in the two eyeballs, the ıntal movements may, by adduction of the muscles of both sides, cause convergence of the f the two eyeballs for the purposes of near vision.

a. **Adduction** and **Abduction.**	
Rectus internus Rectus superior } Rectus inferior }	Rectus externus Obliquus superior } (*correcting* Obliquus inferior } *adductors*)
b. **Elevation** and **Depression.**	
Rectus superior Obliquus inferior	Rectus inferior Obliquus superior
c. **Rotation outwards.**	**Rotation inwards.**
Obliquus inferior	Obliquus superior Rectus superior } Rectus inferior } (*in adduction*)

Muscles of Mastication.

he muscles of mastication comprise the masseter, temporal, external and ıal pterygoids, buccinator (de- ed above).

he **masseter** ın **origin** which ırtly tendinous ıartly fleshy. It s in two parts: ıperficially from lower border of zygoma in its rior two-thirds. (2) more deeply the deep or r surface of the ma in its whole h. The super- l fibres are ted downwards backwards to- s the angle of jaw; the deeper fibres are directed vertically downwards. The muscle is ted by fleshy and tendinous fibres into the outer surface of the ramus and e of the lower jaw and the coronoid process (Fig. 319, p. 407). The deepest s blend with the fibres of the subjacent temporal muscle.

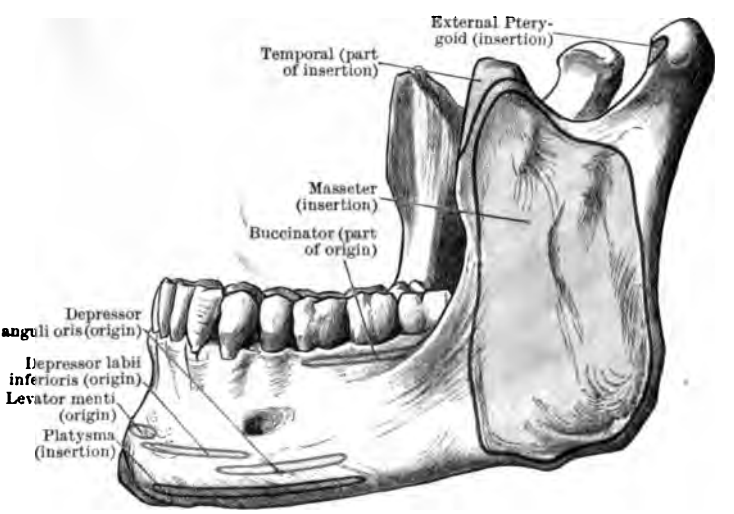

Fig. 319.—Muscle-Attachments to the Outer Aspect of the Lower Jaw.

The masseter muscle occupies the posterior part of the cheek. It is covered by the parotid gland, and is crossed by Stenson's duct and the branches of

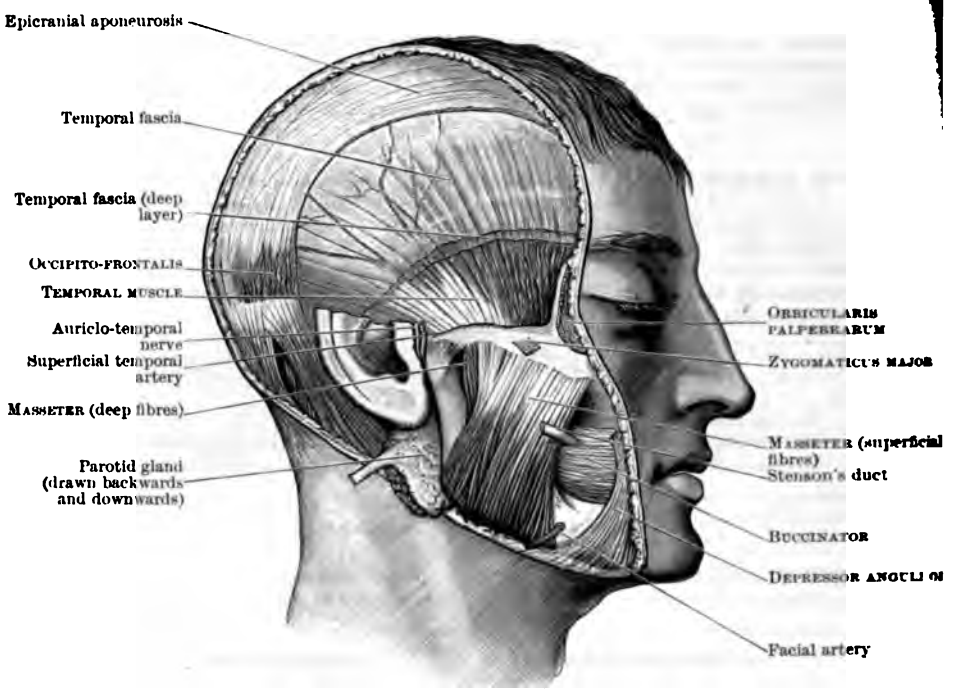

Fig. 320.—Muscles of Mastication (superficial view).

facial nerve. It conceals the lower jaw and a part of the temporal muscle, and separated from the buccinator muscle anteriorly by a pad of fat.

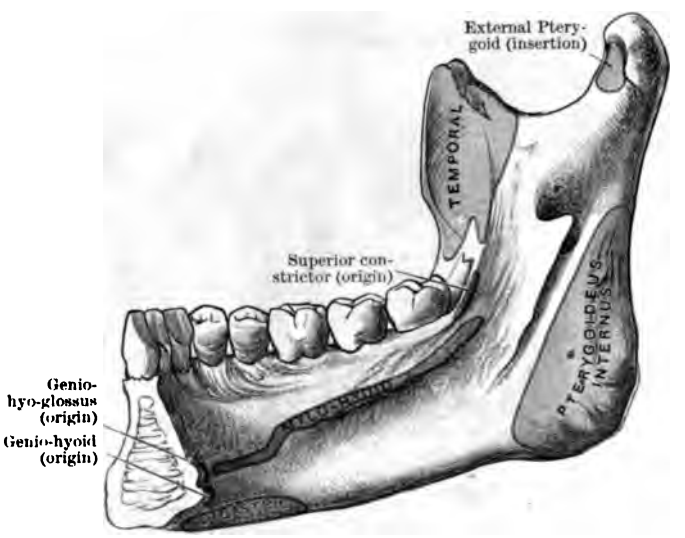

Fig. 321.—Muscle-Attachments on the Inner Side of the Lower Jaw.

The **temporal muscle** is a fan-shaped muscle **arising** from the whole area of the temporal fossa, as well as from the temporal fascia which covers it. Its converging fibres pass beneath the zygomatic arch. In the pterygoid region the muscle is **inserted** into the deep surface and apex of the coronoid process, and into the anterior border of the ramus of the lower jaw (Figs. 319, p. 407, and 321, p. 408).

The muscle is concealed by the temporal fascia, zygoma, the masseter muscle, and the coronoid process. It crosses over the external pterygoid muscle and the internal maxillary artery.

The **external pterygoid muscle arises** by two heads, upper and lower. The upper head is attached to the under surface of the great wing of the sphenoid; the lower head takes origin from the outer surface of the external pterygoid plate. The

uscle is directed outwards and backwards, to be inserted into (1) the depression in ont of the neck of the lower jaw (Figs. 319, p. 407, and 321, p. 408), and (2) the ter-articular fibro-cartilage and capsule of the temporo-maxillary articulation.

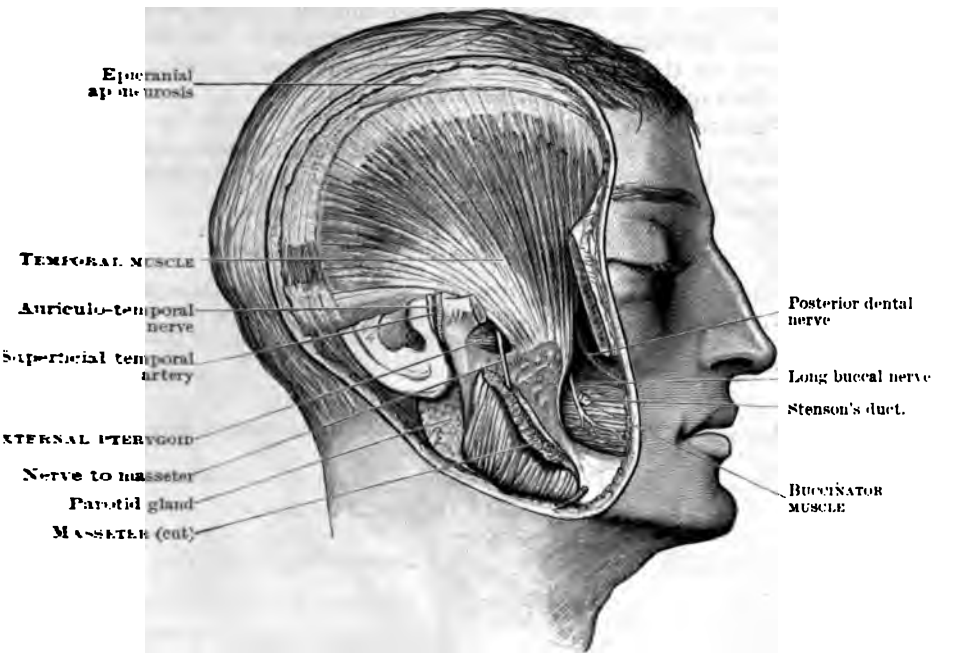

Fig. 322.—Muscles of Mastication, Deeper View (zygoma and masseter muscle removed).

The muscle is placed deeply in the pterygoid region. Covered by the temporal muscle and coronoid process, it partially conceals the internal pterygoid muscle

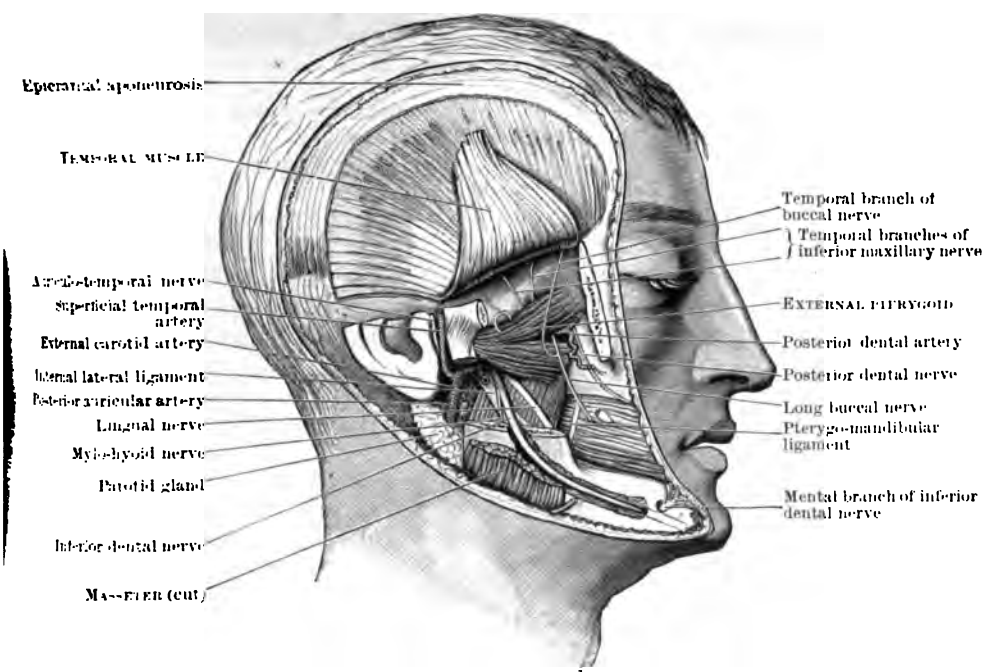

Fig. 323.—Pterygoid Region.

and the trunk and branches of the inferior maxillary nerve. The internal maxillary artery passes over or under the muscle, and disappears between its two heads of origin on its way to the spheno-maxillary fossa.

The **internal pterygoid muscle** has likewise a double **origin**—(1) from the d surface of the external pterygoid plate and the tuberosity of the palate, and by a stout tendon from the tuberosity of the upper jaw. Its two heads of ori embrace the lower fibres of the external pterygoid muscle. It is quadrilateral form, and is directed downwards, outwards, and backwards, to be **inserted int** triangular impression on the inner surface of the lower jaw, between the my hyoid groove and the angle of the bone (Fig. 321, p. 408).

The muscle is covered over by the external pterygoid muscle, by branches the inferior maxillary nerve, and by the internal lateral ligament and ramus the lower jaw. Beneath it are the Eustachian tube, muscles of the soft palate, a the pharynx (superior constrictor).

Nerve-Supply.

The **inferior maxillary division of the fifth nerve** supplies all the muscles of masticati except the buccinator, which is supplied by the **facial nerve**. The internal pterygoid muscle supplied by the nerve before its division into anterior and posterior parts; the other muscles a innervated by the anterior trunk.

Actions.

The above muscles, assisted by others in the neck, produce the various movements of th lower jaw, as follows:—

***a.* Opening and Closure of the Jaw.**	
Weight of the jaw Digastric Mylo-hyoid Genio-hyoid Genio-hyo-glossus Infra-hyoid muscles	Masseter Temporal Internal pterygoid
***b.* Protrusion and Retraction.**	
External pterygoid Internal pterygoid Temporal (*anterior fibres*)	Temporal (*posterior fibres*)
***c.* Lateral Movement of the Jaw.**	
External pterygoid } (*of one side*) Internal „ }	

THE MUSCLES OF THE NECK.

The muscles in the neck include, in addition to those included in the description of the muscles of the back (p. 395), the following series: (1) sterno-cleido-mastoid; (2) the muscles of the hyoid bone (supra-hyoid and infra-hyoid); (3) the muscles of the tongue (extrinsic and intrinsic); (4) the muscles of the pharynx and soft palate; and (5) the prævertebral muscles.

The **sterno-cleido-mastoid muscle** is the prominent muscle projecting on the side of the neck. It **arises** by two heads—(1) a narrow tendinous *sternal* **head**, from the anterior surface of the manubrium sterni (Fig. 246, p. 322), and (2) a broader *clavicular* origin, partly tendinous, partly fleshy, from the upper surface of the clavicle in its inner third (Fig. 243, p. 319). The muscle is **inserted into the** outer surface of the mastoid process and into the superior curved line of the occipital bone (Fig. 324, p. 411).

The sterno-cleido-mastoid muscle stretches obliquely across the neck, and separates the anterior and posterior triangles from one another. Superficially it is covered by the platysma myoides muscle, the external jugular vein, and some of the superficial branches of the cervical plexus. It conceals the splenius capitis, digastric, levator anguli scapulæ, scaleni and infra-hyoid muscles, the carotid

sheath, the cervical plexus, and the spinal accessory nerve. The last-named nerve pierces the muscle.

The sterno-cleido-mastoid muscle is properly divisible into three parts: (1) **sterno-mastoid,** placed superficially, and passing obliquely from the sternum to the mastoid process; (2) **cleido-mastoid,** placed more deeply, and directed vertically upwards from the clavicle to the mastoid

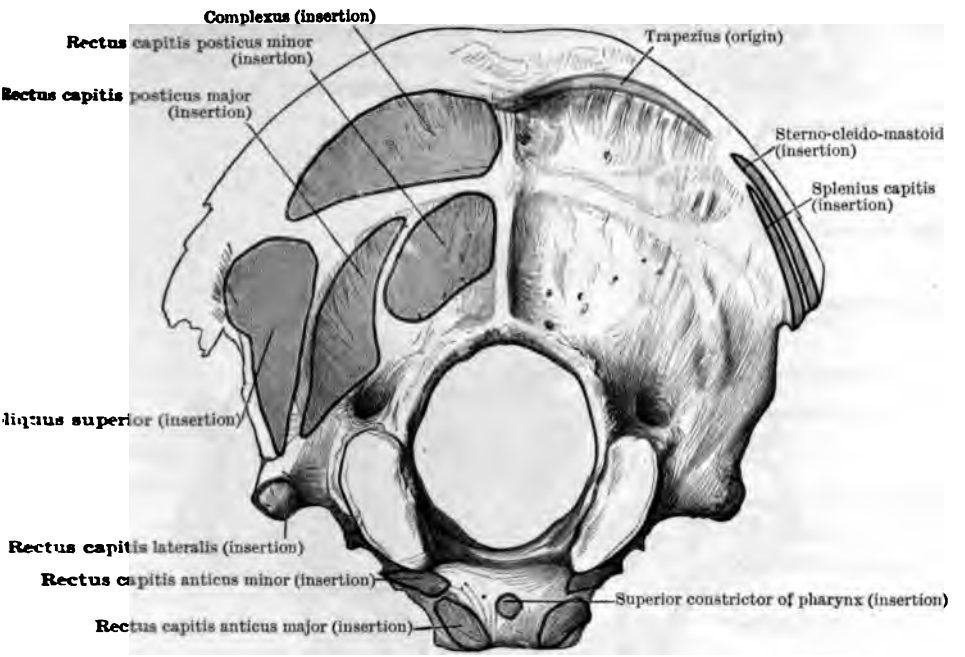

FIG. 324.—MUSCLE-ATTACHMENTS TO OCCIPITAL BONE (Inferior Surface).

process; and (3) **cleido-occipitalis,** passing obliquely upwards and backwards behind the cleido-mastoid to the superior curved line of the occipital bone.

The sterno-mastoid muscle is innervated by the spinal accessory nerve, joined by a branch from the cervical plexus (C. 2).

The action of the muscle is referred to below.

THE MUSCLES OF THE HYOID BONE.

The muscles attached to the hyoid bone are in three series: (1) infra-hyoid muscles, connecting the hyoid bone to the scapula, thorax, and thyroid cartilage; (2) supra-hyoid muscles, connecting it to the lower jaw, cranium, and tongue; and (3) the middle constrictor muscle of the pharynx.

The infra-hyoid muscles comprise the omo-hyoid, sterno-hyoid, sterno-thyroid, and thyro-hyoid muscles.

The omo-hyoid is a muscle with two bellies, anterior and posterior. The *posterior* belly **arises** from the superior border of the scapula and the suprascapular ligament (Fig. 250, p. 325). It forms a narrow muscular band, which is directed obliquely forwards and upwards, to end in an intermediate tendon beneath the sterno-mastoid muscle. From this tendon the anterior belly proceeds upwards to be **inserted** into the outer part of the lower border of the body of the hyoid bone.

The posterior belly of the muscle separates the posterior triangle into occipital and subclavian parts; the anterior belly crosses the common carotid artery at the level of the cricoid cartilage, and in the anterior triangle forms the boundary between the muscular and carotid triangles. A process of the deep cervical fascia binds down the tendon and the posterior belly to the scapula and the first rib.

The sterno-hyoid muscle arises from the posterior surface of the presternum, from the back of the first costal cartilage, and from the clavicle (Fig. 243, p. 319). It passes vertically upwards in the neck, internal to the omo-hyoid and in front of the sterno-thyroid muscle, to be **inserted** into the inner part of the body of the

hyoid bone. Except near its origin the muscle lies superficially in the ante triangle, alongside the omo-hyoid and in front of the sterno-thyroid and thy hyoid muscles, the trachea and the thyroid body.

The **sterno-thyroid muscle arises** beneath the sterno-hyoid from the back the presternum and first costal cartilage. Broader than the preceding muscle passes upwards and slightly outwards in the neck in front of the trachea a thyroid body, and beneath the omo-hyoid and sterno-hyoid muscles, to be inser

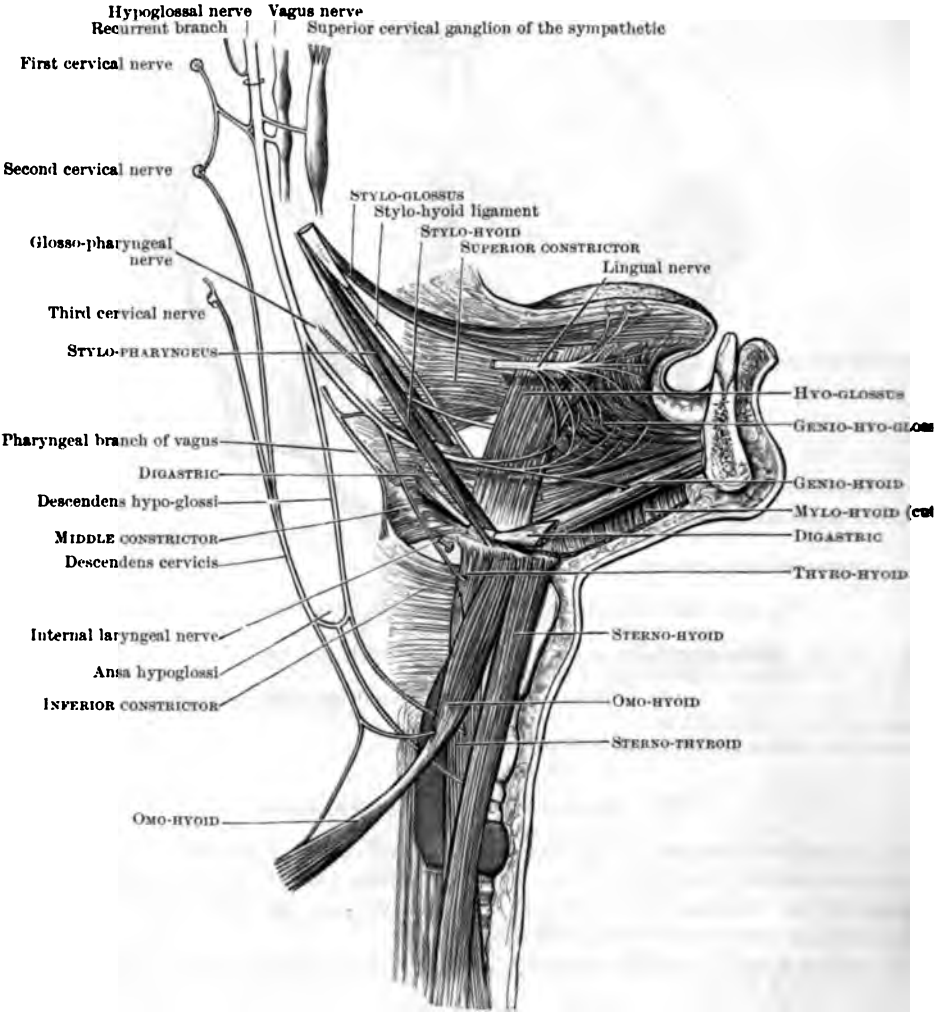

FIG. 325.—THE MUSCLES OF THE HYOID BONE AND STYLOID PROCESS, AND THE EXTRINSIC MUSCLES OF THE TONGUE, WITH THEIR NERVES.

into the oblique line of the thyroid cartilage. The muscle is marked by an oblic tendinous intersection in the middle of its length.

The **thyro-hyoid muscle** continues the line of the preceding **muscle to** hyoid bone. Short and quadrilateral, it **arises** from the oblique line of the thyr cartilage, and passing over the thyro-hyoid membrane beneath the omo-hyoid a sterno-hyoid, it is **inserted** into the body and great cornu of the hyoid bone.

The **levator glandulæ thyroideæ** is an occasional slip stretching between the hyoid b and the isthmus or pyramid of the thyroid body.

The **supra-hyoid muscles** comprise the digastric, stylo-hyoid, **mylo-hyo** genio-hyoid muscles, and also two muscles, the genio-hyo-glossus and **hyo-glos** which will be described along with the extrinsic muscles of the tongue.

The digastric muscle, as its name implies, possesses two bellies—anterior and **posterior.** The posterior belly **arises** from the digastric groove beneath the mastoid **process.** It is directed forwards and downwards to end in an intermediate tendon, **which is connected** by a pulley-like band of cervical fascia to the body of the hyoid **bone.** The anterior belly of the muscle is directed forwards and upwards to the **chin, and is inserted** into an oval impression on the lower border of the mandible **close** to the symphysis (Fig. 327, p. 414). The muscle forms the boundary of the **submaxillary** space. The posterior belly is concealed at its origin by the mastoid

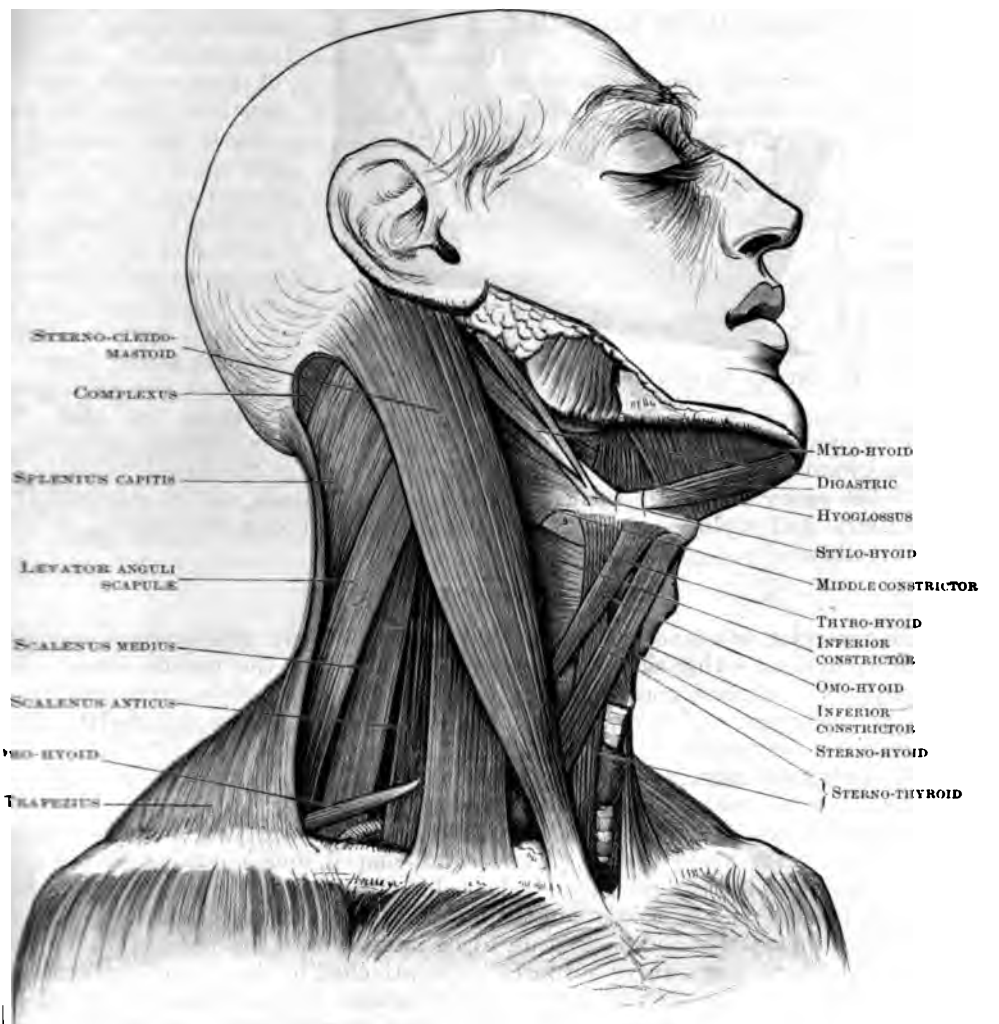

Fig. 326.—The Triangles of the Neck (Muscles).

process and the muscles attached to it. In company with the stylo-hyoid muscle it crosses the carotid vessels and the hypoglossal nerve in the anterior triangle. The anterior belly of the digastric covers the mylo-hyoid muscle.

The **stylo-hyoid muscle arises** from the styloid process of the temporal bone near its base, and is **inserted** into the body of the hyoid bone by two slips which enclose the tendon of the digastric muscle. It is directed downwards and forwards alongside the posterior belly of the digastric, and crosses the anterior triangle in front of the carotid vessels.

The **mylo-hyoid muscle arises** from the lower three-fourths of the mylo-hyoid ridge of the lower jaw (Fig. 327, p. 414). It is directed downwards and inwards, to be **inserted** into (1) the upper border of the body of the hyoid bone, and more

anteriorly (along with the opposite muscle) into (2) a median raphe extendin the hyoid bone nearly to the chin. The muscle forms a diaphragm in the the mouth, and contact with its ficial or external the digastric mus the submaxillary Its deep or in surface is par covered by the r membrane of th of the mouth, separated from th glossus and geni glossus muscles deep part of th maxillary glan sublingual gland, ton's duct and the and hypoglossal

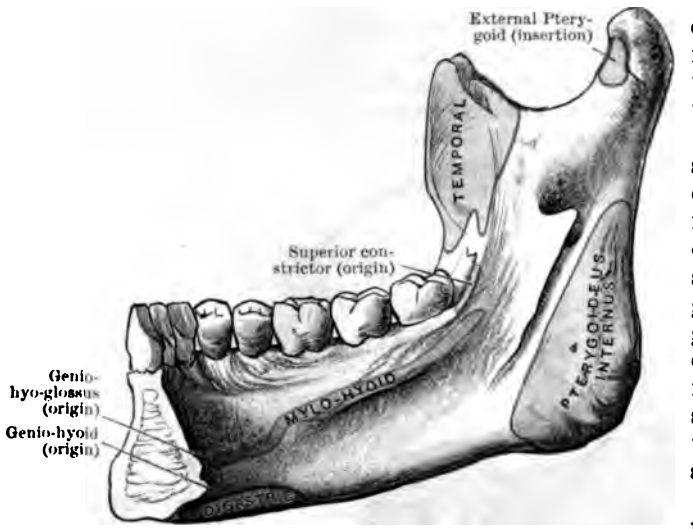

FIG. 327.—MUSCLE-ATTACHMENTS ON THE INNER SIDE OF THE LOWER JAW.

The **genio-muscle arises** fr lower of the two tubercles on the of the symphysis of the lower jaw (Fig. 327, p. 414). It is directed dow and backwards, to be **inserted** into the front of the body of the hyoid bone muscle lies along the lower border of the genio-hyoglossus, and is conce the digastric and mylo-hyoid muscles. The muscles of opposite sides ar fused together.

THE MUSCLES OF THE TONGUE.

The muscular substance of the tongue consists of two symmetrical s muscles placed on either side of a membranous raphe in the middle line. composed of (1) **extrinsic muscles** arising from the soft palate, styloid proces bone and lower jaw, and (2) **intrinsic muscles** proper to the tongue itself. set consists of four series of muscles.

The **extrinsic muscles** are four in number: (1) genio-hyo-glossus, (glossus, (3) stylo-glossus, and (4) palato-glossus.

The **genio-hyo-glossus muscle** (Fig. 325) is an extrinsic muscle of the as well as a supra-hyoid muscle. It is a fan-shaped muscle **arising** by i from the upper of the two genial tubercles behind the symphysis of the low (Fig. 327, p. 414). From this origin the muscular fibres diverge; the lowes are directed downwards and backwards, to be **inserted** into the body of the bone; the highest fibres curve forwards, to be attached to the tip of the t the intermediate fibres are attached to the substance of the tongue in its length between the base and tip. The muscles of opposite sides are separa the median raphe of the tongue. On the outer side of each are the hyo-gloss mylo-hyoid muscles. Between the hyo-glossus and genio-hyo-glossus are pla stylo-hyoid ligament, the lingual artery, and the glosso-pharyngeal nerve.

The **hyo-glossus muscle** is also an extrinsic muscle of the tongue as w supra-hyoid muscle. It **arises** from the hyoid bone (body and great cornu) directed upwards and forwards, to be **inserted** into the side of the tongue, its fibre lacing at its insertion with the fibres of the stylo-glossus. The muscle is quadri and lies between the genio-hyo-glossus and mylo-hyoid muscles, separated fr latter by the mucous membrane of the floor of the mouth, the sublingual ar of the submaxillary glands, the lingual and hypoglossal nerves, and Wharton

The **chondro-glossus** is a small separated slip of the hyo-glossus, not always present.

The **stylo-glossus muscle arises** beneath the parotid gland from the lov

he **styloid process** and from the stylo-mandibular ligament. It sweeps forwards inwards, and is **inserted** into the side and under surface of the tongue, its es spreading out to decussate with those of the palato-glossus and hyo-glossus scles. It is covered by the internal pterygoid muscle and by the mucous nbrane of the tongue.

The **palato-glossus** is a thin sheet of muscular fibres **arising** from the under face of the soft palate, where it is continuous with fibres of the opposite muscle. asses downwards in the anterior pillar of the fauces, and spreads out, to be in-ed into the sides of the tongue, blending with the stylo-glossus and the deep nsverse fibres of the tongue. The muscle is placed directly beneath the mucous nbrane of the soft palate and tongue.

Intrinsic Muscles of the Tongue.—Besides receiving the fibres of insertion he extrinsic muscles, the substance of the tongue is composed of four intrinsic scles on either side, two in the sagittal plane, the superior and inferior linguales; in the coronal plane, the transverse and vertical fibres.

The **superior lingualis muscle** extends from base to tip of the tongue, placed on dorsum immediately under the mucous membrane, into which many of its fibres inserted.

The **inferior lingualis** is a cylindrical band of muscular fibres occupying the under t of the organ on each side, in the interval between the genio-hyo-glossus and hyo-glossus muscles. Posteriorly some of its fibres extend to the hyoid bone.

The **transverse fibres** arise from the median raphe, and radiate outwards to the sum and sides of the tongue, decussating with the extrinsic muscles and the es of the vertical muscle. They occupy the substance of the tongue between superior and inferior linguales.

The so-called **vertical fibres** arise from the dorsal surface of the tongue, and ep downwards and outwards to its sides, intermingled with the fibres of the vious muscle and the insertions of the extrinsic muscles. These two muscles n a very considerable part of the total muscular substance of the organ.

Nerve-Supply.

The muscles of the hyoid bone and of the tongue are for the most part supplied by the **ansa ricalis** (C. 1. 2. 3.) and by the **hypoglossal nerve**. A few of the muscles are supplied by the eminal, facial, and spinal accessory nerves.

Muscles.	Nerves.	Origin.
Omo-hyoid Sterno-hyoid Sterno-thyroid	Ansa cervicalis	C. 1. 2. 3.
Thyro-hyoid Genio-hyoid Genio-hyo-glossus Hyo-glossus Stylo-glossus Intrinsic muscles of tongue	Hypoglossal	C. 1. 2. Hypoglossal.
Palato-glossus	Pharyngeal plexus	Spinal accessory.
Mylo-hyoid Digastric Anterior belly	Mylo-hyoid branch of inferior dental nerve	Trigeminal.
Posterior belly Stylo-hyoid	Facial	Facial.

Actions.

These muscles have a complexity of action, owing to their numerous attachments to more ss movable points. The movements for which they are responsible in whole or part are (1) ements of the hyoid bone in mastication and deglutition, (2) movements of the thyroid lage, (3) movements of the tongue, (4) movements of the head, (5) movements of the shoulder, (6) respiration.

1) **Movements of the Hyoid Bone.**—The hyoid bone is elevated or depressed, and moved

forwards or backwards along with the lower jaw and tongue, in speech, masticatic swallowing.

a. **Elevation** and **Depression.**		*b.* **Protraction** and **Retraction.**	
Digastric	Thyro-hyoid	Genio-hyoid	Stylo-hyoid
Stylo-hyoid	Sterno-hyoid	Genio-hyo-glossus	Middle constrict
Mylo-hyoid	Omo-hyoid		
Genio-hyoid	Sterno-thyroid		
Genio-hyo-glossus			
Hyo-glossus			
Muscles closing the mouth			

(2) **Movements of the Thyroid Cartilage.**—The thyroid cartilage is raised and l during speech and deglutition.

Elevation.	**Depression.**
Thyro-hyoid	Sterno-thyroid
Stylo-pharyngeus	Crico-thyroid
Palato-pharyngeus	Depressors of hyoid bone
Elevators of hyoid bone	
Muscles closing mouth	

(3) **Movements of the Tongue.**—The chief movements of the tongue in speech a glutition are elevation and depression, protrusion and retraction, and lateral movements.

a. **Elevation** and **Depression.**	
Stylo-glossus (base)	Genio-hyo-glossus
Palato-glossus	Hyo-glossus
Muscles elevating hyoid bone	Chondro-glossus
Muscles closing mouth	Muscles depressing the hyoid bone

b. **Protrusion** and **Retraction.**	
Genio-hyo-glossus (*posterior fibres*)	Genio-hyo-glossus (*anterior fibres*)
	Stylo-glossus

c. **Lateral Movements.**—The muscles of one side only.

(4) **Movements of the Head.**—The sterno-mastoid muscles, acting together, flex the l the spinal column, assisted by the supra-hyoid and infra-hyoid muscles. The sterno-m muscle of one side, acting alone, bends the head to the same side, and simultaneously ro to the opposite side, as seen in *torticollis* (wryneck).

(5) **Movements of the Shoulder Girdle.**—The omo-hyoid and sterno-mastoid muscl already been included among the elevators of the shoulder girdle.

(6) **Respiration.**—The muscles in the front of the neck are auxiliary muscles in extraor or difficult inspiration. The masseter and temporal muscles fix the lower jaw; the hyoi is raised and fixed by the supra-hyoid muscles; and the sternum is raised by the sterno-m and infra-hyoid muscles.

The Muscles of the Pharynx.

The muscular envelope of the pharynx is composed of two strata. The *ea* or *circular layer* consists of the three constrictor muscles; the *internal* or *tudinal layer* consists of the fibres of the stylo-pharyngeus and palato-phary muscles.

The **superior constrictor muscle** is triangular or fan-shaped. It successively from the lower half of the posterior border of the internal pte plate, from the pterygo-mandibular ligament, from the mylo-hyoid ridge

ver jaw (Fig. 327, p. 414), and from the mucous membrane of the floor of the outh (*glosso-pharyngeus*). The muscular fibres radiate backwards, and are **inserted** the most part into a median raphe extending down the back wall of the pharynx the middle line. The highest fibres are attached to the pharyngeal spine of the cipital bone (Fig. 333, p. 421), and the lowest fibres are overlapped by the iddle constrictor. A crescentic interval occurs above the muscle, below e base of the skull, in which the ustachian tube and the levator and nsor palati muscles appear. Its wer border is separated from the iddle constrictor by the stylo-aryngeus muscle and the glosso-aryngeal nerve. The superior nstrictor muscle separates the internal carotid artery from the cavity the pharynx and tonsil.

Fig. 328.—Posterior View of the Pharynx and Constrictor Muscles.

The **middle constrictor muscle ises** from the stylo-hyoid ligament nd from both cornua of the hyoid one. From its origin the muscular bres radiate backwards, to be **in-rted** into the median raphe on the osterior aspect of the pharynx. The pper fibres overlap the lower part of he superior constrictor; the lower ibres are concealed from view by the nferior constrictor muscle. In the nterval between the middle and nferior constrictors are found the nternal laryngeal artery and nerve.

The **inferior constrictor muscle rises** from the oblique line of the thyroid cartilage, and from the side of the cricoid cartilage. Its fibres radiate backwards, to be **inserted** into the median raphe on the back of the pharynx, the upper fibres overlapping the lower part of the middle constrictor, the lower fibres blending with the muscular fibres of the œsophagus. Below the lower border of the muscle the inferior laryngeal artery and nerve enter into relation with the larynx.

The **deeper longitudinal stratum** of muscles in the pharyngeal wall is composed of the insertions of the stylo-pharyngeus and palato-pharyngeus muscles.

The **stylo-pharyngeus arises** from the root of the styloid process on its inner side, and passes downwards between the external and internal carotid arteries. It enters the wall of the pharynx in the interval between the superior and middle constrictor muscles. Spreading out beneath the middle constrictor muscle, it is **inserted** into the superior and posterior borders of the thyroid cartilage and into the wall of the pharynx itself, becoming continuous posteriorly with the palato-pharyngeus. In the neck the glosso-pharyngeal nerve winds round it on its way to the tongue.

The **palato-pharyngeus** occupies the soft palate and the pharyngeal wall. In the substance of the soft palate it consists of two layers, a postero-superior layer, thin, and continuous across the middle line with the corresponding layer on the opposite side, and an antero-inferior layer, which is thicker, and is attached to the posterior border of the hard palate. The levator palati and azygos uvulæ muscles are enclosed between the two layers, which unite at the posterior edge of the palate, receiving at the same time additional fibres arising from the Eustachian tube (*salpingo-pharyngeus*). The muscle descends to the pharynx in the posterior pillar

of the fauces. Its fibres spread out in the form of a thin sheet in the wa the pharynx, in continuity anteriorly with the stylo-pharyngeus, and are ins into the posterior border of the thyroid cartilage, and behind that into aponeurosis of the pharynx, reaching down as far as the lower border of the inf constrictor. The muscle is placed beneath the middle and inferior constrictor the pharyngeal wall, and the fibres of the muscles of opposite sides decussate i middle line beneath the median raphe.

The Muscles of the Soft Palate.

The soft palate and uvula form a muscular fold, covered on each surfac mucous membrane, projecting backwards into the pharynx, and forming the post part of the ro the mouth.

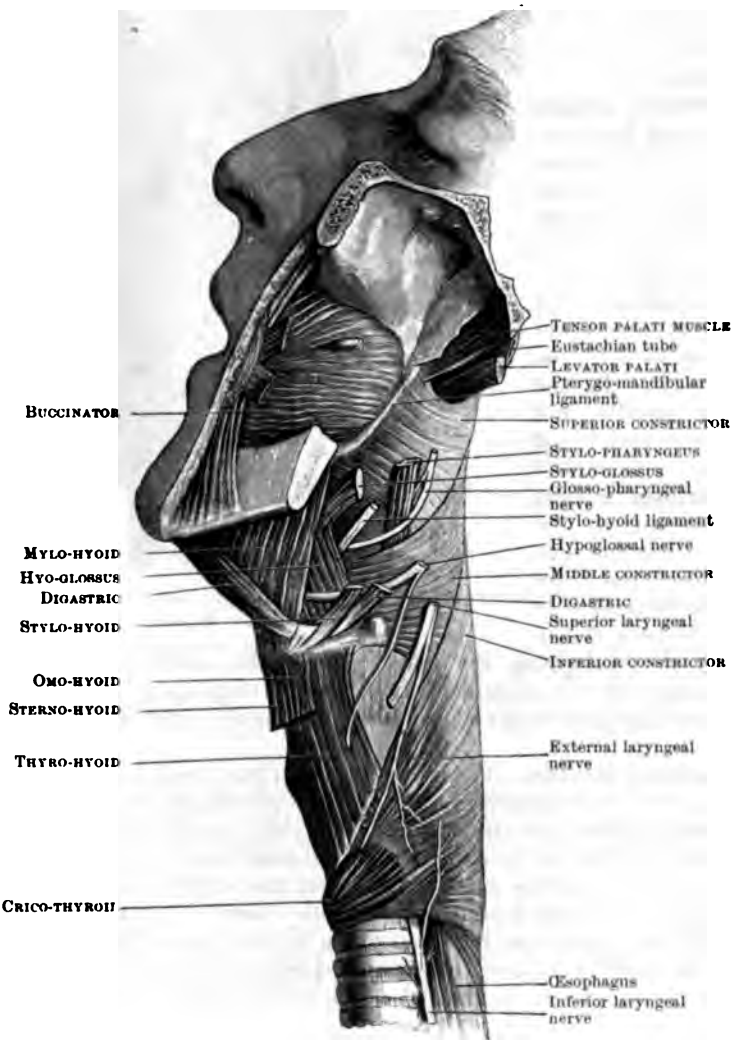

Fig. 329.—Lateral View of the Wall of the Pharynx.

The mus fold is compos five pairs of cles—the pa pharyngeus salpingo-pha geus), az uvulæ, lev palati, te palati, and pa glossus.

The **pal pharyngeus** cle has been ali described (p. among the mu of the pharyn

The **azy uvulæ** consis two narrow bu enclosed, a with the inse of the lev palati, betwee layers of the pa pharyngeus. slips **arise** fro posterior r spine and the neurosis of th palate, and as they pr backwards t in the uvula.

The **lev palati** has a d **origin**: (1) the under su of the apex of the petrous portion of the temporal bone, and (2) from lower part of the cartilaginous Eustachian tube. It passes obliquely d wards and inwards, across the upper border of the superior constrictor m and enters the soft palate between the two layers of the palato-pharyngeus m It is **inserted** into the aponeurosis of the soft palate, and some of its fibres be continuous with those of the opposite muscle. It is separated from the t

palati muscle by the Eustachian tube and the deeper layer of the palato-pharyngeus **muscle.**

The tensor (circumflexus) palati arises (1) from the scaphoid fossa and the alar spine of the sphenoid bone, and (2, from the outer side of the cartilaginous Eustachian **tube.** It descends between the internal pterygoid muscle and the internal pterygoid plate, and ends in a tendon which hooks round the hamular process, and is **inserted** beneath the levator palati into the posterior border of the hard palate, and into the aponeurosis of the soft palate.

The **palato-glossus muscle,** occupying the under surface of the soft palate and the anterior pillar of the fauces, has already been described with the muscles of the tongue (p. 415).

NERVE-SUPPLY.

The chief nerve supplying the muscles of the pharynx and soft palate is the **spinal accessory nerve,** aided by the **fifth** (otic ganglion) and the **ninth** (glosso-pharyngeal) nerves and the laryngeal **branches** of the **vagus nerve.**

Muscles.	Nerves.	Origin.
Constrictors of pharynx Palato-glossus Palato-pharyngeus Levator palati Azygos uvulæ	Pharyngeal plexus	XI.
Tensor palati	Otic ganglion	V.
Stylo-pharyngeus	Glosso-pharyngeal	IX.
Inferior constrictor	External laryngeal Inferior laryngeal	X.

ACTIONS.

The muscles of the pharynx and soft palate are chiefly brought into action in **the act of swallowing.** This act is divided into a *voluntary stage,* in which the bolus lies in front of the pillars of the fauces, and an *involuntary stage,* during which the food passes from the mouth through the pharynx. The movements occurring during the passage of food through the mouth are as follows: the cheeks are compressed by the action of the buccinator muscles; the tongue, hyoid bone, and thyroid cartilage are successively raised upwards by the action of the muscles which close the mouth and elevate the hyoid bone. By these means the food is pushed backwards between the pillars of the fauces.

At the same time, by the contraction of the palato-glossus and palato-pharyngeus, the pillars of the fauces are narrowed, while the muscles of the soft palate, contracting, tighten the soft palate, and by bringing it in contact with the posterior wall of the pharynx, shut off the upper (nasal) portion of the cavity. The elevation of the tongue, hyoid bone, and larynx simultaneously causes the elevation of the epiglottis and the aperture of the glottis, which is closed by the approximation of the arytenoid cartilages and the combined action of laryngeal muscles (arytenoideus, thyro-arytenoideus, and thyro-aryteno-epiglottideus). The food thus slips over the posterior surface of the epiglottis and the closed aperture of the glottis, and between the pillars of the fauces on either side, into the pharynx. It is now clasped by the constrictor muscles, which, by their contractions, force it down into the œsophagus. The contraction of the constrictor muscles results in a flattening of the pharynx and elevation of its anterior attachments.

During the act of swallowing, it is generally thought that the Eustachian tube is opened by the contraction of the tensor palati muscle which arises from it. It has been held, on the other hand, that the Eustachian tube is closed during swallowing by the compression of its wall by the contraction of the levator palati.

DEEP LATERAL AND PRÆVERTEBRAL MUSCLES OF THE NECK.

Three series of muscles are comprised in this group: (1) vertebro-costal (scaleni, nticus, medius, and posticus), (2) vertebro-cranial (recti capitis antici, major and inor, and lateralis), and (3) vertebral (longus colli).

The **scalenus anticus arises** from the anterior tubercles of the transverse rocesses of the third, fourth, fifth, and sixth cervical vertebræ, and descends ehind the carotid sheath, to be **inserted** into the scalene tubercle and ridge on the rst rib (Fig. 330, p. 420). In front of the muscle are the subclavian and nternal jugular veins, and the nerves descending through the neck. Behind, it is

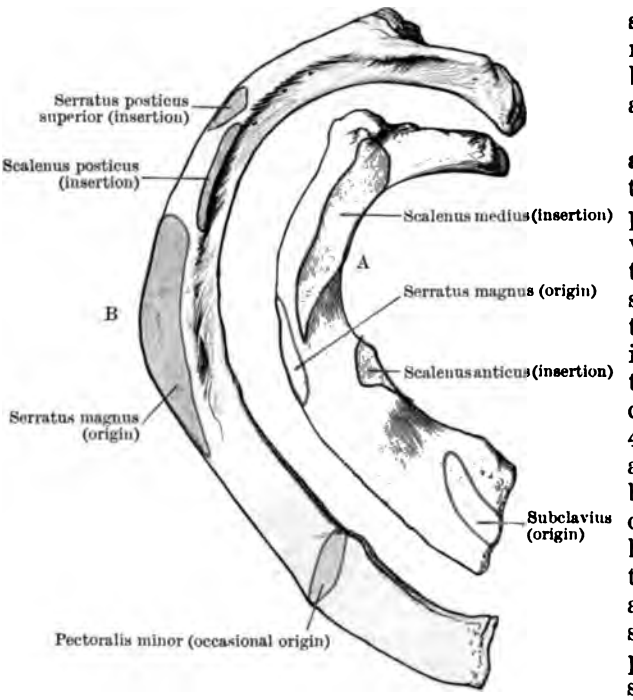

FIG. 330.—MUSCLE-ATTACHMENTS TO THE UPPER SURFACE OF THE FIRST RIB, AND THE OUTER SURFACE OF THE SECOND RIB.

A, First rib; B, Second rib.

and sixth cervical transverse processes, and is **inserted** into a linear impression on the outer side of the second rib. It is concealed behind by the levator anguli scapulæ, and is in contact anteriorly with the scalenus medius.

The **rectus capitis anticus major arises** from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ. It forms a flat triangular muscle, which is directed upwards, to be **inserted** into an impression on the under surface of the basilar process of the occipital bone in front and to the outer side of the pharyngeal spine (Fig. 333, p. 421). It lies on the cervical vertebræ behind the *carotid vessels* and the

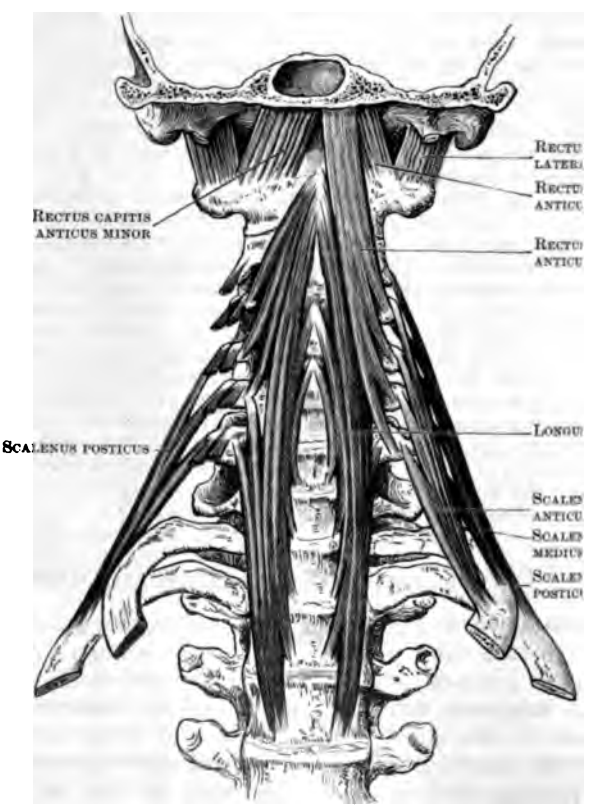

FIG. 331.—THE PRÆVERTEBRAL MUSCLES OF THE NECK

separated from the s medius by the cords brachial plexus, the sub artery, and the pleura.

The **scalenus m arises** from the po tubercles of the tra processes of the c vertebræ, from the sec the sixth inclusive. scends in the floor of t terior triangle, to be i into the rough impress the first rib behind t clavian artery (Fig. 420). The muscle is c anteriorly by the cords brachial plexus, the clavian artery, and th hyoid muscle, and is i tact behind with the anguli scapulæ and scalenus posticus. pierced by the po scapular and pos thoracic nerves.

The **scalenus po arises** from the po tubercles of the fourth

arynx, external to the longus colli, and internal at its origin to the scalenus **icus.**

The rectus capitis anticus minor arises from the anterior arch of the atlas, and

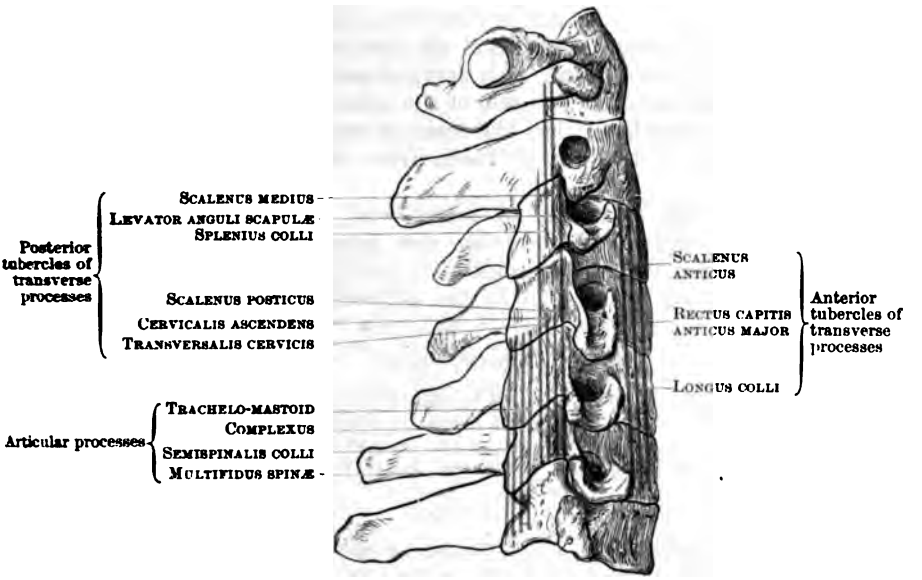

Fig. 332.—Scheme of Muscular-Attachments to Cervical Vertebræ.

is inserted into the basilar process between the previous muscle and the occipital condyle (Fig. 333, p. 421). It is concealed by the rectus capitis anticus major.

The **longus colli** is a flattened muscular band extending from the third thoracic

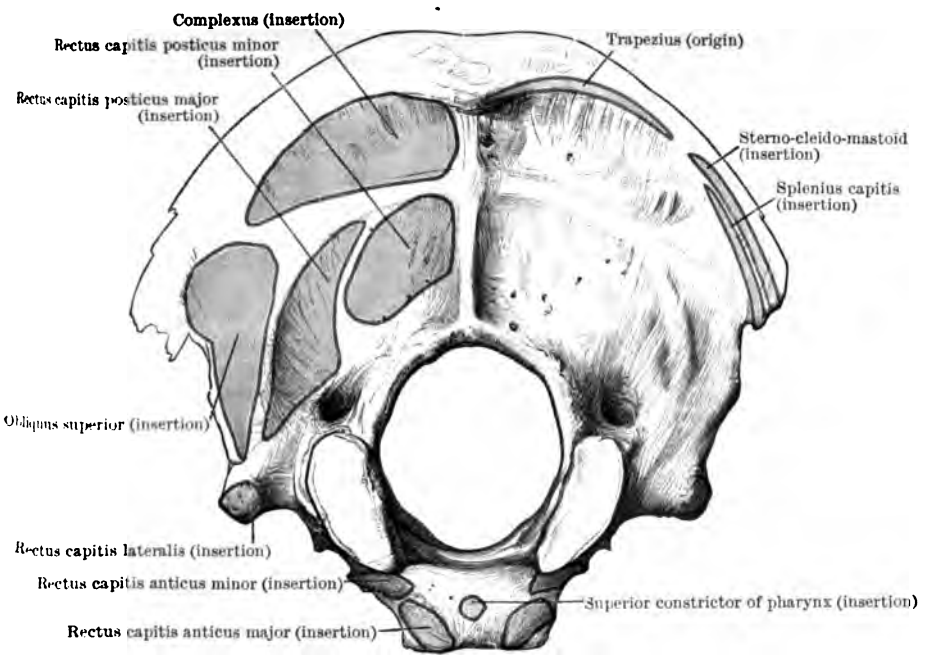

Fig. 333.—Muscle-Attachments to Occipital Bone (Inferior Surface).

rtebra to the atlas. It is divisible into three portions—a vertical, a lower *lique, and an upper oblique portion.*

*The **vertical portion** of the muscle* **arises** from the bodies of the first three

thoracic and the last three cervical vertebræ; and passing vertically upwards, **inserted** into the bodies of the second, third, and fourth cervical vertebræ.

The **lower oblique portion arises** from the bodies of the first three thor vertebræ, and is **inserted** into the anterior tubercles of the fifth and sixth cerv vertebræ.

The **upper oblique portion arises** from the anterior tubercles of the transv processes of the third, fourth, and fifth cervical vertebræ, and is directed upwa to be **inserted** into the anterior tubercle of the atlas.

The longus colli muscle clothes the front of the vertebral column in the n and is separated by the deep cervical fascia from the carotid vessels, pharynx, œsophagus.

The **rectus capitis lateralis**, in series with the posterior inter-transv muscles in the neck, **arises** from the transverse process of the atlas, and is inse into the under surface of the ex-occipital bone. It is placed alongside the r capitis antici, separated from them by the anterior primary division of the cervical nerve.

NERVE-SUPPLY.

The prævertebral muscles are all supplied by anterior primary divisions of the **cervical** s **nerves**: the rectus capitis anticus minor, and rectus capitis lateralis, by the loop between th two nerves; the rectus capitis anticus major by the first four; the longus colli by the se third, and fourth; the scaleni by the lower four or five cervical nerves.

ACTIONS.

The movements produced by these muscles are considered along with those of other m acting on the head, spinal column, and thorax (pp. 398. 426).

THE MUSCLES OF THE THORAX.

MUSCLES OF RESPIRATION.

The muscles which complete the boundaries of the thorax are the diaphr and intercostal muscles (external and internal), along with three series of sm muscles—the triangularis sterni, the levatores costarum, and the infra-costales.

The **intercostal muscles** are arranged in eleven pairs, forming thin la filling up the intercostal spaces.

Each **external muscle arises** from the sharp lower border of a rib, is directed downward and forward, to be **inserted** into the outer edge of upper border of the rib below. It extends from the tubercle of the rib bel nearly to the costal cartilage in front. The *anterior intercostal aponeurosi* continuous with it anteriorly, and extends forwards to the side of the sternum.

Each **internal muscle arises** from the costal cartilage and the inner edge of subcostal groove, and is directed downwards and backwards, to be **inserted** into inner edge of the upper border of the rib and costal cartilage below. It exte from the side of the sternum in front to the angle of the rib behind, wher becomes continuous with the *posterior intercostal aponeurosis* extending to tubercle of the rib.

The external intercostal muscles are covered by the pectoral muscles, serr magnus, and the muscles of the back; the internal muscles are in contact v the pleura. The intercostal vessels and nerve lie between the two muscles in posterior part of the thorax.

The **levatores costarum** are in series with the external intercostal mus They are twelve small slips **arising** from the transverse processes of the sev cervical and upper eleven thoracic vertebræ. They spread out in a fan-like ma as they descend, to be **inserted** into the outer surface of the ribs posterior to angles. They lie under cover of the longissimus dorsi muscle.

The **infra-costales** (subcostales) are slips of muscles found on the inner sur of the lower ribs near their angles. They are in series with the internal in costal muscles, but pass over the deep surface of several ribs.

The **triangularis sterni** (m. transversus thoracis) occupies the posterior as

e anterior thoracic wall. It **arises** from the back of the ensiform cartilage mesosternum as high as the level of the third costal cartilage. From this n its fibres radiate outwards, the lower ones horizontally, the upper ones uely upwards, to be **inserted** into the costal cartilages of all the true ribs ot the first and seventh. The muscle lies against the pericardium and pleura. separated from the chest wall by the internal mammary vessels and the ior branches of the intercostal nerves. The muscle is continuous below with ransversalis abdominis.

he **diaphragm** is the great membranous and muscular partition separating avities of the thorax and abdomen. It forms a thin lamella arching over

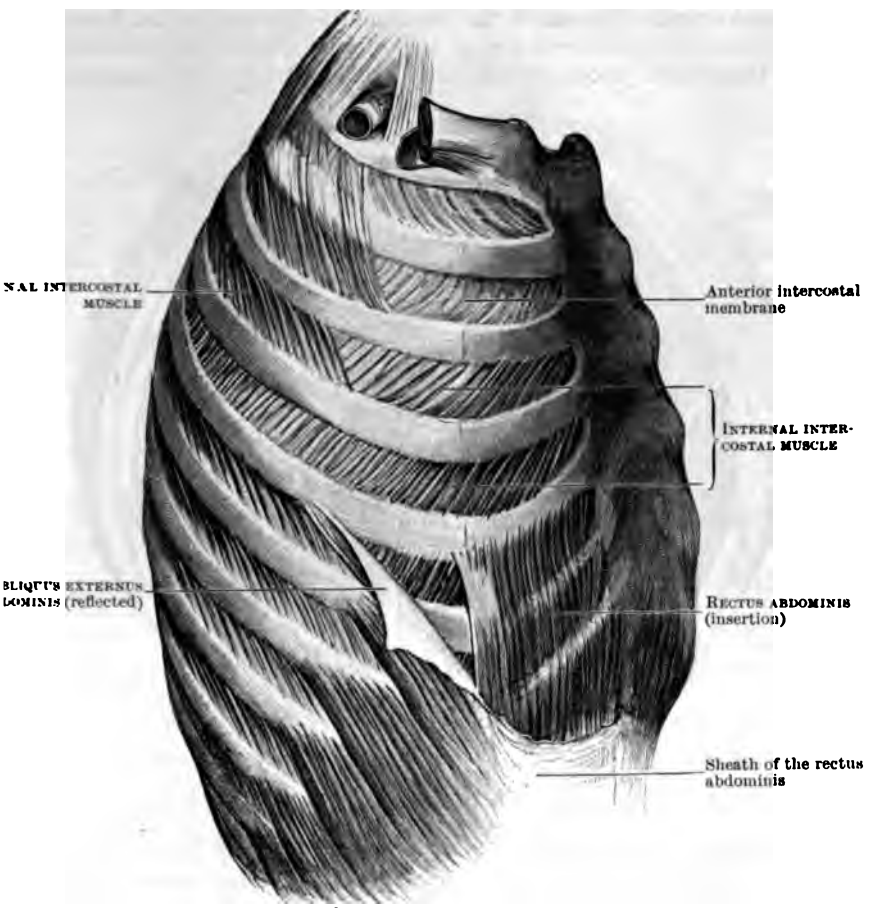

FIG. 334.—THE MUSCLES OF THE THORACIC WALL.

liver, stomach, and spleen, with its convex upper surface in contact with the ardium, pleuræ, and chest wall. It possesses a peripheral origin from the num, ribs, and vertebral column, and an insertion into a central tendon. It s (1) *anteriorly* from the posterior surface of the ensiform cartilage by two ler fleshy slips, directed backwards; (2) *laterally*, from the deep surface of the r six rib-cartilages on each side by fleshy bands which interdigitate with those e transversalis abdominis; (3) *posteriorly*, from the lumbar vertebræ, by the , and from the arcuate ligaments. The **crura** are two elongated fibro-muscular les which arise from the front of the bodies of the lumbar vertebræ, on the side from the first three, on the left side from the first two vertebræ. They irected upwards and, passing in front of the aorta, decussate across the middle in front of that vessel, the fibres of the right crus passing in front of those of eft crus. The fibres then encircle the œsophagus, forming an elliptical opening

for its passage, and finally join the central tendon, after a second decussation in front of the gullet.

The **arcuate ligaments** are five in number.

The **middle arcuate ligament** is a fibrous arch connecting together the crura of the diaphragm in front of the aorta, and giving origin to fibres which join the crura as they decussate to encircle the gullet.

The **internal arcuate ligament** is a thickening formed by the attachment of the psoas fascia to the body of the first lumbar vertebra internally and its transverse process externally. Stretching across the upper end of the psoas muscle, the ligament gives origin to muscular fibres directed upwards on each side of the crura.

The **external arcuate ligament** is the thickened upper end of the fascia over the quadratus lumborum (anterior layer of the lumbar fascia), and is attached internally to the transverse process of the first lumbar vertebra, and externally to the

FIG. 335.—THE DIAPHRAGM (from below).

last rib. It gives origin to another broad band of muscular fibres, separated from those arising from the internal arcuate ligament by an interval, and passing upwards to the central tendon of the diaphragm.

From this extensive origin the muscular fibres of the diaphragm converge to an **insertion** into a large trilobed **central tendon**. Of its lobes the right one is the largest, the middle or anterior is intermediate in size, and the left is the smallest. It does not occupy the centre of the muscle, being placed nearer the front than the back. The fibres of the crura are consequently the longest; those from the sternum are the shortest.

The diaphragm is pierced by numerous structures. The superior epigastric artery enters the sheath of the rectus abdominis between its sternal and costal origins; the musculo-phrenic artery passes between its attachments to the seventh and eighth ribs. The sympathetic cord and the splanchnic nerves pierce or pass behind the diaphragm; the last thoracic nerve passes beneath the external arcuate ligament; and the aorta, the vena azygos major, and thoracic duct pass between the crura, underneath the middle arcuate ligament (*aortic opening*). The special foramina are two in number. The *foramen quadratum* in the right lobe of the central tendon transmits the inferior vena cava, and small branches of the right

phrenic nerve. The *œsophageal opening* is in the muscular substance of the diaphragm, behind the central tendon, and is surrounded by a sphincter-like arrangement of the crural fibres. Besides the œsophagus, this opening transmits the two pneumogastric nerves. The upper convex surface of the diaphragm forms the sloping floor of the thorax, and is in contact with the pleuræ and the pericardium (which is firmly bound down to the central tendon, and less firmly to the

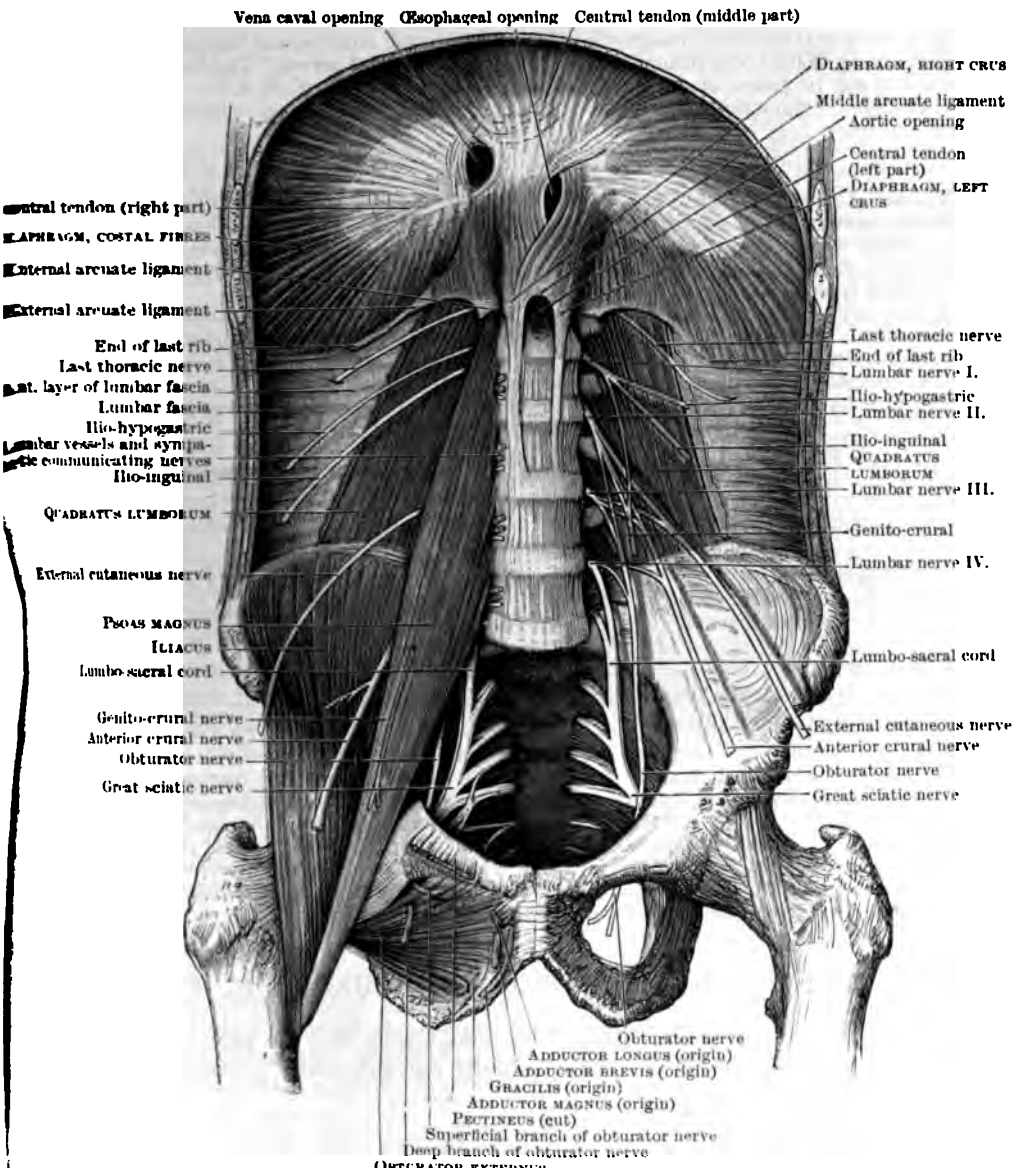

Fig. 336.—View of the Posterior Abdominal Wall, to show the Muscles and the Nerves of the Lumbo-Sacral Plexus.

muscular fibres on the left side). By its lateral margins the diaphragm is in contact on each side with the thoracic wall beyond the reflection of the pleura, and behind with the œsophagus and descending thoracic aorta. The under surface of the diaphragm is concave, and is for the most part invested by peritoneum. It is in relation with the liver, stomach, spleen, kidneys, suprarenal bodies, duodenum and pancreas, the inferior vena cava, and the branches of the cœliac axis. Its vault is higher on the right side than on the left, owing to the upward projection of the liver on that side.

The diaphragm is found as a complete septum between the thorax and abdomen only in mammals. It is occasionally deficient in the human subject, producing *hernia of the diaphragm* either into the pericardial cavity through the central tendon, or into the thoracic cavity through the lateral portions of the muscle. A rare condition is congenital deficiency of a part of the lateral half of the muscle, generally placed posteriorly, and on the left side. This produces, by continuity of the peritoneum and pleura behind the diaphragm, a *congenital diaphragmatic hernia*.

Nerve-Supply.

The intercostal muscles, levatores costarum, infra-costal muscles, and triangularis sterni, are all supplied by the anterior primary divisions of the **intercostal nerves**. The diaphragm receives its chief, if not its entire, motor supply from the **phrenic nerves** (C. 3. 4. 5.) It is innervated also by the diaphragmatic plexus of the sympathetic, and is said to receive fibres from the lower intercostal nerves.

Actions.

The act of respiration consists of two opposite movements, inspiration and expiration.

1. The **movement of expiration** is performed by (1) the elasticity of the lungs, (2) the weight of the chest walls, (3) the elevation of the diaphragm, (4) the action of muscles—triangularis sterni and muscles of the abdominal wall. It is sometimes stated that the interosseous fibres of the internal intercostal muscles are depressors of the ribs.

2. The **movement of inspiration** results in the enlargement of the thoracic cavity in all its diameters. Its antero-posterior and transverse diameters are increased by the elevation and forward movement of the sternum, and by the elevation and eversion of the ribs, while its vertical diameter is increased by the descent of the diaphragm.

The muscles of **inspiration** are divided into two series—ordinary and accessory.

a. **Ordinary Muscles.**	*b.* **Extraordinary and Accessory Muscles**
Diaphragm	Quadratus lumborum
Intercostals	Pectorales
Scaleni	Serratus magnus
Serrati postici	Sterno-mastoid
Levatores costarum	Latissimus dorsi
	Infra-hyoid muscles
	Extensors of the spine

Of the ordinary muscles the diaphragm is the most important. Its action is twofold—**centrifugal**, elevating the ribs and increasing the transverse and antero-posterior diameters of the thorax, and **centripetal**, drawing downwards the central tendon and increasing the vertical diameter of the thorax. Of the two movements the former is the more important. There has been considerable diversity of opinion regarding the action of the intercostal muscles. It is generally agreed that the external muscles elevate the ribs; it is probable that the whole of each internal muscle acts in the same way, although it has been stated by different observers that the whole internal muscle is a depressor; or that the interosseous part is a depressor, the interchondral portion of the muscle an elevator of the ribs.

FASCIÆ AND MUSCLES OF THE ABDOMINAL WALL.

The space between the margins of the bony thorax and the pelvis is filled up by a series of muscular sheets, covered externally and internally by fasciæ.

FASCIÆ.

The fasciæ of the abdominal wall are—*externally*, the superficial and deep fasciæ; *internally*, the fascia transversalis, which is continuous with the diaphragmatic, lumbar, psoas, iliac, and pelvic fasciæ, and is lined within by the **extra-peritoneal tissue**.

The **superficial fascia** of the abdomen is liable to contain a large quantity of fat. It is separated in the groin into *two layers*: a superficial fatty layer continuous over Poupart's ligament with the fascia of the front of the thigh (p. 356), and a deeper membranous layer attached to the inner half of Poupart's ligament, and more externally to the fascia lata of the thigh below Poupart's ligament. The two layers are separated by the lymphatic glands and the superficial vessels of the groin. Higher up in the abdominal wall the two layers blend together, and passing

wnwards over the spermatic cord, they unite to form the fascia and dartos uscle of the scrotum. The attachment of the fascia to the groin prevents the ssage into the thigh of fluid extravasated in the abdominal wall.

The **deep fascia** of the abdominal wall resembles similar fasciæ in other situaons. It forms an investment for the obliquus externus muscle, and becomes thin nd almost imrceptible in reation to the poneurosis of hat muscle.

The **fascial ning** of the abominal cavity **ascia transverlis**) consists of a ontinuous layer f membrane hich receives ifferent names in ifferent parts of ts extent. It overs the deep urface of the ransversalis musle, and is coninuous internally through the lumar fascia) with the fasciæ of the quadratus lumborum and the psoas muscles. It is continuous above with the diaphragmatic fascia, and below (the iliac crest and Poupart's ligament intervening) with the fascia iliaca. Along with the last-named fascia it forms the **femoral sheath**. It is pierced by the spermatic cord or round ligament of the uterus at the internal abdominal ring, and its prolongation into the inguinal canal around the cord forms the **infundibuliform fascia**. It is lined internally by the peritoneum, from which it is separated by a layer of **extra-peritoneal tissue**.

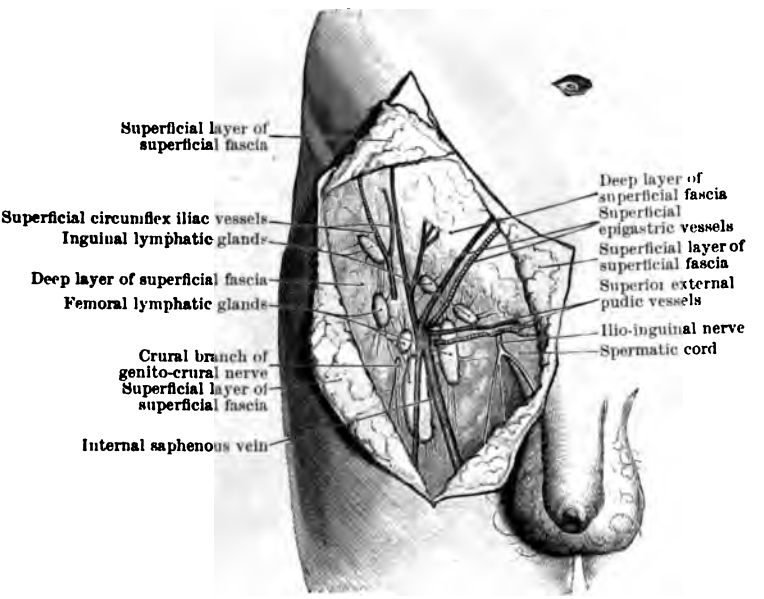

FIG. 337.—THE GROIN. STRUCTURES BETWEEN THE LAYERS OF THE SUPERFICIAL FASCIA.

The **extra-peritoneal tissue** is usually loaded with fat; it envelops the kidneys, ureters, suprarenal capsules, abdominal aorta and inferior vena cava and their branches, and forms sheaths for the vessels and ducts (ureter, vas deferens, etc.) It is continued upwards into the posterior mediastinum of the thorax through the aortic opening in the diaphragm, and below is in continuity with the extra-peritoneal tissue in the pelvis. It not only completely invests the kidneys and suprarenal capsules, but it also becomes interpolated between the layers of peritoneum upholding and enveloping the intestines. This tissue is absent in relation to the diaphragm, on the under surface of which there is also no fat.

THE MUSCLES OF THE ABDOMINAL WALL.

The muscles of the abdominal wall are in three series—lateral, anterior, and osterior.

The **lateral muscles** of the abdominal wall comprise the obliquus externus, bliquus internus, and transversalis abdominis.

The **obliquus externus abdominis** is a broad thin sheet of muscle, with an **igin** from the outer surfaces of the lower eight ribs, by slips which intergitate with the serratus magnus and latissimus dorsi muscles. The muscular bres radiate downwards and forwards, the lowest fibres passing vertically downards. The lower and posterior part of the muscle is **inserted** directly by fleshly bres into the outer lip of the iliac crest in its anterior half or two-thirds (Fig.

The diaphragm is found as a complete septum between the thorax and abdomen only mammals. It is occasionally deficient in the human subject, producing *hernia of the diaphra* either into the pericardial cavity through the central tendon, or into the thoracic cavity thro the lateral portions of the muscle. A rare condition is congenital deficiency of a part of lateral half of the muscle, generally placed posteriorly, and on the left side. This produces continuity of the peritoneum and pleura behind the diaphragm, a *congenital diaphragm hernia.*

NERVE-SUPPLY.

The intercostal muscles, levatores costarum, infra-costal muscles, and triangularis sterni, all supplied by the anterior primary divisions of the **intercostal nerves.** The diaphragm rece its chief, if not its entire, motor supply from the **phrenic nerves** (C. 3. 4. 5.) It is innerv also by the diaphragmatic plexus of the sympathetic, and is said to receive fibres from the lo intercostal nerves.

ACTIONS.

The act of respiration consists of two opposite movements, inspiration and expiration.

1. The **movement of expiration** is performed by (1) the elasticity of the lungs, (2) the we of the chest walls, (3) the elevation of the diaphragm, (4) the action of muscles—triangul sterni and muscles of the abdominal wall. It is sometimes stated that the interosseous fibr the internal intercostal muscles are depressors of the ribs.

2. The **movement of inspiration** results in the enlargement of the thoracic cavity in its diameters. Its antero-posterior and transverse diameters are increased by the elevation forward movement of the sternum, and by the elevation and eversion of the ribs, while vertical diameter is increased by the descent of the diaphragm.

The muscles of **inspiration** are divided into two series—ordinary and accessory.

a. **Ordinary Muscles.**	*b.* **Extraordinary and Accessory Muscles**
Diaphragm	Quadratus lumborum
Intercostals	Pectorales
Scaleni	Serratus magnus
Serrati postici	Sterno-mastoid
Levatores costarum	Latissimus dorsi
	Infra-hyoid muscles
	Extensors of the spine

Of the ordinary muscles the diaphragm is the most important. Its action is twofo **centrifugal,** elevating the ribs and increasing the transverse and antero-posterior diameter the thorax, and **centripetal,** drawing downwards the central tendon and increasing the ver diameter of the thorax. Of the two movements the former is the more important. There been considerable diversity of opinion regarding the action of the intercostal muscles. I generally agreed that the external muscles elevate the ribs; it is probable that the whole of internal muscle acts in the same way, although it has been stated by different observers that whole internal muscle is a depressor; or that the interosseous part is a depressor, the in chondral portion of the muscle an elevator of the ribs.

FASCIÆ AND MUSCLES OF THE ABDOMINAL WALL.

The space between the margins of the bony thorax and the pelvis is filled u a series of muscular sheets, covered externally and internally by fasciæ.

FASCIÆ.

The fasciæ of the abdominal wall are—*externally,* the superficial and deep fas *internally,* the fascia transversalis, which is continuous with the diaphragm lumbar, psoas, iliac, and pelvic fasciæ, and is lined within by the **extra-perit tissue.**

The **superficial fascia** of the abdomen is liable to contain a large quan of fat. It is separated in the groin into *two layers*: a superficial fatty layer tinuous over Poupart's ligament with the fascia of the front of the thigh (p. ; and a deeper membranous layer attached to the inner half of Poupart's ligam and more externally to the fascia lata of the thigh below Poupart's ligament. two layers are separated by the lymphatic glands and the superficial vessels of groin. Higher up in the abdominal wall the two layers blend together, and pas

over the spermatic cord, they unite to form the fascia and dartos
he scrotum. The attachment of the fascia to the groin prevents the
the thigh of fluid extravasated in the abdominal wall.

THE MUSCLES OF THE ABDOMINAL WALL.

uscles of the abdominal wall are in three series—lateral, anterior, and

teral muscles of the abdominal wall comprise the obliquus externus,
ternus, and transversalis abdominis.
liquus externus abdominis is a broad thin sheet of muscle, with an
a the outer surfaces of the lower eight ribs, by slips which inter-
th the serratus magnus and latissimus dorsi muscles. The muscular
te downwards and forwards, the lowest fibres passing vertically down-
e lower and posterior part of the muscle is **inserted** directly by fleshly
the outer lip of the iliac crest in its anterior half or two-thirds (Fig.

290, p. 373). The rest of the muscle is inserted into an extensive triangular aponeurosis covering the anterior abdominal wall. This aponeurosis is broader below than above; it is united with part of the aponeurosis of the obliquus internus in the upper three-fourths of its extent, to form the anterior layer of the **sheath of the rectus muscle**. It thus gains an attachment, above to the ensiform cartilage, below to the symphysis pubis, and by its intermediate fibres to the **linea alba**, a broad interlacing band of fibres about half an inch in width which occupies the middle line of the anterior abdominal wall in its whole extent, and forms the greater part of the ultimate insertion of all the lateral abdominal muscles.

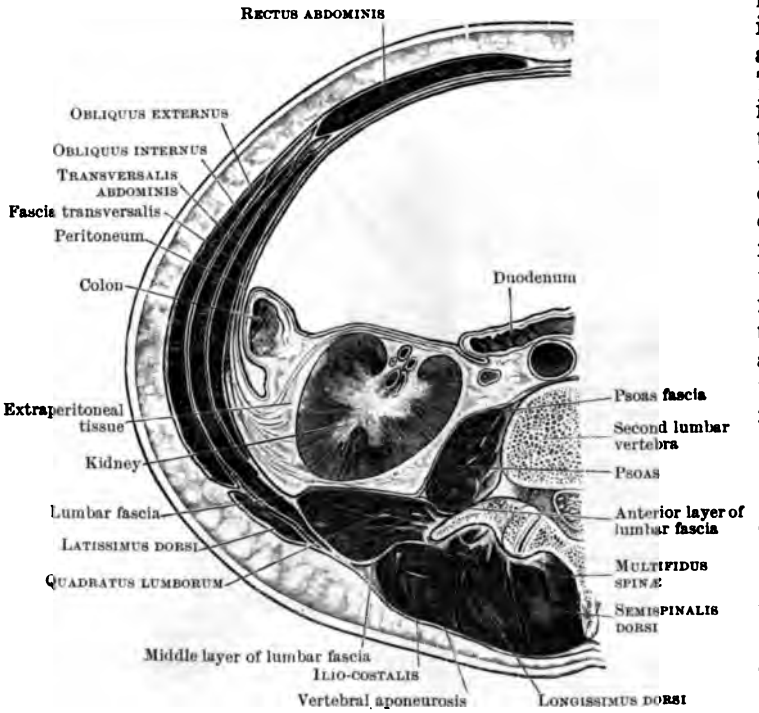

Fig. 338.—Transverse Section through the Abdomen, opposite the Second Lumbar Vertebra.

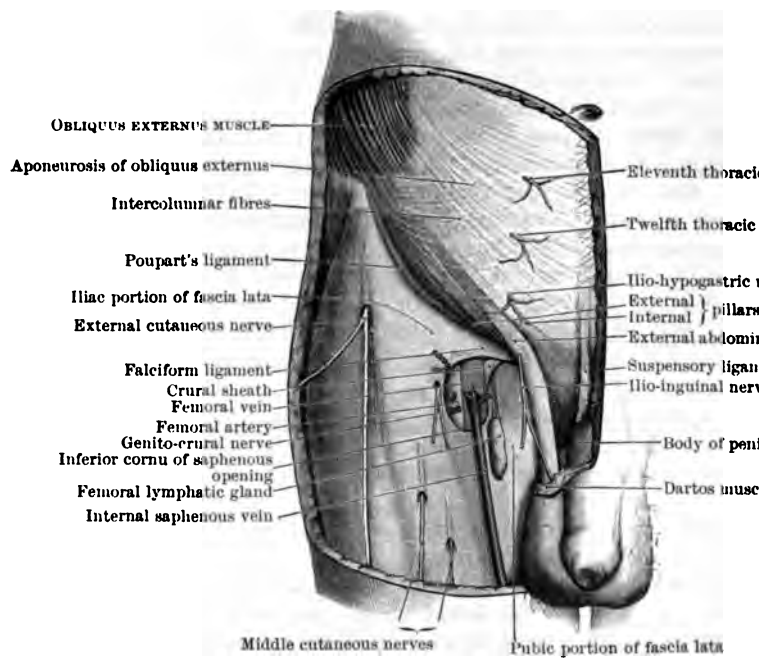

Fig. 339.—The Groin. The Structures seen on removal of the Superficial Fascia.

The upper part of the aponeurosis covers the insertion of the rectus abdominis

muscle on the chest wall, and gives origin to fibres of the pectoralis major. Below, the groin, it gives rise to Poupart's ligament, Gimbernat's ligament, the external abdominal ring with its two pillars, the intercolumnar fascia and fibres, and the triangular fascia.

Poupart's ligament is a fascial band which extends from the anterior superior

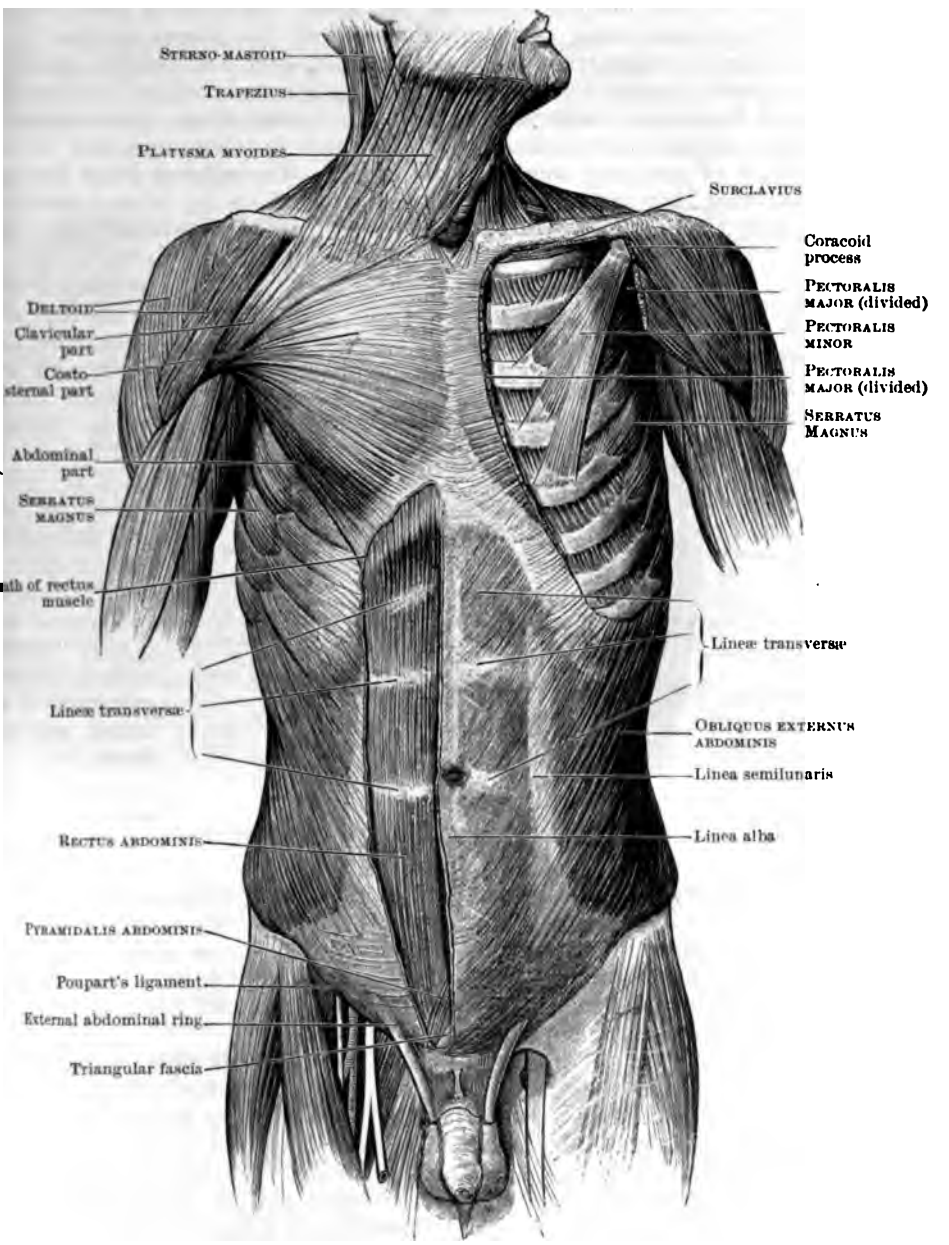

Fig. 340.—Anterior Muscles of the Trunk.

iliac spine to the spine of the pubis, arching over the iliacus, psoas, and pectineus muscles. It represents the lower limit of the aponeurosis of the obliquus externus abdominis, and gives attachment below to the fascia lata of the thigh. Its outer part affords partial origin to the deeper lateral muscles of the abdominal wall, and receives the attachment of the fascia transversalis and fascia iliaca; the inner part forms the gutter-like floor of the inguinal canal. At its inner end a triangular band of fibres is reflected horizontally backwards to the ilio-pectineal line, forming

Gimbernat's ligament, the outer edge of which limits internally **the crural ring**. The femoral vessels enclosed in the femoral sheath enter the thigh beneath Poupart's ligament, in front of the psoas muscle, and the term *superficial crural arch* is given to the part of the ligament which covers the vessels.

The **external abdominal ring**, the place of exit of an inguinal hernia, is a split in the aponeurosis of the obliquus externus, just above the spine of the pubis. It transmits the spermatic cord, or round ligament of the uterus, covered by the cremaster muscle or cremasteric fascia. The opening is of considerable extent, and its edges are drawn together by a thin fascia, strengthened superficially by a number of arched and horizontal fibres, called the **intercolumnar fibres**, which arise from Poupart's ligament and sweep inwards across the cleft in the aponeurosis.

The margins of the ring constitute its pillars. The **external pillar** is narrow and is formed from that part of the aponeurosis which joins the pubic spine, and is continuous with the inner end of Poupart's ligament. The **internal pillar** is the part of the aponeurosis internal to the ring which is attached to the crest and symphysis of the pubis. It is flat and broad.

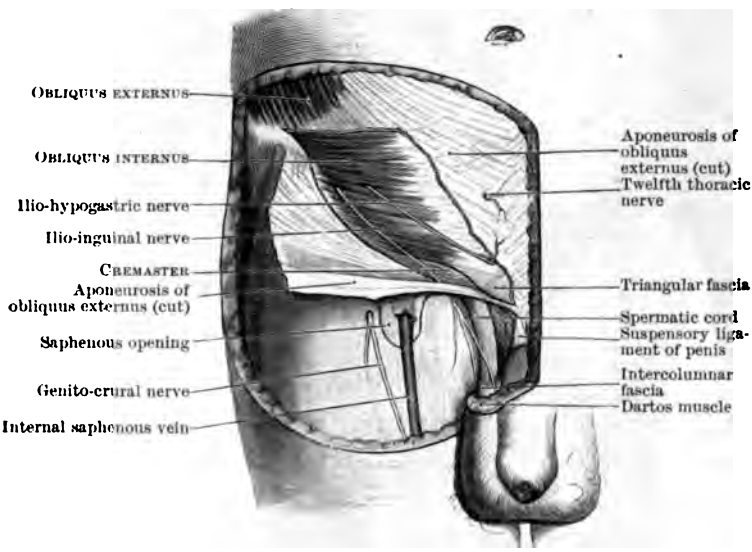

FIG. 341.—THE GROIN. THE STRUCTURES SEEN ON REMOVAL OF PART OF THE OBLIQUUS EXTERNUS.

The **intercolumnar fibres** and the pillars of the external abdominal ring are continuous with a thin tubular sheath, the **intercolumnar** or **external spermatic fascia**, which is attached to the margins of the "ring," and forms an envelope for the spermatic cord or round ligament in their further passage beyond the abdominal wall.

The **triangular fascia**, lastly, is a triangular band of fibres placed behind the internal pillar of the external abdominal ring. It consists of fibres from the *opposite* external oblique aponeurosis, which, having traversed the linea alba, gain an insertion into the crest and spine of the pubis.

The obliquus externus muscle is superficial in almost its whole extent. It is overlapped posteriorly by the latissimus dorsi muscle, but may be separated from it just above the iliac crest by an angular interval (triangle of Petit).

The **obliquus internus abdominis**, a broad thin sheet lying between the obliquus externus and the transversalis, **arises** from (1) the lumbar fascia, (2) the anterior half of the iliac crest, and (3) the outer half of Poupart's ligament. Directed for the most part upwards and forwards, its highest fibres are **inserted** directly into the last three ribs. The rest of the fibres form an extensive aponeurosis, broader above than below, which splits along the **linea semilunaris**, to form, along with the aponeuroses of the obliquus externus and transversalis muscles, the **sheath of the rectus abdominis**, and is thereafter inserted into the seventh, eighth, and ninth costal cartilages, and into the linea alba from the ensiform cartilage to the symphysis pubis. The fibres arising from Poupart's ligament join with those of the transversalis muscle having a similar origin to form the **conjoint tendon**, which passes altogether in front of the rectus muscle, to be attached to the pubic crest and spine and to the ilio-pectineal line.

The obliquus internus is limited above by the costal arch. Its lower fibres, **hing over the spermatic cord, assist in forming, externally, the anterior wall of inguinal canal**; internally, by means of the conjoint tendon, it helps to form **posterior wall of the canal.**

Its lowest fibres are continued into the cremaster muscle, which is prolonged **ng the spermatic cord through the inguinal canal.**

The cremaster muscle may be said to have an **origin** from the lower border of the **iquus internus,** and from the centre of Poupart's ligament. It forms a thin sheet, **reloping the testicle and spermatic cord**; its fibres are arranged in loops which arch **er the cord, and are inserted** into the fascia, and to a less extent (uppermost fibres) into **e pubic spine. The muscle is more largely represented by fascia in the female, and nstitutes the cremasteric fascia.**

The transversalis muscle arises (1) from the under surface of the costal **rtilages of the lower six ribs, inter-digitating with the origins of the diaphragm**; **) from the lumbar fascia**; (3) from the anterior half of the inner lip of the iliac **est**; and (4) from the outer third of Poupart's ligament. The muscular fibres

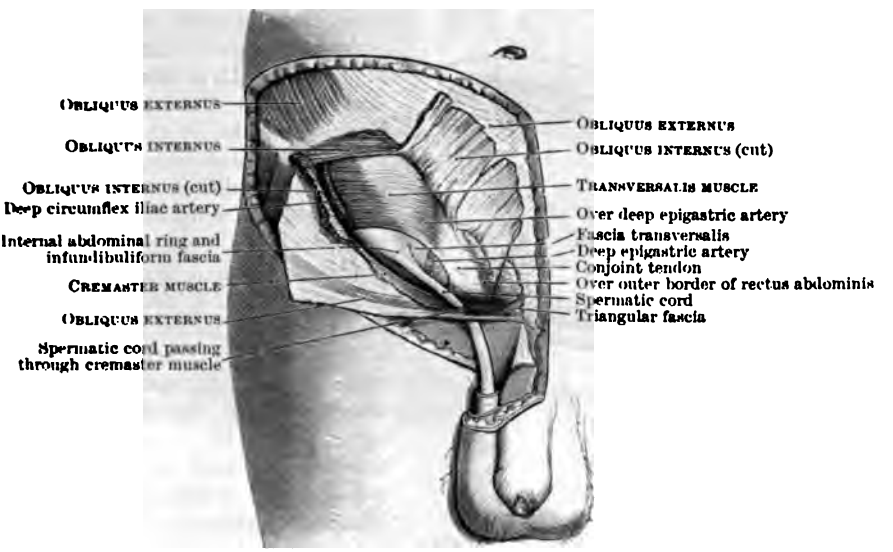

Fig. 342.—The Groin. The Structures seen on reflexion of part of the Obliquus Internus.

are directed for the most part horizontally forwards, and end in an aponeurosis which has a twofold **insertion.** (1) After forming (along with the aponeurosis of the obliquus internus) the posterior layer of the sheath of the rectus, the aponeurosis is attached to the ensiform cartilage and linea alba. (2) The lower fibres of the muscle arising from Poupart's ligament are joined by the lower part of the obliquus internus to form the larger part of the **conjoint tendon,** which passes in front of the lower part of the rectus muscle, to be inserted into the crest and spine of the pubis and the ilio-pectineal line.

The transversalis muscle is separated by the lower intercostal nerves from the obliquus internus muscle, and is lined on its deep surface by the transversalis fascia. Its lower border forms a concave edge, separated from Poupart's ligament by a annular interval in which the transversalis fascia appears, and through which the spermatic cord emerges at the internal abdominal ring, under cover of the obliquus internus muscle and the aponeurosis of the obliquus externus.

The **anterior muscles** of the abdominal wall include the pyramidalis and rectus abdominis, enveloped by the sheath of the rectus on either side of the linea alba.

The **pyramidalis abdominis** is a small triangular muscle **arising** from the pubic crest in front of the rectus muscle (Fig. 282, p. 366). It is directed obliquely

upwards, to be **inserted** for a variable distance into the linea alba. The mu
is often absent.

The **rectus abdominis muscle** is broad and strap-like, and **arises**, by an in
and an outer head, from the symphysis and crest of the pubis (Fig. 282, p. 3
Expanding as it passes upwards, the muscle is **inserted** from within outwards i
the front of the ensiform cartilage (Fig. 246, p. 322), and into the front of
seventh, sixth, and fifth costal cartilages. On its anterior surface, but
extending through the entire substance of the muscle, are three or more transve
tendinous intersections (**lineæ transversæ**), adherent to the sheath of the muscl
the lowest opposite the umbilicus, and the highest about the level of the ensifor
cartilage. Enclosed in its sheath, and covered anteriorly by the pyramidalis muscl
the rectus conceals the superior and dee
epigastric vessels, the terminal branche
of the lower thoracic nerves (whic
pierce the muscle to reach the anteri
abdominal wall), the fold of Dougl
and the fascia transversalis. The inn
border of the muscle lies alongside the
linea alba; its outer border is convex, and
corresponds to the **linea semilunaris**.

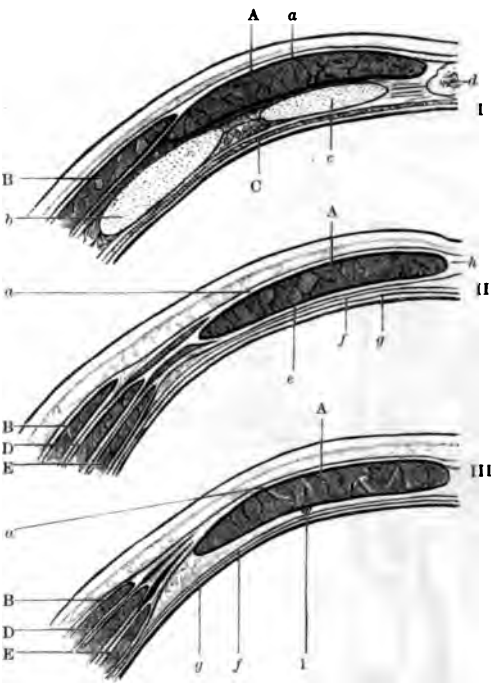

FIG. 343.—THE SHEATH OF THE RECTUS ABDOMINIS MUSCLE.

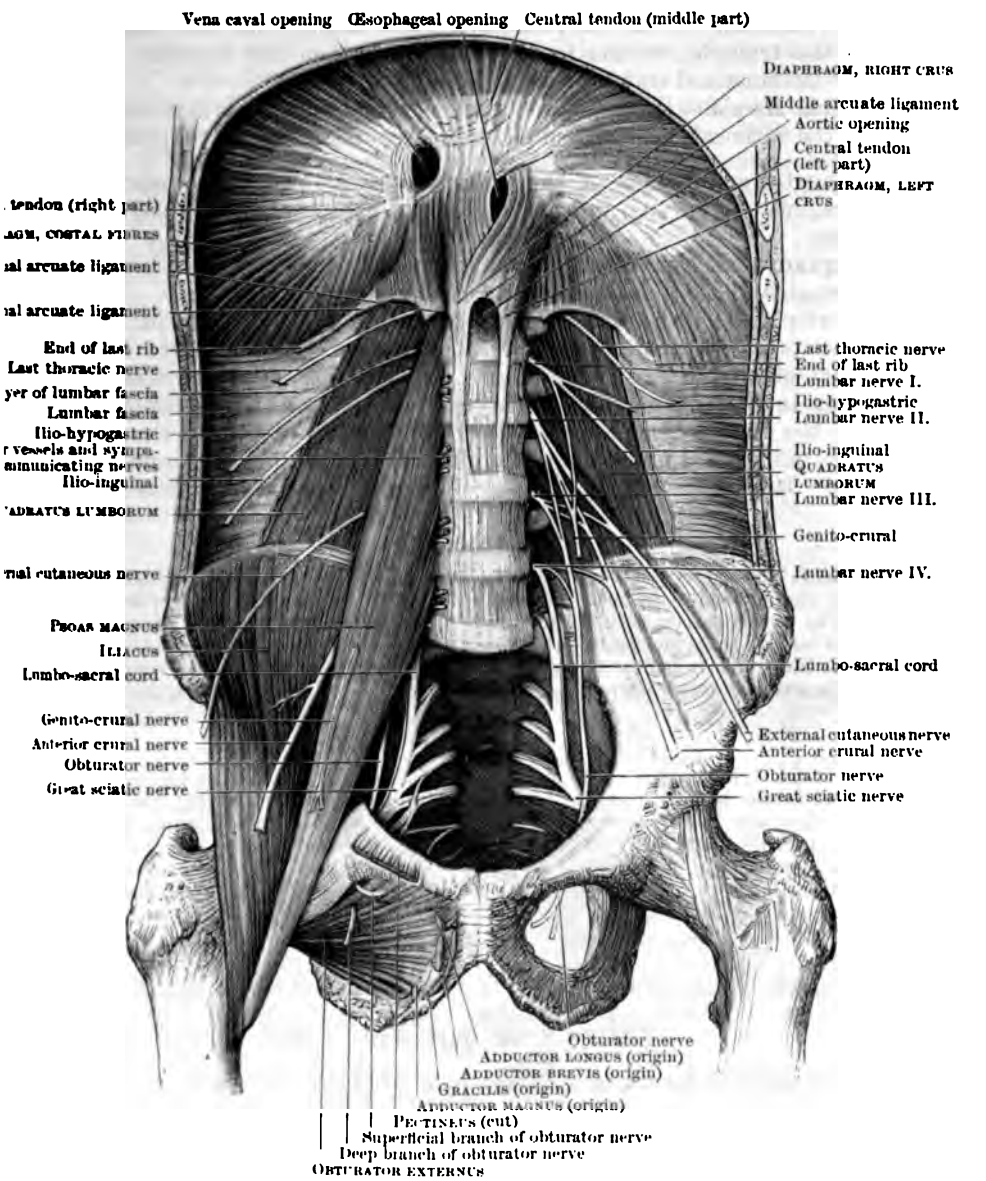
(I.) In the thoracic wall; (II.) In the upper three-quarters of the abdominal wall; (III.) In the lower fourth of the abdominal wall.

A, RECTUS MUSCLE; B, OBLIQUUS EXTERNUS; C, DIAPHRAGM; D, OBLIQUUS INTERNUS; E, TRANSVERSALIS ABDOMINIS. *a*, Anterior layer of rectus sheath; *b*, Fifth costal cartilage; *c*, Sixth costal cartilage; *d*, Xiphoid cartilage; *e*, Posterior layer of rectus sheath; *f*, Transversalis fascia; *g*, Peritoneum; *h*, Linea alba. 1, Deep epigastric artery.

The **sheath of the rectus muscle** is derived from the aponeuroses of the lateral muscles of the abdominal wall, which, after enclosing the muscle, give rise in the middle line to the linea alba. At the linea semilunaris, at the outer border of the rectus muscle, the aponeurosis of the obliquus internus splits into anterior and posterior layers. The anterior layer, joined by the aponeurosis of the obliquus externus, passes in front of the rectus, and constitutes the anterior lamina of the sheath. The posterior layer, joined by the aponeurosis of the transversalis muscle, passes behind the rectus, and constitutes the posterior lamina of its sheath. This arrangement obtains in the upper three-fourths of the abdominal wall. Below the level of the iliac crest the sheath of the muscle is deficient posteriorly, and a crescentic border, the **fold of Douglas**, marks the lower limit of the posterior lamina. In consequence, the rectus in the lower fourth of the abdominal wall rests upon the fascia transversalis directly. Close examination, however, usually reveals a thin layer behind the muscle in continuity with the fold of Douglas, and merging below with the fascia transversalis. In this region the rectus is covered anteriorly by the conjoint tendon of the obliquus internus and transversalis, and by the aponeurosis of the obliquus externus, which is gradually becoming separate from the subjacent aponeurosis. The upper part of the rectus, lying on the chest wall, is only covered anteriorly by a single layer of aponeurosis derived from the obliquus externus, which in this situation is giving origin to the pectoralis major muscle.

Inguinal Canal.—The spermatic cord in the male, and the round ligament in the female, in their passage through the lower part of the abdominal wall, pass through the inguinal canal, which is bounded by these abdominal muscles. The canal begins at the *internal abdominal ring*, placed half an inch above Poupart's

nent, and midway between the anterior superior iliac spine and the symphysis s. It ends at the *external abdominal ring*, placed above the spine and crest he pubis. The *front wall* of the canal is formed by the aponeurosis of the quus externus, and in its outer part by the muscular fibres of the obliquus rnus; the *back wall* of the canal is formed by the fascia transversalis, and in nner part the conjoint tendon; while the *floor* of the canal is formed by



'G. 344.—View of the Posterior Abdominal Wall, to show the Muscles and the Nerves of the Lumbo-Sacral Plexus.

part's ligament, and in its inner part by Gimbernat's ligament. The spermatic l, piercing the transversalis fascia, enters the inguinal canal at the internal ominal ring, and is there invested by its *first envelope*, the **infundibuliform** or **rnal spermatic fascia**, a sheath of fascia derived from the margin of the ring and tinuous with the fascia transversalis. It then passes obliquely inwards, downds, and forwards, and escapes below the lower border of the obliquus internus cle, from which it carries off a *second investment*, partly fascial, partly muscular

—the **cremaster muscle** or **cremasteric fascia**. Continuing its course in front of t conjoint tendon, it emerges through the external abdominal ring, from the edges which the **intercolumnar fascia** is derived, the *third* or *external investment* for the co

Hesselbach's triangle, bounded below by the line of Poupart's ligament, interna by the rectus abdominis muscle, and externally by the deep epigastric artery, the mesial side of the internal abdominal ring, is the site of one form of inguin hernia. The spermatic cord passes over the base of the triangle, covered o by the aponeurosis of the obliquus externus. Behind the cord, and forming t floor of the triangle, are the fascia transversalis and the conjoint tendon of t obliquus internus and transversalis muscles.

Inguinal Hernia.—For an account of the anatomical relations of the inguin canal to the various forms of inguinal hernia, see the section on "Applied Anatomy."

The **posterior muscles of the abdominal wall and false pelvis** include th psoas (magnus and parvus) and iliacus, described already (p. 363), and the quadratu lumborum.

The **quadratus lumborum** lies on the posterior wall of the abdomen extern to the psoas, and extends between the iliac crest and the last rib. It **arises** from the posterior part of the iliac crest, from the ilio-lumbar ligament, and from the transverse processes of the lower lumbar vertebræ. It is **inserted** above into the inner part of the lower border of the last rib and the transverse processes of the upper lumbar vertebræ. It is enclosed between the anterior and middle layers of the lumbar aponeurosis (p. 391), and is placed behind the colon, kidney, and psoas muscle, in front of the multifidus spinæ and the lumbar transverse processes. Its outer border is directed obliquely upwards and inwards.

Nerve-Supply.

The nerve-supply of all the foregoing muscles except the psoas, cremaster, quadratus lumborum, and iliacus, is derived from the anterior primary divisions of the **lower six thoracic nerves**. The pyramidalis muscle is innervated by the **last thoracic nerve**. The cremaster muscle receives its supply from the **genito-crural nerve**, whilst the quadratus lumborum is innervated by the first three or four **lumbar nerves**. The psoas and iliacus muscles are supplied, directly or through the **anterior crural nerve**, from the second, third, and fourth lumbar nerves.

Actions.

Many of the actions of the above muscles have already been given in previous sections. (1) Their chief action is to retract the abdominal walls, and, by compressing the contents of the abdomen, they are powerful agents in vomiting, defæcation, micturition, parturition, and laboured expiration. (2) They are also flexors of the spine and pelvis—the muscles of both sides acting together; the spine and pelvis are laterally flexed, when one set of muscles acts alone. (3) The quadratus lumborum is a muscle of inspiration, an extensor of the spine, and a lateral flexor of the spine and pelvis.

FASCIÆ AND MUSCLES OF THE PERINEUM AND PELVIS.

FASCIÆ OF THE PERINEUM.

The **superficial fascia** of the perineum possesses certain special features. It is continuous with the superficial fascia of the abdominal wall, thigh, and buttock, and is prolonged on to the penis and scrotum. In relation to the penis, it is devoid of fat and consists only of areolar tissue. In relation to the scrotum, it is intermingled with involuntary muscular fibres, and constitutes the **dartos muscle**, which assists in suspending the testicles and corrugating the skin of the scrotum. This fascia also forms the **septum of the scrotum**, which, extending upwards, incompletely separates the two testicles and their coverings. In the female the superficial fascia takes a large share in the formation of the mons veneris and labia majora, in which a considerable quantity of fat occurs.

The fascia over the posterior part of the perineum fills up the ischio-rectal fossæ, in the form of two pads of adipose tissue, on either side of the rectum and anus. Over the tuberosities of the ischium the fat is largely replaced by bands of fibrous tissue closely adherent to the subjacent deep fascia.

The fascia in the anterior part of the perineum closely resembles the same cia in the groin. It is divisible into a superficial fatty and a deeper membranous er; the former continuous with the same layer in the thigh, and with the fat the ischio-rectal fossa posteriorly. The deeper membranous layer is attached erally to the pubic arch, posteriorly to the base of the triangular ligament, and the middle line to the root of the penis (bulb and corpus spongiosum) by a dian raphe continuous farther forwards with the septum of the scrotum entioned above. Anteriorly the fascia is continued over the spermatic cords to e anterior abdominal wall. The importance of this fascia lies in relation to the travasation of urine from a rupture of the urethra. By the fascial attachments e fluid is prevented from passing backwards into the ischio-rectal fossa, or terally into the thigh. It is directed forwards into relation with the scrotum d penis, and along the spermatic cord to the anterior abdominal wall. The ptum of the scrotum being incomplete, fluid extravasated on one side can pass ross the middle line to the opposite half of the perineum and scrotum.

The **deep fascia** of the perineum only exists in the form of the delicate oneuroses of the muscles.

THE MUSCLES OF THE PERINEUM.

The perineal muscles are naturally separated into a superficial and a deep set by e triangular ligament. Superficially are the sphincter ani externus, transversus

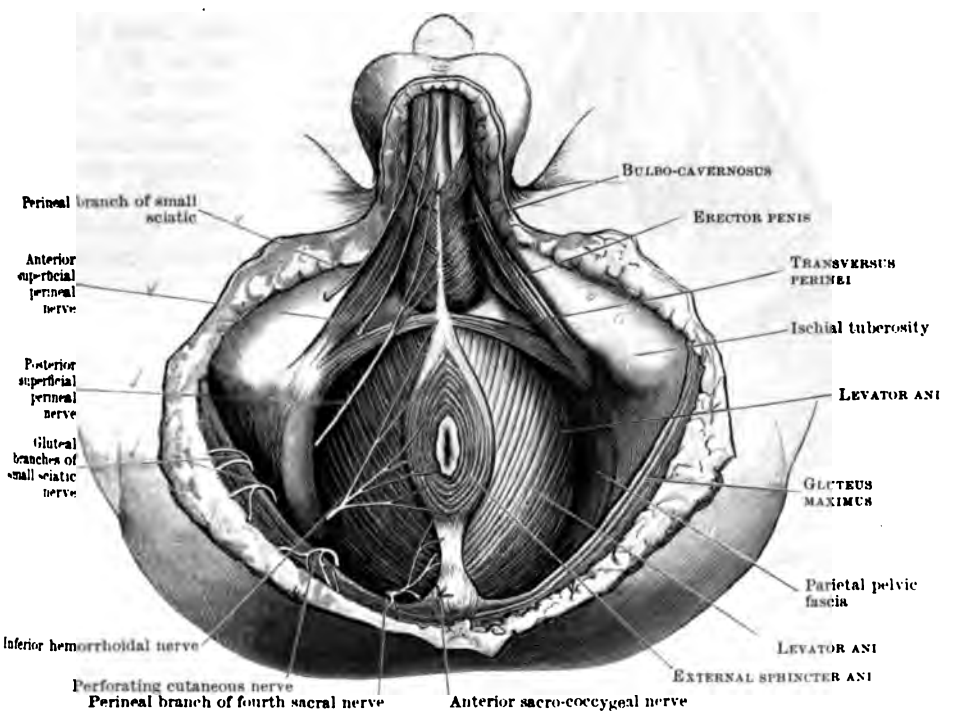


Fig. 345.—The Muscles and Nerves of the Male Perineum.

erinei superficialis, bulbo-cavernosus, and ischio-cavernosus; beneath the triangular gament is the compressor urethræ.

Sphincter ani Externus.—This muscle is fusiform in outline, flattened, and bliquely placed around the anus and anal canal. It can be separated into ree layers,—subcutaneous, superficial, and deep. (1) The most **superficial lamina** nsists of subcutaneous fibres decussating behind and in front of the anus, but thout bony attachments. (2) The **sphincter ani superficialis** constitutes the ain portion of the muscle. It is attached posteriorly to the coccyx, and in ont of the anus reaches the central point of the perineum. (3) The **deep fibres**

of the muscle form for the most part a complete sphincter for the anal canal. They are continuous with the fibres of the levator ani; they encircle the anal canal, and blend anteriorly with the central point of the perineum and the transverse perinei.

The muscle surrounds the anus, covered only by the skin, superficial fascia, and the **corrugator cutis ani** (a series of non-striated muscular fibres radiating from the anal opening). It rests on the edge of the levator ani, and forms the medial boundary of the ischio-rectal fossa.

The **transversus perinei superficialis** is not always present. It consists of a more or less feeble bundle of fibres, **arising** from the ascending ramus of the ischium and the fascia over it, and from the base of the triangular ligament. It is directed inwards and forwards to be **inserted** into the central point of the perineum. It conceals the base of the triangular ligament, and has a variable relation to the superficial perineal vessels and nerves.

The **bulbo-cavernosus** (ejaculator urinæ), *in the male*, surrounds the bulb, corpus spongiosum, and root of the penis. It is sometimes separated into two parts—*posterior* (compressor bulbi), and *anterior* (compressor radicis penis). It **arises** from the central point of the perineum, and from a median raphe on the under surface of the bulb and corpus spongiosum. The muscular fibres are directed outwards and forwards, and have a triple **insertion**: from behind forwards, (1) into the under surface of the triangular ligament; (2) into the membrane covering the corpus spongiosum; and (3), after encircling the corpora cavernosa, into the fascia covering the dorsum of the penis.

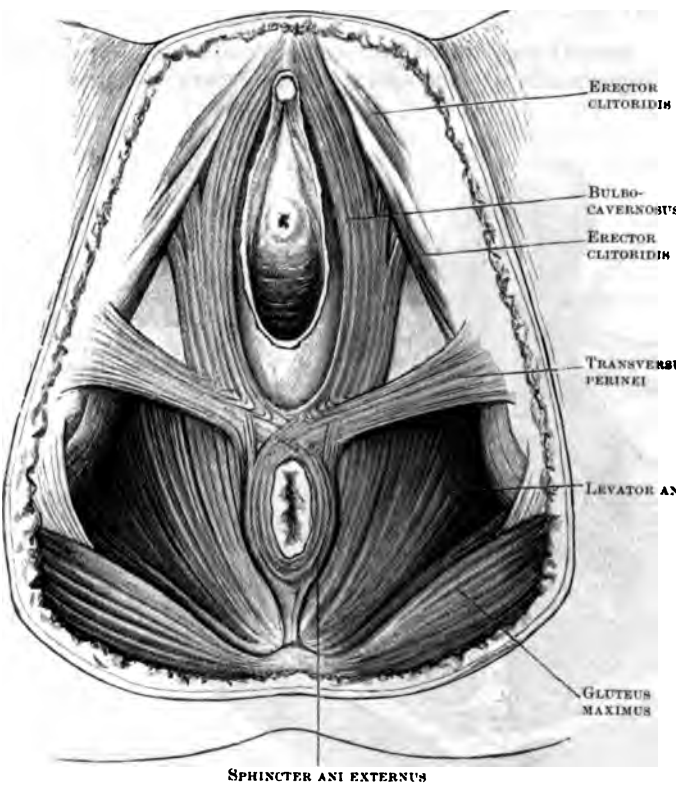

FIG. 346.—THE MUSCLES OF THE FEMALE PERINEUM (after Peter Thompson).

The **ischio-bulbosus**, not always present, **arises** from the ischium, and passes obliquely inwards and forwards over the bulbo-cavernosus, to be **inserted** into the raphe superficial to that muscle. It belongs to the same stratum as the transversus perinei and erector penis.

The **compressor hemispherium bulbi** is frequently absent. It consists of a thin cap-like layer of muscular fibres surrounding the extremity of the bulb under cover of the bulbo-cavernosus.

The **bulbo-cavernosus** (sphincter vaginæ), *in the female*, is separated into lateral halves by the vaginal and urethral openings. It forms two thin lateral layers covering the vaginal bulbs, and **arises** behind the vaginal orifice from the central point of the perineum. Anteriorly it is **inserted** into the root of the clitoris, some of its fibres embracing the corpora cavernosa so as to reach the dorsum of the clitoris.

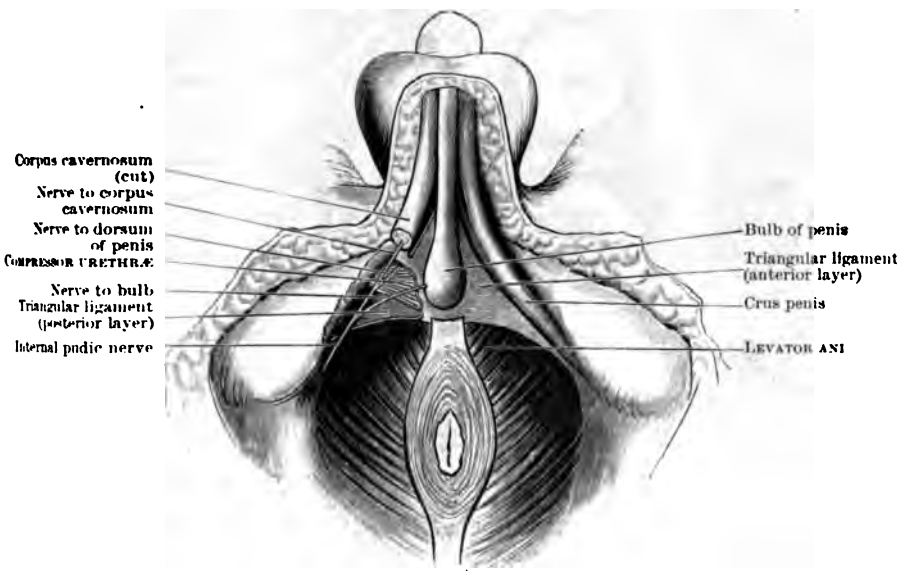
The **ischio-cavernosus** (erector penis), *in the male*, covers the crus penis. It

s from the ischial tuberosity and the great sacro-sciatic ligament, and passing ards, is **inserted** by a fascial attachment into the under surface of the crus s, and into the outer side and dorsal aspect of the corpus cavernosum.
The **ischio-cavernosus** (erector clitoridis), *in the female*, has a similar disposition, is of much smaller size than in the male.

The **pubo-cavernosus** is an occasional slip **arising** from the pubic ramus, and **inserted** into dorsum of the penis. It corresponds to the levator penis of lower animals.

The **compressor urethræ** (constrictor urethræ) constitutes the deeper muscular tum of the perineum. It is placed on the pelvic aspect of the triangular ment. It **arises** from the lower part of the pubic ramus, and is directed inwards, fibres radiating so as to enclose the membranous urethra. It is **inserted** into a lian raphe, partly in front of the urethra, but for the most part behind it. The es most intimately related to the urethra form a tubular sheath for the canal, have no bony attachments.

The most anterior and most posterior fibres of the compressor urethræ exist sometimes eparate muscles.
The **transversus perinei profundus** consists of a bundle of fibres on either side, **ing** from the ascending ramus of the ischium just below the compressor urethræ. It **serted** into a median raphe continuous with that of the compressor urethræ. The cle, in fact, constitutes a separate bundle below and behind the compressor urethræ.
The **ischio-pubicus** is a term applied to a feeble bundle of fibres which, when



347.—The Triangular Ligament of the Perineum, and the Termination of the Pudic Nerve.

sent, lies above and in front of the compressor urethræ. It **arises** from the pubic nus, and is **inserted** into a median raphe in front of the membranous urethra. This scle is homologous with the **compressor venæ dorsalis penis** of lower animals.

The **compressor urethræ** *in the female* is smaller than in the male. Its ertion is modified by the relations of the urethra to the vagina. The anterior es are continuous with those of the opposite side in front of the urethra; the rmediate fibres pass between the urethra and vagina, and the posterior fibres attached, along with the **transversus perinei profundus** (transversus vaginæ), into side of the vagina.

Nerve-Supply.

The **pudic nerve** (S. 2. 3. 4.) supplies all the muscles in this group; the external sphincter ugh the inferior hemorrhoidal, and the others through the perineal branch of the nerve. external sphincter is also supplied by the perineal branch of the **fourth sacral nerve.**

ACTIONS.

The **external sphincter** closes the anal canal. The **transversus perinei superficialis** d... back and fixes the central point of the perineum, assisted by the external sphincter. The **bu... cavernosus** of the male constricts the bulb and corpus spongiosum, and so expresses the last d... of urine or semen. In the female it acts as a feeble sphincter of the vagina. The **is... cavernosus** and **bulbo-cavernosus** help in erection of the penis or clitoris. The **compr... urethræ** constricts the membranous urethra, and in the female helps to flatten and fix the wa... the vagina. It also assists in causing erection of the penis or clitoris by compression of the v... in relation to it.

FASCIA OF THE PELVIS.

The pelvic basin, placed obliquely, deeper and more hollowed behind than ... front, and imperfect in its bony boundaries, is to a large extent completed by li... ments. The sacro-sciatic ligaments behind, the obturator membrane laterally, a... the triangular ligament in front assist in filling up its osseous deficiencies. It ... almost entirely clothed internally by muscles: by the pyriformis on each s... behind, the obturator internus at the side, and the compressor urethræ in cont...

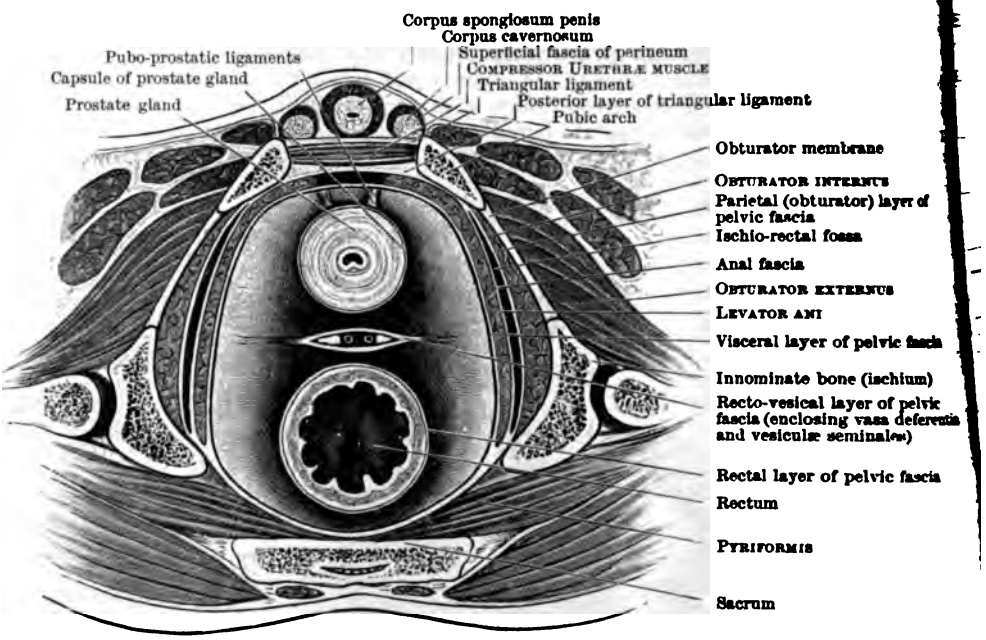


FIG. 348.—DISSECTION OF THE PELVIC FASCIA FROM ABOVE (diagrammatic).

with the triangular ligament in front. Indeed, the bones of the pelvis only project into the cavity in three places; the spines of the ischium project into the cavity on each side, and the pubis appears in its anterior wall.

The pelvic fascia forms a cylindrical membrane lining the wall of the pelvis, as an aponeurosis for its muscles. It is attached above and below to the inlet and outlet of the pelvis; above to the promontory of the sacrum, ilio-pectineal line, and back of the pubis; below to the coccyx, great sacro-sciatic ligament, tuber ischii, and the base of the triangular ligament. This cylindrical membrane is the **parietal pelvic fascia**; it forms the **pyriformis fascia** behind, the **obturator fascia** at the side of the pelvis, and the so-called **posterior layer** of the **triangular ligament** in front. As this fascia lines the pelvic wall it obtains attachments to the projecting bones, to the back of the pubis anteriorly, and to the spine of the ischium on each side. It is deficient in relation to the obturator groove, through which the obturator artery and nerve pass to reach the thigh.

The **white line**, a thickened band of the fascia, extends between the back of the pubis and the spine of the ischium, and roughly indicates the line of separation of the pelvic cavity from the ischio-rectal fossa. The white line serves two purposes; it gives origin to fibres of the levator ani muscle, and also to a **secondary**

fascia, known as the **visceral pelvic fascia**, which arches downwards and across the floor of the pelvis to be connected with the pelvic viscera. This ane is thin and unimportant behind, as it passes forwards from the lower ertebræ to the rectum. It is thicker at the sides and front of the pelvis, it forms nembrane upwards, ious mesi- with the coats of tum and , and en- g the pros- land and e semin- t the front pelvis this extends ne back of ubis, to it is di- attached, eck of the and pros- land, and

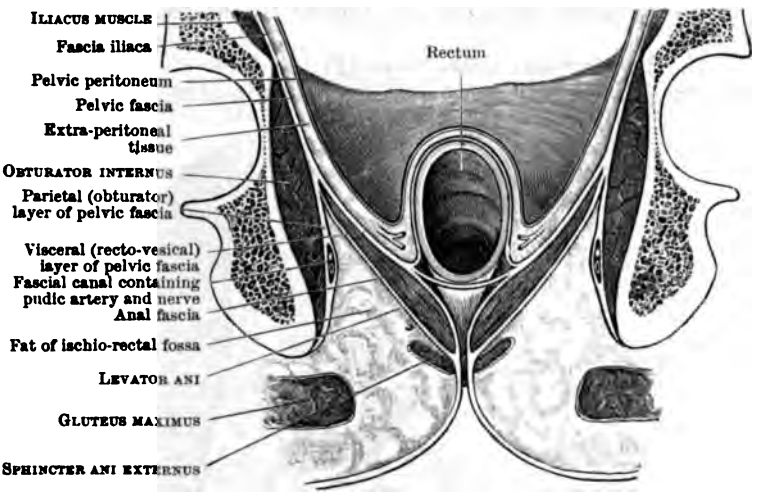

Fig. 349.—Oblique Section across the Pelvis, to show the Disposition of the Pelvic Fascia and the Boundaries of the Ischio-Rectal Fossa.

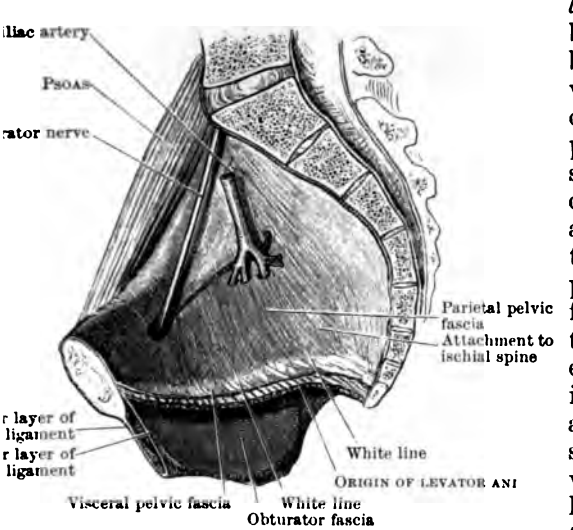
ise to two lateral folds—the **pubo-prostatic ligaments**, which enclose a them a hollow on the pelvic aspect of the fascia, known as the **cavum** The lateral portion of the visceral pelvic fascia constitutes the **recto-vesical** ivisible into three parts—*vesical*, *rectal*, and between these the *recto-vesical layer*, a partition insinuated between the rectum and bladder, and enclosing the vesiculæ seminales and vasa deferentia. This visceral pelvic fascia thus forms a support for the pelvic viscera, and at the same time acts as a partition between the pelvic cavity and the perineum. It is separated from the pelvic cavity by the peritoneum and the extra-peritoneal tissue, and is in contact with the levator ani muscle on its perineal surface. The internal iliac vessels and their branches lie on the pelvic aspect of the fascia, and the parietal vessels pierce it, and are en-



350.—The Outer Wall of the Pelvis (Pelvic Fascia).

d by it as they leave the pelvis. On the other hand the spinal nerves the sacral plexus lie outside the fascia with one exception. The obturator fter piercing the inner border of the psoas muscle and the psoas fascia, leaves vis through a special hole in the pelvic wall, after traversing the extra- eal tissue.

pelvic fascia in the female only differs in slight detail from that of the It encloses the neck of the bladder and vagina instead of the prostate and invests the lower part of the neck of the uterus instead of the vesiculæ les.

MUSCLES OF THE PELVIS.

The pelvic diaphragm consists of several more or less rudimentary mus slips, constituting the levator ani and ischio-coccygeus muscles, which serv uphold the pelvic floor, and are related to the rectum and the prostate glan vagina.

The **levator ani arises** from (1) the back of the body of the pubis, (2 parietal pelvic fascia above or along the *white line*, and (3) the spine of the isch

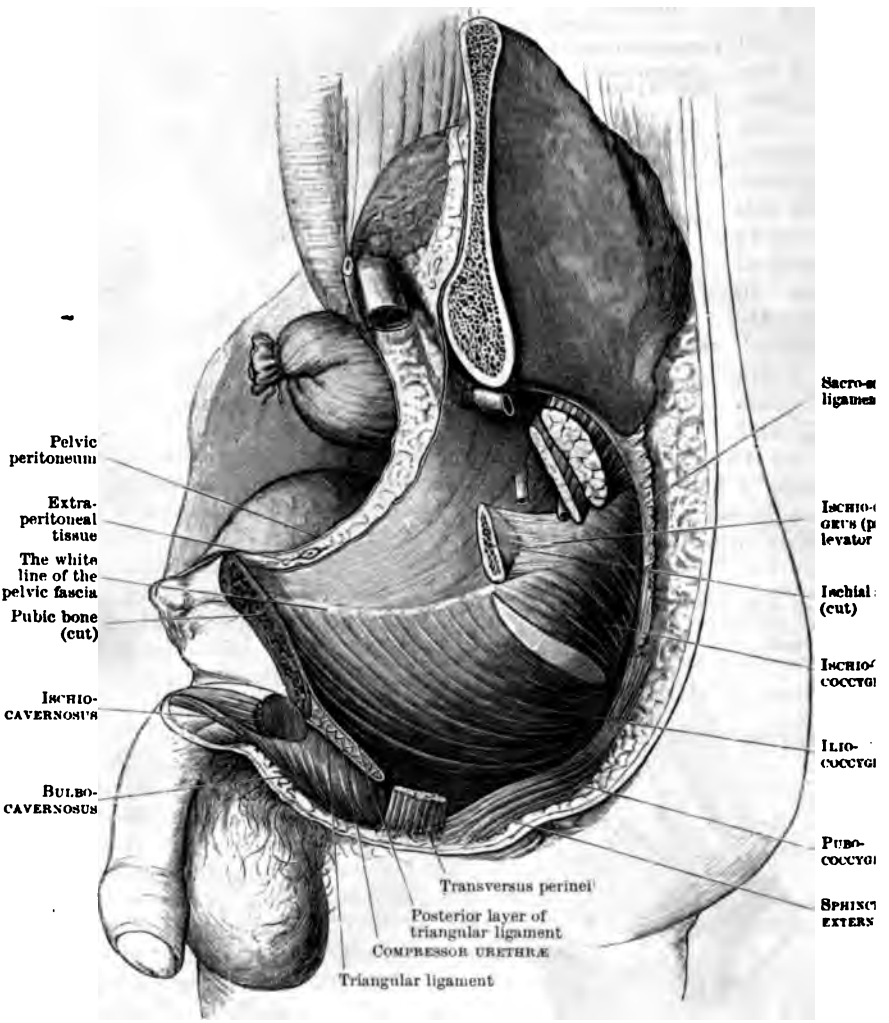


Fig. 351.—The Fascial and Muscular Wall of the Pelvis after Removal of Part of the Innominate Bone.

Its fibres are directed downwards and backwards, to be **inserted** into (1) the ce point of the perineum, (2) the external sphincter around the anus and the coccygeal raphe behind the anus, and (3) into the sides of the lower sacral an coccygeal vertebræ.

The concave upper surface of the muscle is covered in part by the vis pelvic fascia; in part it is in contact with the rectum behind and the pro gland or vagina in front. The inferior convex surface of the muscle form inner wall of the ischio-rectal fossa. Its posterior edge is overlapped by ischio-coccygeus; its anterior edge is in contact with the posterior layer o triangular ligament.

ıe **levator ani** is divisible into four parts—pubo-rectalis, pubo-coccygeus, ilio-ɔeus, and ilio-sacralis. The **pubo-rectalis** (levator prostatæ) is the part inserted into ntral point of the perineum. The **pubo-coccygeus** is the part inserted into the anus ıe ano-coccygeal raphe, and the **ilio-coccygeus** and **ilio-sacralis** are represented by ɔres attached to the sacrum and coccyx. The first two are best developed; the last ries of fibres are the most rudimentary. These several parts of the muscle represent mains of the flexor caudæ of tailed animals.

he **ischio-coccygeus** is a rudimentary muscle overlapping the posterior border e levator ani. It **arises** from the ischial spine and the small sacro-sciatic ıent, and is **inserted** into the sides of the lower two sacral and upper two geal vertebræ. The muscle is separated from the rectum by the visceral c fascia, and is in contact externally with the sacro-sciatic ligaments.

NERVE-SUPPLY.

ıe **levator ani** is supplied from two sources: by the perineal (muscular) branch of the pudic , and, on its pelvic surface, by special branches from the third and fourth sacral nerves. **schio-coccygeus** is supplied on its pelvic surface by the third and fourth sacral nerves.

ACTIONS.

The levator ani and ischio-coccygeus serve to uphold and slightly raise the pelvic floor. hey are likewise capable of producing slight flexion of the coccyx. (3) The anterior fibres e levator ani, in the female, sweeping round the vagina, compress its walls laterally, and with the sphincter vaginæ, help to voluntarily diminish the lumen of the tube. (4) The part of the muscle in the male elevates the prostate gland (levator prostatæ). (5) The chief ı of the levator ani is in *defæcation*. Along with the external sphincter it acts as a sphincter e rectum, closing the anal canal. During defæcation the muscle draws upwards the anus the fæcal mass, and so assists in its expulsion. (6) *In parturition*, in the same way, the le, contracting below the descending fœtal head, retards delivery. Contracting on the fœtal it draws upwards the pelvic floor over the fœtus, and so assists delivery.

IE DEVELOPMENT AND MORPHOLOGY OF THE SKELETAL MUSCLES.

ur knowledge of the development and morphology of the muscular system is very nplete. It has already been shown, in the chapter on general embryology, that the blast on either side of the embryonic medullary tube separates into three main parts—**nyotome, nephrotome,** and **sclerotome** or **lateral plates** (somatopleure and splanchno-e).

he **myotomes** are probably directly or indirectly the source of the striated muscles ıe whole body. Each consists at first of a quadrilateral bilaminar mass, resting ıst the medullary tube and notochord on either side. The cleft between its two layers sents the remains of the cœlomic cavity. In the early stages of embryonic life the th of the myotome is rapid. On its inner side masses of cells arise, which grow in- s and surround the medullary tube and notochord to form the foundation of the bral column. On its outer side cells appear to be given off which participate in the ation of the cutis vera. At the same time the dorsal and ventral borders of the tome continue to extend, and present extremities (growing points) with an epithelial ture for a considerable period. *On the dorsal side* it overlies the medullary tube, and rise to the muscles of the back; while by its *ventral extension*, which traverses the topleuric mesoblast in the body wall, it produces the lateral and ventral muscles of runk. By an inward extension it probably gives rise also to the hypaxial muscles of ıeck and loin. The cells of the inner layer of the myotome are responsible for the ation of the muscle fibres. The cells elongate in a direction parallel to the axis of the embryo, and give rise, by fusion with the cells of neighbouring myotomes, e columns and sheets of muscles of the back and trunk. For the most part (*e.g.* back abdomen) the originally segmental character of the muscular elements is lost by the or less complete fusion of adjacent myotomes. The intercostal muscles, however, he direct derivatives of individual myotomes.

Muscles of the Limbs.—In fishes and (doubtfully) reptiles there is evidence that nyotomes are concerned in the formation of the limb-muscles by their extension into imb-bud in a manner similar to that described for the trunk. In birds and mammals, ver, in which the limb-bud arises as an undifferentiated, unsegmented mass of blastic tissue, partly from the mesoblast surrounding the notochord, and partly from somatopleuric mesoblast, the myotomes stop short at the root of each limb, and ot penetrate into its substance. Instead, the muscular elements of the limb take

origin independently as *double dorsal* and *ventral strata* of fusiform cells on the dorsal and ventral surfaces of the limb-bud. These strata are *unsegmented*; they are grouped around the skeletal elements of the limb, and they gradually become differentiated into the muscle masses and individual muscles of the limb.

Muscles of the Head.—Notwithstanding the obscurity and complexity of this

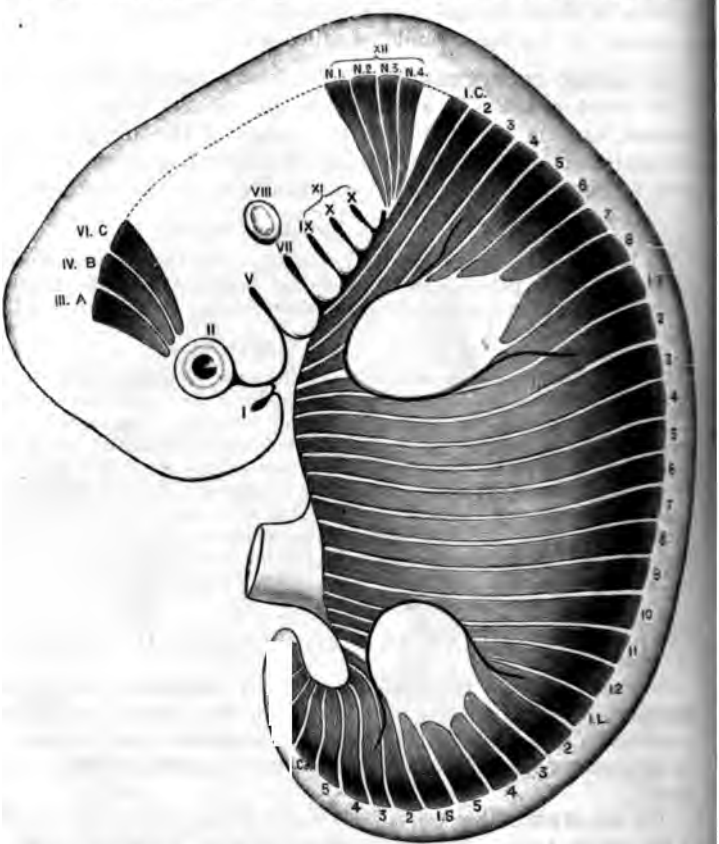

FIG. 352.

SCHEME TO ILLUSTRATE THE DISPOSITION OF THE MYOTOMES IN THE EMBRYO IN RELATION TO THE HEAD, TRUNK, AND LIMBS.

A, B, C, First three cephalic myotomes; N, 1, 2, 3, 4, Last persisting cephalic myotomes; C., T., L., S., Co., The myotomes of the cervical, thoracic, lumbar, sacral, and caudal regions; I., II., III., IV., V., VI., VII., VIII., IX., X., XI., XII., refer to the cranial nerves and the structures with which they may be embryologically associated.

subject, it appears certain that *at least two series* of elementary structures are concerned in the formation of the muscles of the head and face—the **cephalic myotomes** and the muscular structure of the **branchial arches.**

The number of myotomes originally existing in the region of the head is not known, although it is stated with some authority that nine is the perfect number. The *first three* are described as persisting in the form of the ocular muscles, the *last three* in relation to the muscles of the tongue, while the *three intervening myotomes* disappear.

The following table shows the possible fate of the cephalic myotomes:—

First, Superior, internal and inferior recti, obliquus inferior, levator palpebræ superioris.
Second, Obliquus superior.
Third, Rectus externus.
Fourth, *Fifth* and *Sixth*, Absent.
Seventh, *Eighth*, } Muscles of the tongue.
Ninth, *Tenth* (*first cervical*) } Muscles connecting the cranium and shoulder girdle.

The **mesoblastic tissue of the branchial arches** is probably concerned in the production of the following muscles of the face and neck:—

First (*mandibular*) *arch* . .	Muscles of mastication.
Second (*hyoid*) *arch* . . .	Platysma myoides and facial muscles. Muscles of the soft palate. Stapedius, stylo-hyoid, and digastric.
Third (*thyro-hyoid*) *arch* . .	Stylo-pharyngeus. Superior constrictor.
Fourth and Fifth (*branchial*) *arches*	Middle and inferior constrictors. Muscles of the larynx.

THE NERVOUS SYSTEM.

THE BRAIN AND SPINAL CORD, WITH THEIR MENINGES.

By D. J. CUNNINGHAM.

The nervous system connects the various parts of the body with each other and **co-ordinates them** into one harmonious whole. Its relatively great bulk and its **extreme complexity** constitute two of the most distinctive structural features **of man.** It consists of two parts, viz. the cerebrospinal nervous system and the **sympathetic** nervous system.

The sympathetic nervous system is composed of a chain of serially disposed **ganglia, bound** to each other by intervening nervous cords, and placed one on either **side of the vertebral** column. In addition to these gangliated cords, the sympathetic **system includes** certain dense plexuses of nerves and numerous scattered ganglia. **The whole is most** intimately connected with the cerebrospinal nervous system, and **both have** apparently a common developmental origin. The separation of the **nervous system** into the two leading subdivisions of sympathetic and cerebro-**spinal is therefore** of a somewhat arbitrary kind.

The **cerebrospinal nervous system** consists of the brain, which very nearly completely fills the cranial cavity, and the spinal cord or spinal marrow, which only partially fills the vertebral canal. These are continuous with each other, and together constitute the cerebrospinal axis. Attached to the brain and spinal cord are the numerous nerves which bring the various parts of the body into connexion with the central nervous axis. There are thirty-one pairs of symmetrically disposed **spinal nerves** attached to the sides of the spinal cord. Each of these nerves is connected to the side of the cord by a **ventral** or **anterior** and a **dorsal** or **posterior root**, and the dorsal root is distinguished by presenting a distinct oval swelling, termed a **spinal ganglion**, on that part of its course immediately internal to the place where the two roots unite to form the **spinal nerve-trunk** (Fig. 365, p. 453).

The **cranial nerves** are twelve in number on each side, but one only (viz. the fifth or trigeminal) presents a double-rooted attachment similar to a spinal nerve Several, however, possess ganglia in every respect comparable with the ganglia on the dorsal roots of the spinal nerves. These are the fifth or trigeminal, the seventh or facial, the eighth or auditory, the ninth or glosso-pharyngeal, and the tenth or vagus cranial nerves.

CEREBROSPINAL NERVOUS SYSTEM.

The brain and spinal cord are composed of two substances which present a different appearance to the eye, and which are distinguished by the terms **white matter** and **gray matter**. The difference in colour between these two substances depends not only upon the different elements which enter into their formation, but also upon the fact that the gray matter is the more vascular of the two. The white matter is chiefly composed of nerve-fibres, whilst the essential constituents of the gray matter are nerve-cells which give origin to nerve-fibres. An all pervading matrix termed the neuroglia forms the bed in which the nerve-fibres and

nerve-cells lie, and is present both in the gray and the white matter. The elements therefore, which constitute nervous tissue are nerve-cells, nerve-fibres, and neuroglia.

Nerve-fibres.—Nerve-fibres arranged in bundles of greater or less bulk form the nerves which pervade every part of the body. They also constitute the greater part of the brain and spinal cord. Nerve-fibres are the conducting elements of the nervous system; they serve to bring the nerve-cells into relation both with each other and with the various tissues of the body.

There are different varieties of nerve-fibres, but in all the leading and essential constituent is a delicate thread-like band, termed the **axis-cylinder.** The difference between individual fibres depends upon the fact that in some cases the axis-cylinder becomes invested by one or two coats, whilst in other cases it remains naked. When the axis-cylinder is coated on the outside by a more or less thick sheath of a fatty substance termed **myelin,** it is said to be a myelinated or medullated fibre. When the coating of myelin is absent, the fibre is termed a non-myelinated or a non-medullated fibre. A second sheath—thin, delicate, and membranous, and placed externally—may also be present in both cases. It is termed the **primitive sheath** or the **neurolemma.** From a structural point of view, therefore, four different forms of nerve-fibre may be recognised:—

FIG. 353. NERVE-FIBRE FROM A FROG (after v. Kölliker).

Non-medullated	1. Naked axis-cylinders.
	2. Axis-cylinders with primitive sheaths.
Medullated	3. Primitive sheath absent.
	4. Primitive sheath present.

Every nerve-fibre near its origin and as it approaches its termination is unprovided with sheaths of any kind, and is simply represented by a non-medullated naked axis-cylinder. The fibres of the olfactory nerves afford us an example of non-medullated fibres furnished with a primitive sheath.

Medullated fibres are present in greater quantity in the cerebro-spinal system than non-medullated fibres. Thus all the nerves attached to the brain and cord, with the exception of the olfactory and optic, are formed of medullated fibres provided with a primitive sheath; whilst the entire mass of the white substance of the brain and cord, and also the optic nerves, are formed of medullated fibres devoid of a primitive sheath.

It is important to note that the distinction between the medullated and non-medullated fibres is not one which exists throughout all stages of development. As will be presently pointed out, every fibre is a direct outgrowth from a cell, and in the first instance it is not provided with a medullary sheath. Indeed, it is not until about the fifth month of fœtal life that those fibres which are to form the white substance of the cerebrospinal axis begin to acquire their coating of myelin. Further, this coating appears in the fibres of different strands or tracts at different periods, and a knowledge of this fact has enabled the anatomist to follow out the connexions of the tracts of fibres which compose the white matter of the brain and cord.

But it may be asked: How does a nerve-fibre arise and how does it end? Every fibre is directly continuous by one extremity with a nerve-cell, whilst its opposite extremity breaks up into a number of ramifications, all of which end freely in relation to another nerve-cell, or in relation to certain tissues of the body, as, for example, to muscle-fibres or to the epithelial cells of the epidermis. The length of nerve-fibres, therefore, varies very greatly. Some fibres are short and merely bring two neighbouring nerve-cells into relation with each other: others travel long distances. Thus a fibre arising from one of the motor cells of the lower end of the spinal cord may, after leaving the cord, extend to the most outlying muscle in the sole of the foot before it reaches its destination. But even when a fibre does not leave the central axis a great length may be attained, and cells

uated in the motor area of the cortex of the cerebrum give origin to fibres which s down to the lower end of the cord.

Physiologists classify the fibres which form the nerves into two sets, afferent l efferent. **Afferent nerve-fibres** conduct the impulse of impressions from the ipheral organs into the central nervous system; and as a change of consciousness, in other words, a sensation is a frequent result, these fibres are often called sory. **Efferent nerve-fibres** carry impulses out from the brain and cord to peri- ral organs. The majority of these fibres go to muscles and are termed *motor*; ers, however, go to glands and are called *secretory*; whilst some are *inhibitory* d serve to carry impulses which restrain or check movement or secretion. As viously stated, spinal nerves are ch attached to the rd by a ventral or terior root, and a sal or posterior ot; the fibres com- sing the former e efferent; whilst ie fibres of the sterior root are most entirely ferent.

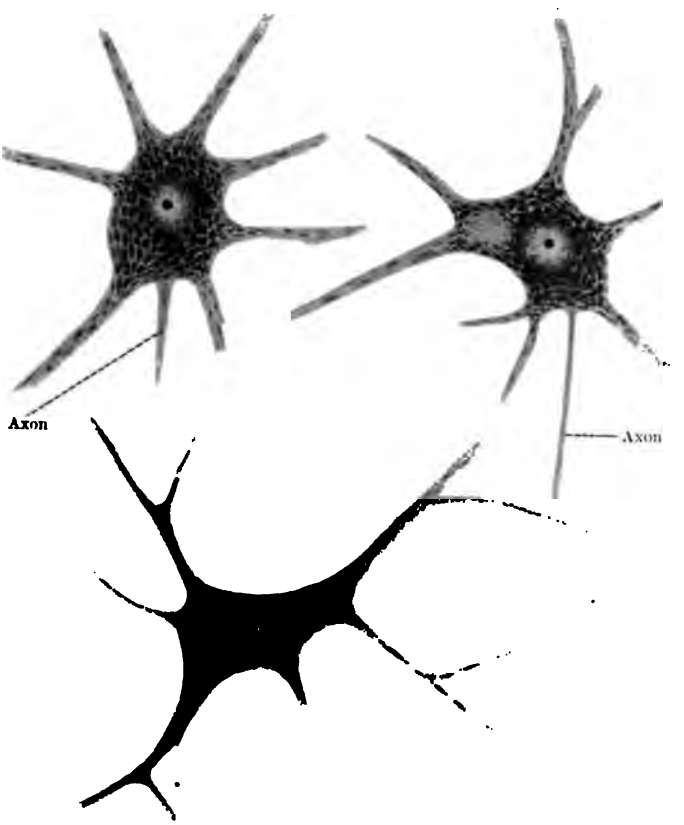

Fig. 354.—Three Nerve-Cells from the Anterior Horn of Gray Matter of the Human Spinal Cord.

Nerve-cells.—he nerve-cells con- itute the active nd all-essential lements of nerve- issue. At the very art it is necessary o draw a broad listinction between he ganglionic cells, hich are found in he spinal ganglia, nd the cells which re so plentifully attered through he gray matter of he brain and cord. They differ not only n their mode of rigin and in their ubsequent develop- ent, but also in the connexions of the nerve-fibres to which they give origin.

Nerve-cells of the Brain and Cord.—The cells in the gray matter of the erebrospinal axis are variable both in size and form. Some are relatively large, s, for example, certain of the pyramidal cells of the cerebral cortex and the motor ells in the gray matter of the cord, which almost come within the range of unaided ision; others are exceedingly minute, and require a high power of the microscope o bring them into view. The cell consists of a protoplasmic nucleated body, from hich certain processes proceed. One process is termed the **axis-cylinder process** or **xon**: and as a rule it is easily distinguished from the others, which are collectively alled the **protoplasmic processes of Deiters**, or the **dendrites**.

The **axon** presents a uniform diameter and a smooth and even outline. It gives ff in its course fine collateral branches, but does not suffer thereby any marked liminution in its girth. The most important point to note in connexion with the xon, however, is the fact that it becomes continuous with the axis-cylinder of a erve-fibre. The significance of this is obvious, and will become more striking

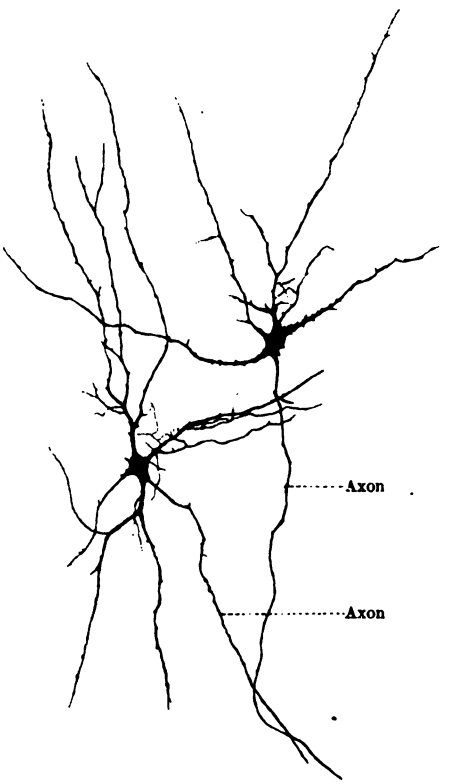

FIG. 355.—TWO MULTIPOLAR NERVE-CELLS, from a specimen prepared by the Golgi method.

basket-work. In cases where the axon emerges from the cerebrospinal axis its terminal arborisation ends in relation to a muscle-fibre or some other tissue in the manner already referred to. In all cases, however, it would appear that the terminal branches of the axon, no matter how complicated the connexion may seem, are free, and that the connexion is simply one of contact or contiguity, and not one of continuity.

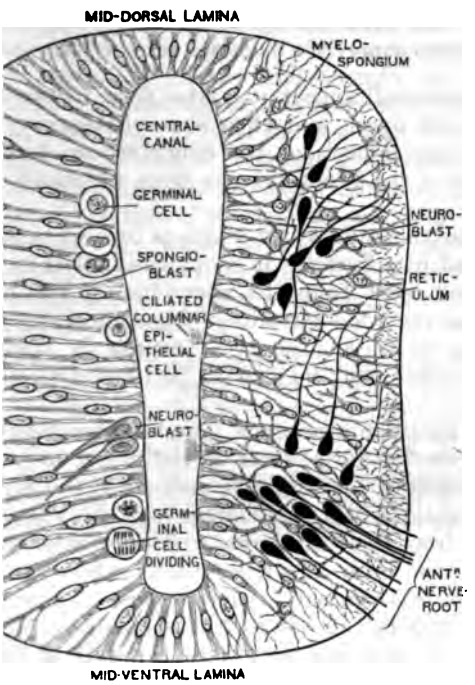
Held maintains that, although at first the terminal arborisations of an axon are quite free, in the process of growth and development they exhibit a tendency to become fused with the dendrites and even the bodies of other nerve-cells.

when the development of the ne is studied. The axon then is s nerve-fibre, and in certain circumst assumes, as already stated, one investing sheaths. The axon may entire course within the substance brain or cord either for a short or distance, or it may emerge from th or cord in one of the cranial or nerves as the essential part of an nerve-fibre, and run a variable before it finally reaches the pe structure in relation to which it end axon and the collaterals which spri it terminate either in small butt swellings or knobs, or more freque terminal arborisations, the extrem which are free and are furnished w ceedingly small terminal varicositi those cases where the axon or its col end within the brain or cord, some terminal arborisations interlace w dendrites of nerve-cells, whilst oth twined around the bodies of oth In the latter case the interlaceme be so close and complete that it presents the appearance of an e

FIG. 356. — NERVE-CELL FROM CEREBELLUM (CELL OF P SHOWING THE BRANCHING OF THE DENDRITIC PROCES a lantern slide by Professor Symington).

dendrites, or protoplasmic processes of the nerve-cell, are thicker than the d present a rough-edged irregular contour. They divide into numerous , and these gradually, as they pass from the cell-body, become more and enuated until they finally end in free extremities. The branching of the processes sometimes attains a marvellous degree of complexity (Fig. 356), ept in exceptional circumstances, there is no *anastomosis* between the s of neighbouring cells, or between the dendrites of the same cell. It ppear, therefore, that nothing in the shape of a network is formed by these s.

he chapter upon Embryology it has been shown that in the early condition erebrospinal axis the brain and cord consist simply of a tube (p. 21). The this tube is formed of a single layer of tall columnar neuro-epithelial cells,



-TRANSVERSE SECTION THROUGH THE EARLY NEURAL
liagrammatically represented (Alfred H. Young).
ft side of the section exhibits an earlier stage of development than the right side.

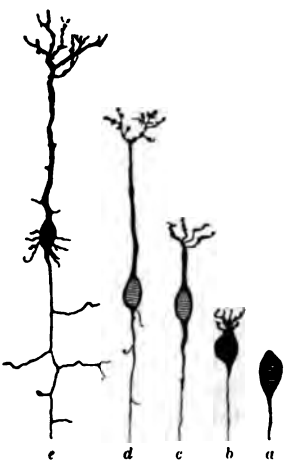


FIG. 358. — THE DEVELOPMENTAL STAGES EXHIBITED BY A PYRAMIDAL CELL OF THE BRAIN (after Ramón y Cajal).

its deepest or most internal part large round cells make their appearance ntervals between the epithelial columns. These new cells are termed the . **cells**, and from them the nerve-cells are derived. They are present in able numbers, and towards the fourth week of embryonic life they form an continuous layer. Although these cells ultimately become nerve-cells they lutely without processes in their early state, and therefore at this period, there is a nervous system, there are, as His remarks, no nerves. In of time, and as the wall of the neural tube thickens, the germinal cells migrate in an outward direction. They leave the deep part of the wall neural tube and proceed to take up the positions they occupy in the gray of the cord and brain of the adult. These migrating cells assume a pyriform nd are termed **neuroblasts**. The drawn-out portion or stalk of the pear- neuroblast represents the early axon, and this continues to grow and increase gh until it ultimately attains the terminal relations characteristic of the The study of embryology presents few more remarkable phenomena than the in which this axon grows out, and, in the efferent nerve-fibres, emerges

from the central axis, and yet pursues its allotted path with the most u exactitude and precision until it ultimately reaches the nerve-cell or the per tissue element with which it becomes associated. The growing point of t and its collaterals is slightly bulbous, and it is out of this that the te arborisation is formed.

This conception in regard to the outgrowth of the axon in the case of the pe nerve-fibres has not been allowed to pass unchallenged, and it must be admitt certain facts recently observed militate against it.

Whatever opinion may be held in regard to the developmental origin of t cylinder and medullary sheath of a peripheral nerve-fibre, there is every reason belief that the neurolemma is mesodermic in its origin, and is therefore formed fr outside the ectodermic neural tube. There are some who think that the axis-cyl secreted *in situ* by a chain of these cells, whilst others consider that the mesoblas of a nerve-fibre merely constitute a cellular tube through which the growing axo its way to its destination, and perhaps also supply the pabulum necessary for its g

The dendritic processes of the nerve-cell appear at a later period than th The surface of the neuroblast becomes rough and then somewhat spiny. growth and subdivision of these spiny projections the dendrites are forme His remarks, the nerve-cell is therefore the genetic centre from which all th of a nervous element proceed.

It must now be clear that each nerve-cell is a unit which is separate and from the nerve-cells which lie around it. Further, it is obvious that it is w consider the nerve-cell as something apart from the nerve-fibre. The ne with its dendrites and axon, however wide-spreading these processes n constitutes an independent system to which the term **neuron** is applie the only relation which it has with other neurons or with peripheral tissue of contact.

Ganglionic Nerve-Cells.—The ganglionic neurons found in the gangli cranial nerves and in the ganglia on the dorsal roots of the spinal nerves different origin, and present many points of contrast with neurons in the gray of the brain and cord. As already indicated in the chapter on Embryology the ganglia in question are derived from the neural crest. The cells formin ganglionic masses are somewhat oval in form, and from either extremity o process grows out, and the neurons in this manner become bipolar. These p are distinguished as central and peripheral, according to the direction whi take. The central processes grow inwards, and penetrate the wall of the tube. In the region of the spinal cord they form almost the whole of th which enter into the composition of the dorsal roots of the spinal nerves. substance of the cerebrospinal axis they give off numerous collaterals, and course of varying extent they end, after the manner of an axon, in t arborisations, which enter into relationships of contact with certain nerve- the cerebrospinal axis. The peripheral processes grow outwards along the the particular nerve with which they are associated, and they finally e peripheral contact relations. Thus, to take one example: the majority of th which go to the skin break up into fine terminal filaments, which end between the epithelial cells of the epidermis. The two processes of a gangli therefore, form the afferent fibres of the cerebrospinal nerves, and constit path along which the influence of peripheral impressions is conducted towa brain and cord. The body of the cell is as it were interposed in the path impulses.

But the original bipolar character of these cells, with very few exc (ganglia in connexion with the auditory nerve and the bipolar nerve-cells olfactory mucous membrane), gradually undergoes a change which ultimate to their transformation into unipolar cells. This is brought about by the te which the cell-body has to grow to one side, viz. the side towards the surfac ganglion (v. Lenhossek). This unilateral growth leads to a gradual app tion of the attached ends of the processes, and finally to a condition in whi appear to arise from the extremity of a short common stalk in a T-shaped

. 360). It is interesting to note that in certain fish the original bipolar lition of these cells is retained throughout without change.

Both the central and peripheral processes these ganglionic cells become the axis- nders of nerve-fibres, which, acquiring a lullary sheath, belong therefore to the lullated variety. From this it might very urally be thought that the ganglionic ron, with its two axons and no typical drites, is a nervous unit very different n a neuron in the gray matter of the ebrospinal axis. It is believed by some, vever (van Gehuchten and Cajal), that the ipheral process, in spite of its enclosure hin a medullary sheath, and though pre- ting all the characters of a true axon, is in lity a dendrite. If this be the case, the rphological difference between a dendrite l an axon disappears, and van Gehuchten's ctional distinction alone remains character- c, viz. that the axon is *cellulifugal* and ducts impulses away from the cell, whilst dendrites are *cellulipetal* and conduct im- ses towards the cell.

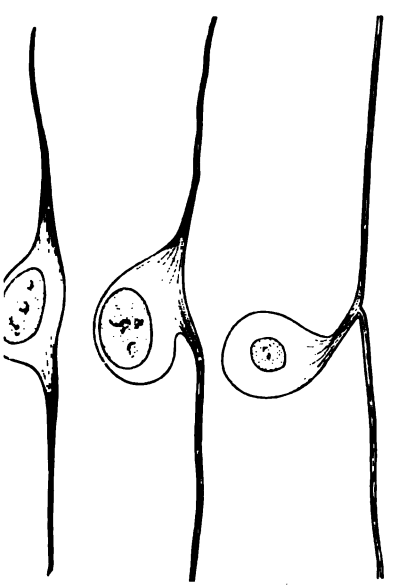
[n the foregoing brief account of the elements which d up the nervous system, the neuron doctrine, as it been enunciated by Waldeyer, has been followed. observations of Ramón y Cajal and His form foundation upon which this doctrine mainly rests, ough it should not be forgotten that many other tomists, amongst whom may be mentioned v. liker, van Gehuchten, and v. Lenhossek, have by ir investigations greatly strengthened the concep- . Two primary considerations may be considered to constitute its leading support: (1) the absolute independence of the early nerve-cell or neuroblast and its processes, as was first clearly shown by His; (2) the fact that when nerve tissue is treated by the Golgi method or by the vital methylene blue method no continuity of any kind can be observed between neighbouring cells, although the processes of the cells can apparently be traced to their ultimate divisions. Further, it should be noted that the neuron doctrine receives strong support from pathological observations, and that before it assumed concrete form ideas of a somewhat similar kind were present in the minds of pathologists.



. 360.—THREE STAGES IN THE DEVELOPMENT OF A CELL FROM A SPINAL GANGLION.

Still the neuron theory is not accepted by several leading Histologists. Apáthy, Nissl, and Bethe at the present moment form a powerful combination against it. It is therefore necessary to indicate the views entertained by these observers.

More than thirty years ago Max Schultze called attention to the fact that the axis-cylinder of a nerve-fibre is composed of exceedingly fine fibrils[1] which, when traced to the cell from which the fibre takes origin, are there seen to enter the cell-body and spread out within it. By more delicate methods of research, Apáthy and Bethe have been able to place this early observation of Schultze beyond the realm of doubt. Apáthy, who worked chiefly at the invertebrate nervous system, not only traced the neuro-fibrillæ through the cell-body but

[1] It may be mentioned that Remak, the discoverer of the axis-cylinder in 1838, stated that it was finely iated in the longitudinal direction.

into all its processes, and he believes that he has been able to follow them beyond these into a delicate fibrillar interlacement which constitutes a bond of union between all the nerve-cells of the nervous system. Bethe's observations have been carried out in vertebrates. Two illustrations from his book are reproduced in Fig. 361. The cell represented in A is from the gray matter of the anterior horn of the human spinal cord, and the relation presented by the neuro-fibrils within the cell and to its various processes are very clearly depicted. The axon appears to receive a contribution of neuro-fibrillæ from all the dendritic processes; this, according to Bethe, is characteristic of the great majority of nerve-cells. In the cells indicated by the letter B, which are from the cerebral cortex of man, it will be noticed that the axons as they leave the cell become exceedingly fine and delicate, and the neuro-fibrillæ which compose them are so closely packed together that all trace of their individual existence disappears. When the medullary sheath is assumed by the fibre the neuro-fibrillæ of the axis-cylinder again become apparent.

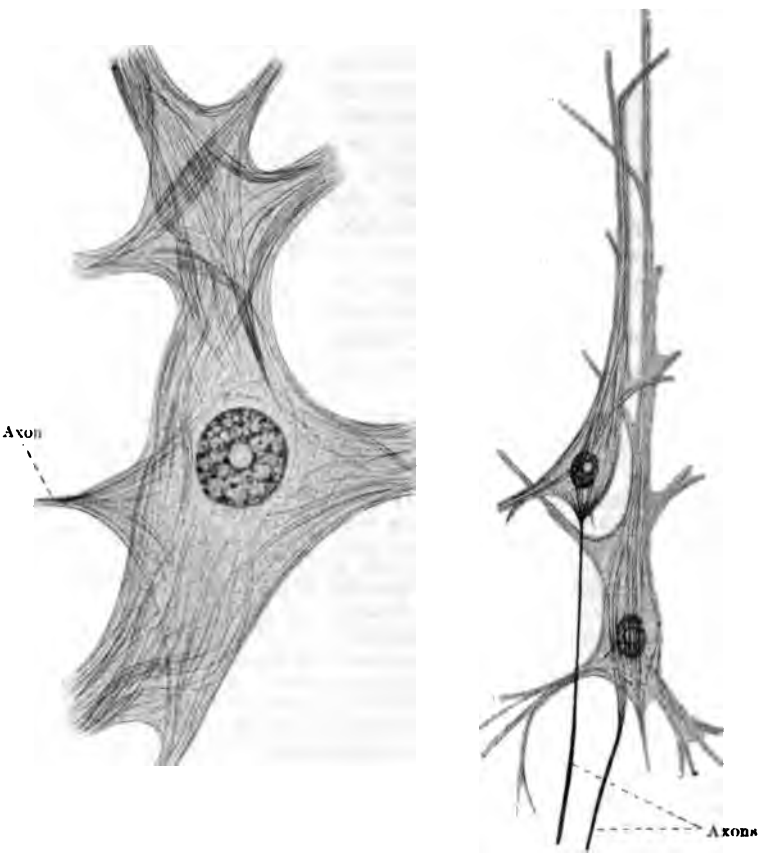


FIG. 361.—NERVE CELLS AS DEPICTED BY BETHE.

A, A cell from the anterior horn of gray matter of the spinal cord of man.
B, Two cells from the human cerebral cortex.

In vertebrates Bethe has not been able to trace the neuro-fibrils into an all-pervading fibrillar network such as Apáthy has described as binding the various nerve elements together in the invertebrates, but he has followed them into the finest of the dendritic branchings, and he assumes that the connecting network exists in the higher as well as in the lower members of the animal kingdom.

This conception of the structure of the axon renders the giving off by the nerve-fibre of collateral branches and also its terminal splitting or arborisation, matters which can be the more easily understood.

On the strength of the observations detailed above, Apáthy, Bethe, and Nissl, all of whom are authorities who deserve the highest degree of attention, have assailed the neuron theory. Apáthy has advanced the hypothesis that the all-pervading fibrillar interlacement, which streams continuously throughout the whole nervous system and is found not only in the cell and its processes but also in the form of a connecting network outside the cells, is the essential part of the nervous system and not the so-called independent neurons of the neuron theory. It is also contended that axons or axis-cylinders may arise in two ways: (1) directly from the nerve-cells; (2) indirectly from the neuro-fibrillar network between the nerve-cells.

In a striking address recently delivered by Professor Waldeyer to the Royal Society of Edin-

gh the essential points of the neuron doctrine were vigorously maintained and several new parations by Ramón y Cajal and Beilschowsky were demonstrated. In the latter the neuro-illæ were seen to enter the cell-body, spread out and break up into a plexus within it, but e could be detected pursuing an uninterrupted course right through the cell and then passing from it.

As Edinger remarks, investigation in the immediate future will be largely concerned in the empt to further elucidate the following questions: (1) Are the connexions between neurons rely those of contact? (2) Do the fibres which proceed from one cell fuse with the constituent ts of another neuron? (3) Do the neuro-fibrillæ form an inter-connecting network between nerve-cells, and do axons or axis-cylinders arise from such a network? It is questionable n if the last two of these queries are answered more or less in the affirmative whether it will necessary to abandon the essential points in the neuron theory.

Since the foregoing has been printed an instructive monograph on the subject has been blished by Professor Gustaf Retzius ("Punktsubstanz 'Nervöses Grau' und Neuronenlehre," *logische Untersuchungen*, Neue Folge, xii.).

Neuroglia.—The neuroglia is the supporting tissue of the cerebrospinal axis. may be considered to include two different forms of tissue, viz. the lining endymal cells and the neuroglia proper. We place these under the one heading, ing that in all probability they both have a common developmental origin.

The **ependymal cells** are the columnar epithelial cells which line the central nal of the spinal cord and the ventricles of the brain. In the embryonic condi-n a process from the deep extremity of each cell traverses the entire thickness the neural wall and reaches the surface. It is not known whether this process ists in the adult.

The **neuroglia proper** is present in both the white and the gray matter of the ebrospinal axis. It constitutes an all-rvading basis substance, in which the rious nerve elements are embedded in ch a way that they are all bound together to a consistent mass and are yet all sever-ly isolated from each other. Neuroglia nsists of cells and fine filaments. The rils are present in enormous numbers, id by their interlacements they constitute hat appears to be a fine feltwork. At the ints where the fibrils intercross may be en the flattened glial cells. Whilst the euroglia is for the most part intimately ntermixed with the nerve elements, there e in both brain and cord certain localities here it is spread out in more or less pure yers. Thus upon the surface of the brain id of the spinal cord there is such a layer; ewise beneath the epithelial lining of the ntral canal and of the cavities of the brain ere is a thin stratum of neuroglia.

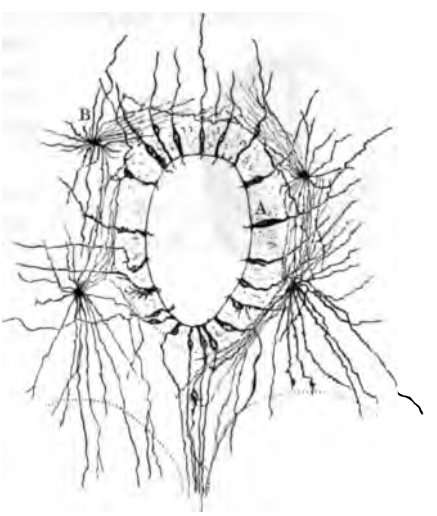

FIG. 362. — SECTION THROUGH THE CENTRAL CANAL OF THE SPINAL CORD OF A HUMAN EMBRYO, SHOWING EPENDYMAL AND NEUROGLIAL CELLS (after v. Lenhossek).
A, Ependymal cell. B, Neuroglial cell.

The ependymal cells are derived from e original neuro-epithelial cells of the rly neural tube, and in all probability e neuroglia proper has a similar origin. They both, therefore, are products of the toderm.

Summary.—1. The cerebrospinal nervous system is composed of two parts, viz.) a **medullary part**, consisting of the brain and spinal cord, with the efferent nerve-res which pass out from them; (*b*) the **ganglionic part**, with the afferent nerve-fibres.

2. Each of these parts has a different origin and is composed of neurons which ssess characteristic features.

3. The ganglionic neurons are derived from the primitive cells of the neural est, and have each one process which divides into two. Of these the central vision enters the cerebrospinal axis and probably represents the axon, whilst the ripheral division, which becomes connected with a peripheral part, may pro-sionally be regarded as a dendrite. The central fibres from the ganglionic cells

in the region of the cord form the dorsal or posterior roots of the spinal nerv These roots have thus an origin outside the cord, and grow into its substance the process of development in the same manner that the roots of a plant str into the soil.

4. The cerebrospinal neurons are derived from the germinal cells in the w of the early neural tube. Certain of these furnish efferent nerve-fibres, wh issue from the cord in separate bundles termed the anterior or ventral roots of t spinal nerves. In the case of the cranial nerves, however, with the exception the trigeminal and facial nerves, the efferent fibres are not thus separated from t afferent fibres at their attachment to the brain.

5. The brain and cord when studied by the naked eye are seen to be compos of white matter and gray matter. The white matter forms very nearly two-thir of the entire cerebrospinal axis. It is composed of medullated nerve-fibr embedded in neuroglial tissue. The gray matter is composed of nerve-cells wi their dendrites and axons. Some of the axons are in the form of naked ax cylinders, whilst others have a coating of medulla. Intimately intermixed wi these parts is the neuroglia, which isolates them more or less completely fro each other.

SPINAL CORD.

The **spinal cord** is that part of the cerebrospinal axis which occupies the upp two-thirds of the spinal canal of the vertebral column. It is an elongated cylin drical structure, slightly flattened in front and behind, which extends from th margin of the foramen magnum to the level of the lower border of the body of th first lumbar vertebra or to the upper border o the body of the second lumbar vertebra. It average length in the male is 45 cm. and in the female 43 cm.

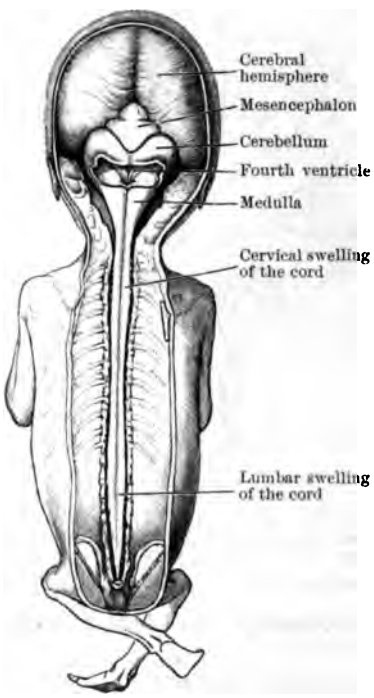

FIG. 363.—HUMAN FŒTUS IN THE THIRD MONTH OF DEVELOPMENT, WITH THE BRAIN AND SPINAL CORD EXPOSED FROM BEHIND.

A considerable amount of variation within certain limits (viz. the mid-point of the body of the last dorsal vertebra and the upper border of the body of the third lumbar vertebra) is observed in different individuals as to the precise level at which the spinal cord ends inferiorly, and in the female there would appear to be a tendency for the cord to reach a slightly lower point in the canal than in the male. Further, the relation presented by the spinal cord to the vertebral column differs in a marked degree in the fœtus and infant at different periods of development. Up to the third month of intrauterine life the cord occupies the entire length of the spinal canal; it extends downwards to the lowest limit of the canal. But from this time on, as growth proceeds, the vertebral column lengthens at a more rapid rate than the cord. The spinal cord, therefore, has the appearance of shrinking in an upward direction within its canal, and at birth its lower end is usually found to be opposite the body of the third lumbar vertebra.

The attitude assumed by the individual affects to a small degree the position of the lower end of the cord. Thus, when the trunk is bent well forwards, it is noticed that the terminal part of the cord rises slightly within its bony canal.

At the margin of the foramen magnum the spinal cord becomes continuous with the medulla oblongata of the brain, whilst below, it tapers rapidly to a point and forms a conical extremity termed the **conus medullaris**. From the end of the conus medullaris a slender glistening thread is prolonged downwards within the spinal canal, and finally anchors the spinal cord to the back of the coccyx. This prolongation receives the name of the **filum**

le. The diameter of the cord is very much shorter than that of the spinal within which it lies. A wide interval between its surface and the walls of al, and this excess of space is clearly a on for allowing free movement of the al column without producing any jar- ntact between the delicate spinal cord e surrounding bones.

ee protective membranes are wrapped the cord. From within outwards these med (1) the pia mater, (2) the arachnoid and (3) the dura mater. The **pia mater** brous membrane which forms the im- e investment. It is closely applied to d, and from its deep surface numerous pta penetrate into the substance of the The **arachnoid mater** is an exceedingly e transparent membrane which is loosely d around the cord so as to leave a rable interval, termed the subarachnoid between itself and the pia mater, in which s always a varying amount of cerebro- fluid. Outside the arachnoid mater, the **ater** forms a wide, dense, fibrous, tubular which extends downwards within the canal for a considerable distance beyond nical extremity of the cord. The spinal suspended within its sheath or *theca* of ater by two lateral wing-like ligaments, the **ligamenta denticulata.** These extend ds from the sides of the cord and are ed by a series of pointed or tooth-like processes to the inner surface of the theca of dura mater. Between the wall of the spinal canal and the dura mater there is a narrow interval, which is filled up by soft areolo-fatty tissue and numerous thin-walled veins arranged in a plexiform manner.

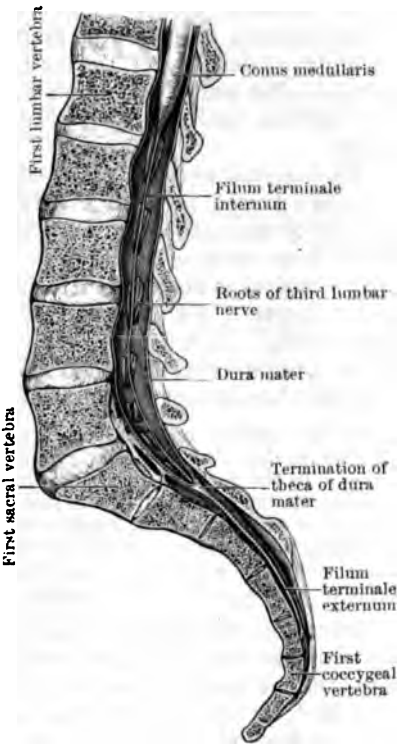

FIG. 364.—THE CONUS MEDULLARIS AND THE FILUM TERMINALE EXPOSED WITHIN THE SPINAL CANAL.

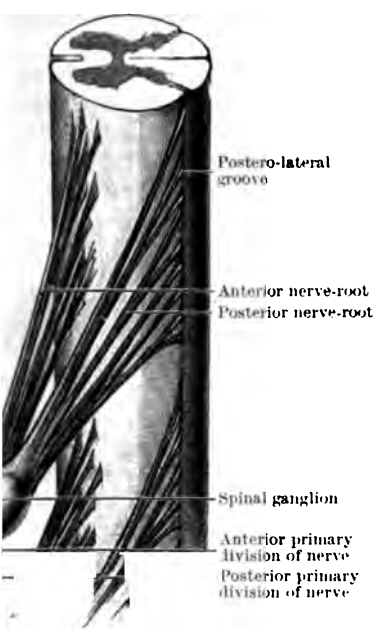
Thirty-one pairs of spinal nerves arise



5.—THE ROOTS OF ORIGIN OF THE ENTH DORSAL NERVE (semi-diagram- ic).

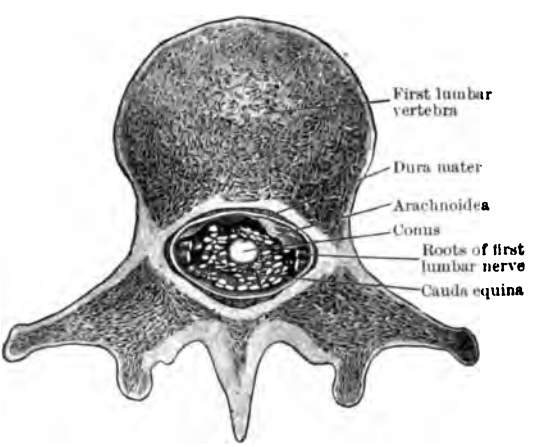


FIG. 366.—SECTION THROUGH THE CONUS MEDULLARIS AND THE CAUDA EQUINA AS THEY LIE IN THE SPINAL CANAL.

he sides of the spinal cord. These are classified into eight cervical, twelve

dorsal, five lumbar, five sacral, and one coccygeal; and according to the attachments of these groups of nerves the spinal cord is arbitrarily subdivided into cervical, dorsal, lumbar, and sacral regions. In employing these terms, therefore, for different districts of the cord, it must be understood that the regions are determined by the nerve attachments, and not by any direct relationship between the parts of the cord and the sections of the vertebral column which bear the same names.

Each spinal nerve is attached to the cord by a ventral and a dorsal root, and if these are traced to their central attachments they are seen to break up into a number of separate nerve fascicles or bundles, which spread out, in some cases very widely from each other, as they approach the side of the cord (Fig. 365). Each pair of nerves is therefore attached to a portion of spinal cord of some length, and such a portion, with its pair of nerves, receives the name of a "segment of the spinal cord." It must be clearly understood, however, that, in so far as the surface of the cord is concerned, there is absolutely no means of marking off one segment from another, except by the nerve attachments.

In the cervical and lumbar regions of the cord the nerve-roots are somewhat crowded together, so that little or no interval is left between the adjoining root fascicles of neighbouring nerves. In the dorsal region, however, distinct intervals may be observed, and the root fascicles are more loosely arranged. From this, it will be evident that the cord segments in different parts of the cord are not of equal length. In the cervical region the segments measure about 12 mm. in length, in the dorsal region from 20 to 24 mm., and in the lumbar region about 10 mm. The number of fascicles which attach the different nerve-roots to the cord is very different in different nerves, and is not necessarily the same in the same nerve-root in different individuals.

Owing to the great difference which exists between the length of the spinal cord and the length of the vertebral column, the farther we pass down the greater the distance becomes between the attachment of the various nerve-roots to the cord and the invertebral foramina through which the corresponding nerves leave the spinal canal. The lower nerve-roots, therefore, have to traverse the spinal canal for a considerable distance before they reach their apertures of emergence. It thus happens that the nerve-roots which spring from the lumbar and sacral regions of the cord attain a very great length and descend vertically in the lower part of the spinal canal in a bunch or leash, in the midst of which lie the conus medullaris and the filum terminale. This great bundle of nerve-roots receives the appropriate name of the **cauda equina**.

Enlargements of the Cord.—Throughout the greater part of the dorsal region, the spinal cord presents a uniform girth and a very nearly circular outline when seen in transverse section. In the cervical and lumbar regions, however, it shows marked swellings. The **cervical enlargement** (intumescentia cervicalis) is the more evident of the two. It begins very gradually at the upper end of the cord, attains its greatest breadth (12 to 14 mm.) opposite the fifth or sixth cervical vertebra, and finally subsides opposite the second dorsal vertebra. To this portion of the cord are attached the great nerves which supply the upper limbs. The **lumbar enlargement** (intumescentia lumbalis) begins at the level of the tenth dorsal vertebra, and acquires its maximum transverse diameter (11 to 13 mm.) opposite the last dorsal vertebra. Below, it rapidly tapers away into the conus medullaris. To the lumbar enlargement are attached the great nerves of the lower limbs.

These enlargements of the cord are associated with the outgrowth of the limbs. In the earlier developmental stages of the spinal cord they are not present, and they only take form as the limbs become developed. In the lower mammalia their size corresponds with the degree of development of the limbs. Thus, in the long-armed orang and gibbon, the cervical swelling stands out with a remarkable degree of prominence. It is, however, interesting to note that although in the cetacea there are no visible hind-limbs, there is nevertheless a well-marked lumbar enlargement of the cord.

Fissures and Furrows of the Cord.—When cross-sections of the spinal cord are made, it is seen to be a bilateral structure which is partially subdivided into a right and left half by two median clefts—one upon the anterior and the other upon the posterior aspect. These clefts are termed the antero-median and the postero-median fissures, and they extend along the entire length of the cord. At the same

nust be noted that these two median clefts present many points of differ-
'he **antero-median fissure** (fissura mediana anterior) is for the greater part of
:h much shallower than the postero-median fissure.
:ervical and dorsal regions it only penetrates for a
corresponding to somewhat less than a third of the
osterior diameter of the cord. Further, the antero-
cleft is much the wider and more apparent of the

observed on the surface of the posterior column. It
rather nearer to the postero-median than to the
ateral furrow, and as it is traced down into the
egion it gradually becomes indistinct and finally
rs. This is called the **posterior paramedian groove**,
narks on the surface the position of a septum of
:r which dips into the cord and subdivides the
column into an outer part, termed the **funiculus**
or the **column of Burdach**, and an inner portion, which receives the name
niculus gracilis or the **column of Goll**.

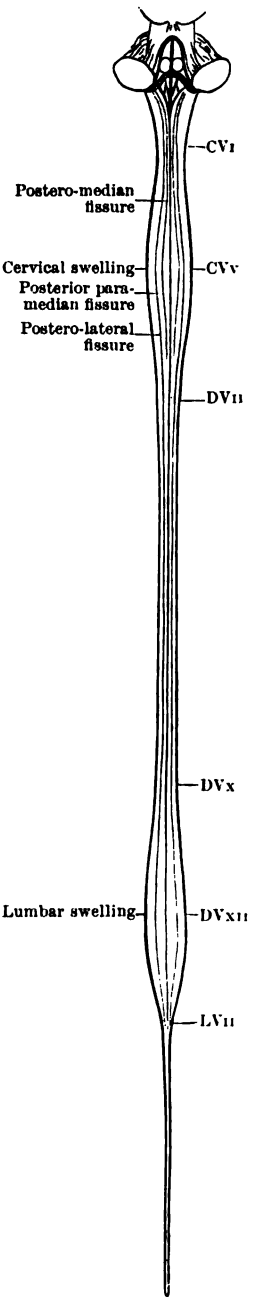

FIG. 367.—DIAGRAM OF THE SPINAL CORD AS SEEN FROM BEHIND.

CVI shows the level of the 1st cervical vertebra; CVv of the 5th cervical vertebra; DVII of the 2nd dorsal vertebra; DVx of the 10th dorsal vertebra; DVXII of the 12th dorsal vertebra; LVII of the 2nd lumbar vertebra.

Internal Structure of the Spinal Cord.

The spinal cord is composed of a central core of gray matter thickly coated on the outside by white matter. At only one spot does the gray matter come close to the surface, viz. at the bottom of the postero-lateral groove.

Gray Matter of the Cord.—The gray matter in the interior of the cord has the form of a fluted column, but it is customary to describe it as it appears in transverse sections through the cord. It then presents the appearance of the capital letter H. In each lateral half of the cord there is a semilunar or crescentic mass, shaped somewhat like a comma, the concavity of which is directed outwards and the convexity inwards. The two crescents of opposite sides are connected across the middle line by a transverse band, which receives the name of the **gray commissure** (commissura grisea). The postero-median fissure cuts through the cord until it reaches the gray commissure. The bottom of the antero-median fissure, however, is separated from it by an intervening strip of white matter, which is termed the **anterior white commissure** (commissura alba anterior alba). In the gray commissure may be seen the **central canal** of the cord (canalis centralis), which tunnels the entire length of the cord and is just visible to the naked eye as a minute speck. The portion of the gray commissure which lies behind the central canal is called the *posterior gray commissure* (commissura grisea posterior); whilst the portion in front receives the name of the *anterior gray commissure* (commissura grisea anterior).

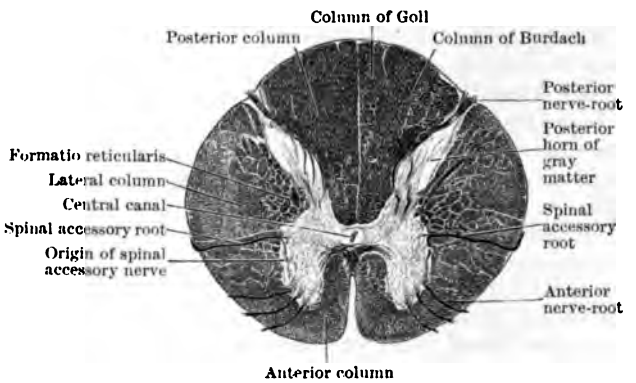

Fig. 368.—Transverse Section through the Upper Part of the Cervical Region of the Cord of an Orang. (From a specimen prepared by the Weigert-Pal method, by which the white matter is rendered dark whilst the gray matter is bleached.)

Each crescentic mass of gray matter presents certain well-defined parts. The projecting portions which extend behind and in front of the connecting transverse gray commissure are termed respectively the posterior and the anterior cornua of gray matter (columnæ griseæ). These stand out in marked contrast to each other. The **anterior cornu** (columna grisea anterior) is short, thick, and very blunt at its extremity. Further, its extremity falls considerably short of the surface of the cord and is separated from it by a tolerably thick coating of white matter. Through this the fascicles of the anterior nerve-roots, as they emerge from the gray matter of the anterior horn, pass on their way to the surface. The thickened end of the anterior cornu is called the **caput cornu**, whilst the part close to the gray commissure is termed the **cervix** or **basis cornu**. Throughout the greater part of the cord the **posterior cornu** (columna grisea posterior) is elongated and narrow, and is drawn out to a fine point, which almost reaches the bottom of the postero-lateral sulcus. This pointed extremity receives the name of the **apex cornu**; the slightly swollen part which succeeds it is the **caput cornu**; whilst the slightly constricted part adjoining the gray commissure goes under the name of the **cervix** or **basis cornu**.

The apex or tip of the posterior cornu differs considerably in appearance from the general mass of the gray matter. It is composed of a material which presents a lighter hue and has a somewhat translucent look. It is called the **substantia gelatinosa Rolandi**, and, when seen in transverse section, it exhibits a V-shaped outline and fits on the caput cornu like a cap.

A pointed and prominent triangular projection juts out from the external aspect of gray matter nearly opposite the gray commissure. This is the **lateral horn** (columna grisea lateralis), and it is best marked in the upper dorsal region (Fig.

raced upwards it becomes absorbed in the greatly expanded anterior horn ical swelling, but it reappears again in the upper part of the cord and rly noticeable in the second and third cervical segments; followed in a direction it blends with the anterior horn in the lumbar swelling and to the thickening of that cornu.

y matter is for the most part mapped off from the surrounding white matter siderable degree of sharpness; but in the cervical region, on the outer he crescentic mass and in the angle between the anterior and posterior bands of gray matter penetrate the white matter, and, joining with each a network the meshes of which enclose small islands of white matter. titutes what is called the **formatio or processus reticularis.** Although ed in the cervical region, traces of the same reticular formation may be n lower segments of the cord.

cters presented by the Gray Matter in Different Regions of the Cord.

y matter is not present in equal quantity nor does it exhibit the same ll regions of the cord. Indeed, each cord segment presents its own aracters in both of these respects. It is not necessary, however, in the stance to enter into this matter with any degree of minute detail. It fficient if we point out the broad distinctions which are evident in the egions.

y be regarded as a general law that, wherever there is an increase in the ie nerves attached to a particular part of the cord, a corresponding n the amount of gray matter will be observed. It follows from this regions where the gray matter bulks most largely are the lumbar and al swellings. The great nerve-roots which go to form the nerves of the -plexuses enter and pass out from those portions of the cord. In the ion there is a reduction in the quantity of gray matter in correspondence smaller size of the dorsal nerves.

dorsal region (Fig. 369, B) both horns of gray matter are narrow, although ction between the anterior horn and the still more attenuated posterior afficiently manifest. In this region the lateral horn of gray matter is haracteristic, and the substantia gelatinosa Rolandi in transverse section and spear-shaped.

upper three segments of the *cervical region* the anterior horns of gray rge and resemble the corresponding horns in the dorsal region. A lateral so present. But in these segments (and more especially in the first and ere is a marked attenuation of the neck of the posterior horn, and the gray commissure is very broad.

cervical swelling of the cord the contrast between the two cornua is ing; the anterior horn is of great size and presents a very broad surface he anterior aspect of the cord, whilst the posterior horn remains narrow. t increase in the bulk of the anterior horn is due to a marked addition atter on the outer side of the horn, and seeing that this additional matter d by a greater number of fibres, it stands out, in well-prepared specimens, ss distinctly from the part of the horn which lies to the inner side, and y be considered to represent the entire anterior horn in the dorsal and vical segments. Within this lateral addition to the anterior horn are se collections of cells which constitute the nuclei of origin of the motor the muscles of the upper limb. The characteristic thickening of the orn of gray matter is evident, therefore, in those segments of the cord the nerves which enter the brachial plexus are attached, viz. the lower al segments and the first dorsal segment.

lumbar swelling the anterior horns again broaden out, and for the same

consequently no difficulty in distinguishing from an inspection of the gray matter alone between transverse sections of the cord taken from the cervical and lumbar swellings of the cord.

FIG. 369.—SECTION THROUGH EACH OF THE FOUR REGIONS OF THE CORD. (From specimens prepared by the Weigert-Pal method, therefore the white matter is rendered dark in colour whilst the gray matter is bleached.)

In the lower part of the *conus medullaris* the gray matter in each lateral half of the cord assumes the form of an oval mass joined to its fellow of the opposite side by a thick gray commissure. Here almost the entire bulk of the cord consists

ray matter, seeing that the white matter is reduced to such an extent that it ns only a thin coating on the outside.

White Matter of the Spinal Cord.—In transverse sections of the cord the ee columns into which the white matter is subdivided become very apparent. e **posterior column** is wedge-shaped, and lies between the postero-median fissure l the posterior horn of gray matter. The **lateral column** occupies the concavity the gray crescent. Behind, it is bounded by the posterior horn of gray matter d the **postero-lateral sulcus**, whilst in front it extends as far as the outermost sciculi of the anterior nerve-roots as they pass out from the anterior gray horn. e **anterior column** includes the white matter between the antero-median fissure d the anterior horn of gray matter, and also the white matter which separates the ad extremity of the anterior gray cornu from the surface of the cord. This ter portion of the anterior column is traversed by the emerging fascicles of the terior nerve-roots.

In cross-sections of the cord the partition of pia mater, which dips in at the sterior paramedian groove and divides the posterior column into the column of ll and the column of Burdach, is very strongly marked in the cervical regions, t as it is traced downwards into the dorsal region it becomes shorter and fainter, d finally disappears altogether at the level of the eighth dorsal nerve. Below is point there is no visible demarcation of the posterior column into two parts.

The white matter is not present in equal quantity throughout the entire length the cord. It increases steadily from below upwards, and this increase is most ticeable in the lateral and posterior columns. In the lower part of the conus edullaris the amount of gray matter is actually greater than that of the white atter: but very soon this state of affairs is changed, and in the lumbar region the oportion of gray to white matter is approximately as 1 : 2·1; in the dorsal region 1 : 5; and in the cervical region as 1 : 5·1. When it is remembered how the gray atter expands in the lumbar and cervical regions, and how greatly it becomes reduced the dorsal region, the significance of these figures will become more apparent.

Central Canal (canalis centralis).—As previously stated, the central canal is nd in the gray commissure. It is a very minute tunnel, barely visible to the ked eye when seen in transverse section, and it traverses the entire length of the d. Above, it passes into the medulla oblongata, and finally opens into the fourth ntricle of the brain; below, it is continued for a variable distance into the filum rminale, and in this it ends blindly. Only in the lumbar region does the central nal occupy the centre of the cord. Above this level, in the dorsal and cervical gions, it lies very much nearer the anterior than the posterior aspect of the cord; hilst below the lumbar region, as it is traced down into the conus medullaris, it clines backwards and approaches the posterior aspect of the cord. The calibre of e canal likewise varies somewhat in different parts of the cord. It is narrowest the dorsal region; and in the lower part of the conus medullaris it expands into distinct fusiform dilatation (very nearly 1 mm. in transverse diameter), which is rmed the **ventriculus terminalis** (Krause).

The central canal is lined by a layer of ciliated columnar cells, the deep taper- g ends of which are prolonged into slender processes, which penetrate into the bstance of the cord. These cells constitute the lining ependymal cells of the nal. The cilia of the epithelial cells are very early lost, and it is not uncommon find the canal blocked up by epithelial debris.

The central canal is of interest because it represents in the adult the relatively ide lumen of the early ectodermal neural tube from which the spinal cord is veloped.

Filum Terminale.—The delicate thread to which this name is applied is con- nuous with the lower tapered end of the conus medullaris. It is easily distin- uished by its silvery and glistening appearance from the numerous long nerve-roots auda equina) amidst which it lies. It is about six inches long, and down to the vel of the second sacral vertebra it is inclosed with the surrounding nerve-roots ithin the theca of dura mater. Piercing the tapered and closed end of the theca this point, and receiving an investment from it, the filum terminale proceeds ownwards in the sacral canal, and finally receives attachment to the periosteum on

the dorsal aspect of the coccyx (Fig. 364, p. 453). It is customary to speak of the filum as consisting of two parts, viz. the filum terminale internum and the filum terminale externum, or the part inside and the part outside the theca of dura mater.

The **filum terminale externum** is simply a fibrous thread, strengthened by the prolongation it receives as it pierces the dura mater. The **filum terminale internum** is largely composed of pia mater; but in its upper half it incloses the terminal part of the central canal, and around this a variable amount of the gray substance of the cord is prolonged downwards into the filum. When transverse sections are made through the upper part of the filum terminale internum some bundles of medullated nerve-fibres are observed clinging to its sides, and with these are associated some nerve-cells identical with those in the spinal ganglia. These represent rudimentary or aborted caudal nerves (Rauber).

Summary of the Chief Characters presented by the Cord in its Different Regions.

Cervical Region.	Dorsal Region.	Lumbar Region.	Sacral Region.
In transverse section, **outline of cord** transversely oval; in the middle of the cervical swelling the transverse diameter being nearly one-third longer than the antero-posterior diameter.	In transverse section, **outline of cord** more nearly circular; but still the transverse diameter is greater than the antero-posterior diameter.	In transverse section, **outline of cord** more nearly circular than in dorsal region.	In transverse section, **outline of cord**, nearly circular, but still somewhat compressed from before backwards.
Postero-median cleft very deep, extending beyond the centre of cord; **antero-median cleft** shallow.	**Postero-median cleft** very deep, extending beyond centre of cord: **antero-median cleft** shallow.	**Postero-median cleft** not nearly so deep as in regions above: **antero-median cleft**, on the other hand, much deeper.	**Postero-median** and **antero-median clefts** of equal depth.
Gray matter greatly increased in quantity in the cervical swelling: anterior horn thick and massive; posterior horn slender in comparison. Lateral horn only evident above the level of the fourth cervical nerve. Formatio reticularis strongly marked.	**Gray matter** greatly reduced in quantity. Both horns slender. Lateral horn well marked. Formatio reticularis scarcely apparent.	**Gray matter** greatly increased in the lumbar swelling. Both horns very thick and massive. Lateral horn absorbed in anterior horn. Formatio reticularis absent.	Both horns of **gray matter** very thick and massive. Lateral horn apparent. No formatio reticularis.
White matter in great quantity, and especially massed in the lateral and posterior columns.	**White matter** less in quantity than in cervical region, but bulking largely in comparison with the quantity of gray matter.	**White matter** small in quantity in relation to higher regions, and very small in amount in relation to increased quantity of gray matter.	**White matter** very small in quantity in comparison with the gray matter.
Posterior paramedian groove and septum well marked.	**Posterior paramedian groove** absent; but the corresponding septum can be traced as low down as the eighth dorsal nerve.	No **posterior paramedian groove** or septum.	No **posterior paramedian groove** and no corresponding septum.
Central canal considerably nearer the anterior surface than the posterior surface of the cord.	**Central canal** considerably nearer the anterior surface than the posterior surface of the cord.	**Central canal** in the centre of the cord.	**Central canal** in the centre of the cord.

OMPONENT PARTS OF THE GRAY MATTER OF THE SPINAL CORD.

glia enters largely into the constitution of the gray matter of the cord. a bed within which the nervous elements are distributed. These nervous consist of (1) nerve-cells and (2) nerve-fibres—both medullated and non-ed. The nerve-cells lie in small spaces within the neuroglia, whilst the res traverse fine passages the walls of which are formed of the same sub- The neuroglia is thus an all-pervading basis substance, which isolates more ompletely the nervous elements from each other, and at the same time em together into a consistent solid mass. In two situations the gray presents special characteristics which have earned for it the name of **a gelatinosa**, viz. the gray matter which constitutes the immediate sur- of the central canal, and which is called the **substantia gelatinosa** ; and that which forms the apical part of the posterior horn of gray nd which receives the name of **substantia gelatinosa Rolandi.** In both s the substantia gelatinosa stains more deeply with carmine and presents ranslucent appearance; in other respects the substantia centralis and the ia Rolandi are very different.

ubstantia gelatinosa centralis forms a thick ring around the central canal, traversed by the fine processes which proceed from the deep ends of the al cells which line the canal. It is almost entirely composed of neuroglia. ansverse sections of the cord the *substantia Rolandi*, in the cervical and gions, presents the appearance of a V-shaped mass, embracing the extremity put of the posterior horn of gray matter; in the lumbar region this cap a semilunar outline.

ie substantia gelatinosa Rolandi the neuroglia is present in small quantity, ll nerve-cells are developed within it in considerable numbers.

e-Cells.—The nerve-cells are scattered plentifully throughout the gray ut perhaps not in such great numbers as might be expected when we note mous number of nerve-fibres with which they stand in relation. They are ut exception, multipolar, and send off from their various aspects several g protoplasmic processes or dendrites, and one axon, which becomes the nder of a nerve-fibre. In size they vary considerably, and it is generally l that the bulk of a nerve-cell has a more or less definite relation to the f the axis-cylinder which proceeds from it.

n the nerve-cells are studied in a series of transverse sections of the cord, e noticed that a large proportion of them are grouped in clusters in certain of the gray matter; and as these groups are seen in very much the same in successive sections, it is clear that these cells are arranged in longitudinal of greater or less length. Thus we recognise (1) a ventral group or column in the anterior horn of gray matter; (2) an intermedio-lateral group or in the lateral horn of gray matter, where this exists; and (3) a posterior column of cells (Clarke's column), forming a most conspicuous group in al part of the cervix of the posterior horn in the dorsal region of the

r cells besides those forming these columns are scattered somewhat irregu- oughout the gray matter of the posterior horn and the part of the gray which lies between the two horns; and although these also in some measure classified into groups, the arrangement thus effected is not of so definite a r as to justify us in dwelling upon it in the present instance.

ral Cell-Column and the Origin of the Fibres of the Anterior Nerve- -The ventral cell-group occupies the anterior horn of gray matter, and in nd the largest and most conspicuous cells in the spinal cord. It extends end of the cord to the other. These ventral nerve-cells have numerous ading dendritic processes, and it is to be noticed that certain of these s do not confine their ramifications to the gray matter. Thus, some of the ng the mesial border of the anterior horn of gray matter send dendrites ie mesial plane in the anterior commissure to end in the anterior gray the opposite side; whilst others, lying along the lateral or outer margin of

the anterior horn of gray matter, send dendrites in amongst the nerve-fibres of adjoining white matter.

The axons or axis-cylinder processes of a large proportion of the ventral converge together; and, becoming medullated, form bundles which pass out the gray matter, and through the white matter which separates the thick the anterior horn from the surface of the cord, to finally emerge as the fascic the anterior nerve-roots. These cells, then, are the sources from which the

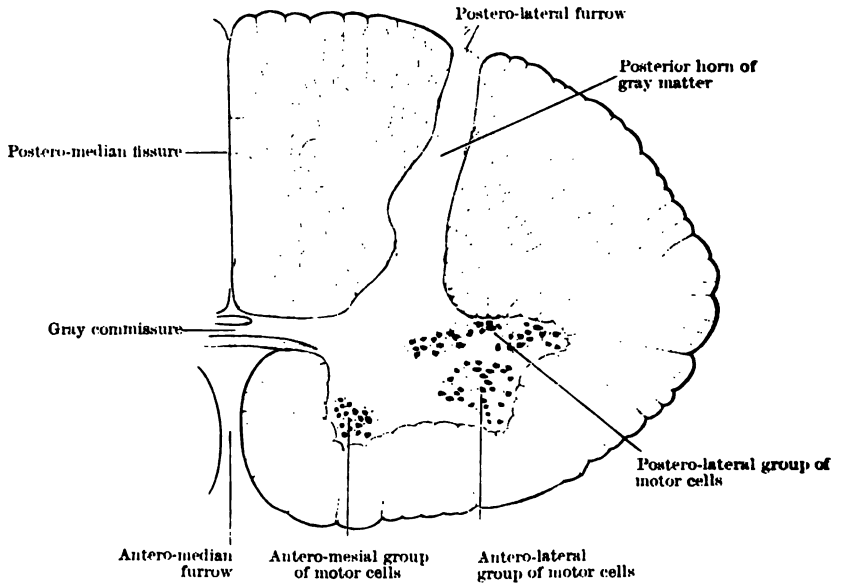

FIG. 370.—SECTION THROUGH THE FIFTH CERVICAL SEGMENT OF THE CORD. (To a large extent found on Plates in Dr. Bruce's *Atlas*.)

fibres of the anterior nerve-roots proceed, and in consequence they are frequently spoken of as the "motor cells" of the cord. Whilst this is the arrangement of the axons of the great majority of the motor cells, it should be noted that a few cross the mesial plane in the anterior white commissure and emerge in the fascicles of origin of the opposite anterior nerve-root.

The ventral cells are not scattered uniformly throughout the anterior horn of gray matter. They are aggregated more closely together in certain parts of the anterior horn, and thus form sub-groups or columns more or less perfectly marked off from each other.

Thus one sub-group or column of ventral cells occupies the inner or mesial part of the anterior horn of gray matter throughout almost its whole length. In only two segments of the cord is it absent, viz. the fifth lumbar and the first sacral; at this level in the cord alone is its continuity broken (Bruce). It is termed the *ventro-mesial column* or *group* of ventral cells. Behind this cell-column there is another which is classed with it to which the name of *dorso-mesial column* or *group* is given, but this column of cells is not continuous throughout the entire length of the cord. It is present in the dorsal region of the cord where the motor nuclei for the muscles of the limbs are absent, and it is also seen in two or three of the segments of the cervical region and in the first lumbar segment (Bruce); elsewhere it is not represented.

In the cervical and lumbar swellings of the cord, where the marked lateral outgrowth is added to the outer side of the anterior horn of gray matter, certain groups of large multipolar cells are visible. These are the nuclei of origin of the motor-fibres which supply the muscles of the limbs, and consequently they are not represented in the upper three cervical segments of the cord; nor in any of the dorsal segments, with the exception of the first dorsal segment; nor in the two lowest sacral segments.

These *lateral cells* are arranged in several columns, which extend for varying distances in the superadded lateral parts of the anterior horn of gray matter. The two main columns are a *ventro-lateral* and a *dorso-lateral column*; in certain segments there is likewise a *post-dorso-lateral column*, and in a number of segments in the lumbar and sacral regions a *central column* of cells (Bruce).

e cannot be a doubt that the grouping of the motor cells in the anterior horn of ter of the cord stands in relation to the muscle groups to which their axis-cylinder are distributed; but at has been said it will ent that sharply defined ers associated with par- muscles do not exist. ich can be learned re- the localisation of the uclei in the anterior gray matter of the cord study of the changes cur in the cell-columns phies of isolated muscles s of muscles, and after or partial amputations It has been pointed the long muscles of k (as, for example, the parts of the erector nuscle) receive nerve- rom all the segments cord. Now, we have hat there is only one mn, the ventro-mesial which pursues an almost upted course throughout the entire length of the cord. It may be assumed, , that the nerve-fibres which go to these long trunk-muscles take origin in these lls.

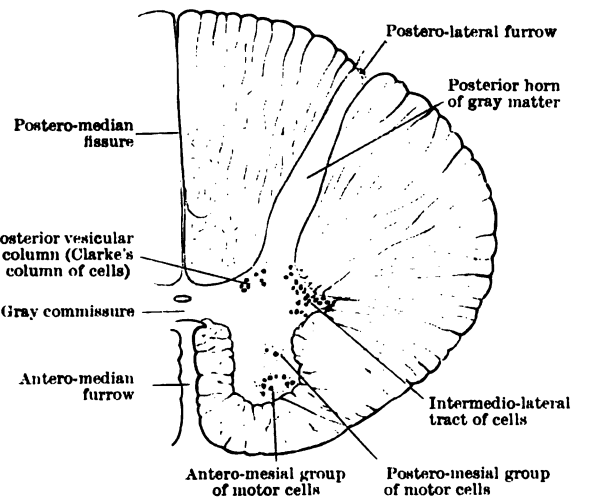

FIG. 371.—SECTION THROUGH THE EIGHTH DORSAL SEGMENT OF THE SPINAL CORD. (To a large extent founded on Plates in Dr. Bruce's *Atlas*.)

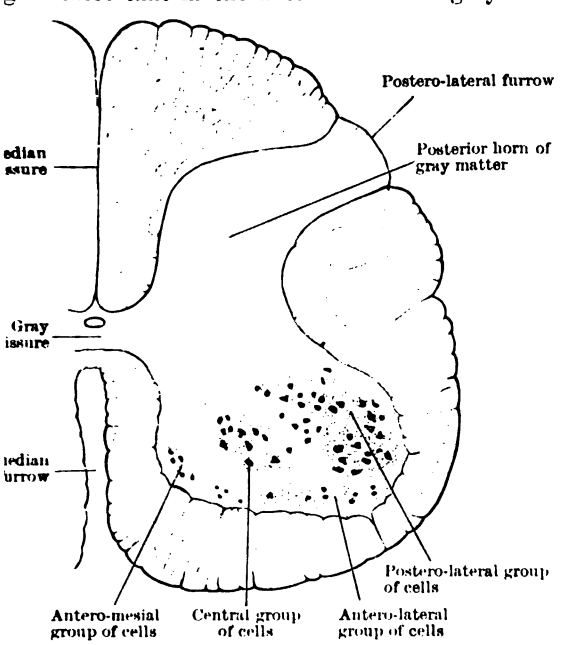
ger states that in the anterior horn of gray matter the nuclei of origin of the nerves which supply the proximal muscles are medially placed; that those for the distal muscles are in general situated laterally. If this be the case, the cells connected with the shoulder muscles would lie nearer the middle of the anterior horn of gray matter than those which are connected with the hand-muscles. In cases where the forearm and hand, or the leg and the foot, are amputated, it would appear that it is the postero-lateral column of cells that shows changes in consequence of its separation from the muscles to which its fibres are distributed.[1]



—SECTION THROUGH THE THIRD LUMBAR SEGMENT OF THE AL CORD TO SHOW THE GROUPING OF THE MOTOR CELLS. (To ge extent founded on Plates in Dr. Bruce's *Atlas*.)

Intermedio-lateral Cell-column.—The intermedio-lateral cells form a long slender column which extends throughout the entire region of the cord in the lateral horn of gray matter. It is also prolonged ards into the first and second lumbar segments, where it disappears. In

[1] se who seek further information regarding the grouping of the ventral cells of the cord, may with study Dr. Alexander Bruce's *Atlas of the Spinal Cord*.

transverse sections through the cord this cell-group presents a very characteristic appearance, because the cells which compose it are small and are closely packed together. Although the cells, as a continuous column, are restricted to the region indicated, it should be noted that the same group of cells appears above in certain of the cervical segments and also in the third and fourth sacral segments. The function and connexions of these cells are unknown. It has been suggested that they give origin to vaso-motor, pilo-motor, and sweat-gland nerves, and have a very close connexion with the sympathetic nervous system.

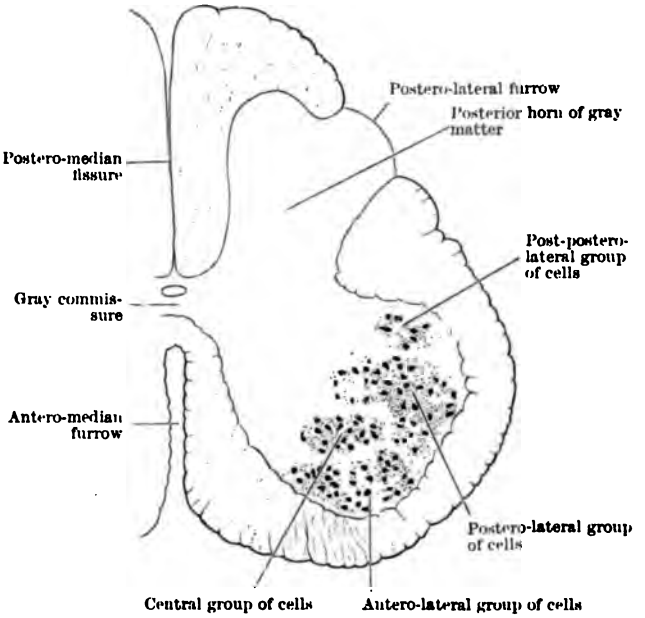


FIG. 373.—SECTION THROUGH THE FIRST SACRAL SEGMENT OF THE SPINAL CORD TO SHOW THE GROUPING OF THE MOTOR NERVE-CELLS. (To a large extent founded on Plates in Dr. Bruce's *Atlas*.)

In a recent research by Bruce the following important points in regard to the intermedio-lateral cell-column have been determined.

It is not quite continuous. In the eighth cervical, first dorsal, and also in a part of the second dorsal segment, as well as in the first and second lumbar segments, the cells are in separate clusters. Throughout the rest of the dorsal region it forms a moniliform chain of cells, situated partly in the lateral horn and partly in the gray matter behind it. Some outlying cells are situated in the white matter in the neighbourhood of the lateral horn.

The limits of the tract are from lower two-thirds of eighth cervical to the lower end of the second lumbar or perhaps the upper end of the third lumbar segment. It is found also in the first, second, and third cervical, and in the third and fourth sacral segments. It reaches its maximum size in the third and fourth dorsal segments.

Posterior Vesicular Column—Clarke's Column.—This occupies the posterior horn of gray matter and is the most conspicuous of all the cell-groups in the cord. It does not, however, extend along the whole length of the cord; indeed it is almost entirely confined to the dorsal region, and in consequence it is sometimes referred to as the "dorsal nucleus." Above, it begins opposite the seventh or eighth cervical nerve, whilst below, it may be traced to the level of the second lumbar nerve, where it disappears. In transverse section of the cord it presents an oval outline, and is seen in the inner part of the cervix of the posterior horn of gray matter immediately behind the gray commissure (Fig. 369 B, p. 458). On the outer side it is circumscribed by numerous curved fibres from the entering posterior nerve-root, and in the lower dorsal region of the cord (opposite the eleventh and twelfth dorsal nerves) it becomes so marked that it forms a bulging on the inner aspect of the posterior gray horn.

The cells of Clarke's column are large, and possess several dendritic processes. The axons enter the lateral column of white matter and there form a strand of fibres, which will later on be described under the name of the **direct cerebellar tract**.

In addition to the topographical subdivision of the nerve-cells of the cord indicated above, it is now usual to classify them according to the nature of the axons which proceed from them. Thus we have (1) the cells of Golgi or cells with short axons, and (2) cells with long axons.

The **cells of Golgi** possess axons which do not emerge from the gray matter, but bring neighbouring cells into touch with each other. The **cells with long axons** are of two kinds, viz. radicular cells and strand-cells.

The **radicular cells** are those from which the axon emerges from the cord in the shape of an efferent nerve-fibre. Thus the "motor cells" which supply the axis-cylinder processes of the

re-roots belong to this class. The **strand-cells** are those which contribute their axons ation of those fibres which form certain of the strands or tracts which are found in atter of the cord.

fibres in the Gray Matter of the Cord.—Nerve-fibres both of the l and non-medullated variety pervade every part of the gray matter. of three kinds, viz. (1) collaterals, (2) terminations of nerve-fibres, (3) n off by the cells. Many of the nerve-fibres which compose the columns natter of the cord give off numerous fine collateral branches, which pass gray matter from all sides and finally end in relation with the nerve- e majority of the nerve-fibres themselves, which thus give off collaterals, er the gray matter, and end similarly. As already noted, the axons of of Golgi remain within the gray matter, but the others emerge either for se of entering a peripheral nerve or for the purpose of entering a strand n the white matter of the cord.

erve-fibres thus derived are interwoven together in the gray matter of the dense inextricable interlacement.

Component Parts of the White Matter of the Cord.

hite matter of the cord is composed of medullated nerve-fibres embedded glia. The fibres, for the most part, pursue a longitudinal course; and deep surface of the pia mater which the cord fibrous septa or partitions are along vertical planes between the fibres, so m an irregular and very imperfect fibrous k of support. The neuroglia is disposed in f varying thickness around the cord, sub- the pia mater, and is carried into the cord ive a coating to both sides of the various pial The neuroglia also is disposed around the erve-fibres, so that each of these may be said a canal or tunnel of this substance. The es are all medullated, but they are not with primitive sheaths. It is the medullary of the nerve-fibres which gives to the tter its opaque, milky-white appearance. hin transverse section of the cord is stained e and examined under the microscope the tter presents the appearance of a series of plied circles, each with a dot in the centre. s the transversely divided axis-cylinder of bre, and the dark ring which forms the nce of the circle represents the wall of the canal which is occupied by the fibre. llary substance is very faintly seen. It a filmy or cloudy appearance between the ler and the neuroglial ring.

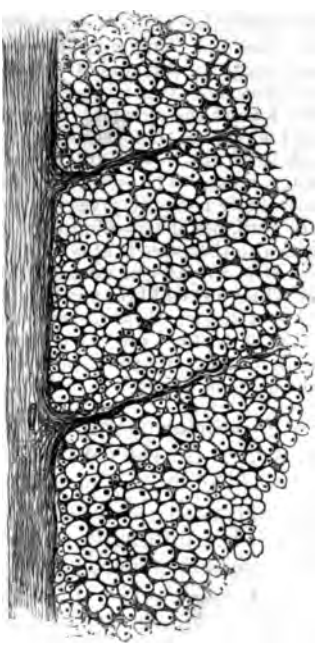

Fig. 374.—Transverse Section through the White Matter of the Cord, as seen through the microscope.

gement of the Nerve-fibres of the White n Strands or Tracts.—When the white a healthy adult cord is examined the fibres which compose it are ary considerably in point of size; and although there are special places ge fibres—or it may be small fibres—are present in greater numbers where, yet as a rule both great and small fibres are mixed up Absolutely no evidence can be obtained in such a cord, by any means sposal, of the fact that the longitudinally arranged fibres are grouped n more or less definite tracts or strands, the fibres of which run a definite l present definite connexions. Yet we know this to be the case, and the of these separate tracts has been proved both by physiological and by ical investigation.

The **physiological evidence** depends on the fact that when a nerve-fibre is severed the p which is detached from the nerve-cell from which it is an offshoot degenerates, whilst the p which remains connected with the nerve-cell undergoes little or no change. This is called t law of "Wallerian" degeneration. Thus, if in a living animal one-half of the cord be cut acr and after a few weeks the animal be killed and the cord examined, it will be seen that th are degenerated tracts of fibres in the white matter, both above and below the plane of divisi but, still further, it will also be manifest that the tracts which are degenerated above the pl of division are not the same as those which are degenerated in the part of the cord which l below this level. The interpretation of this is obvious. The nerve-tracts which have degenera above the plane of section are the offshoots of nerve-cells which lie in lower segments of the co or in spinal ganglia below the plane of section. Severed from these nerve-cells, they unde what is called ascending degeneration. The nerve-tracts, on the other hand, which ha degenerated in the portion of the cord below the plane of division are the axons of cells whi lie at a higher level than the plane of section, either in higher segments of the cord or in th brain itself. Cut off from the nerve-cells from which they proceed, they present an example descending degeneration.

The **embryological evidence** we owe to Flechsig, and it is no less satisfactory. It depe upon the fact that nerve-fibres in the earliest stages of their development consist of naked axi cylinders, and are not provided with medullary sheaths. Further, the nerve-fibres of differe strands assume the medullary sheaths at different periods. By examining the fœtal cord different stages of its development, it is a comparatively easy matter to locate the different tract of fibres by evidence of this kind. Speaking broadly, the tracts which myelinate first are thos which bring the cord into relation with the peripheral parts (skin, muscles, etc.); then thos fibres which bind the various segments of the cord together; next, those which connect the cord with the cerebellum; and, lastly, the tracts which connect the cord with the cerebrum. Th nervous apparatus for the performance of automatic movements is fully provided, therefore, befor this is put under the control and direction of the higher centres. It by no means follows that in all the higher animals corresponding strands myelinate at relatively corresponding periods. Take the case of a young animal which from the time of its birth is able to move about and perform voluntary movements of various kinds in a more or less perfect manner, and compare it with the helpless new-born human infant which is only capable of exhibiting automatic movements. In the former the pyramidal tracts, or motor tracts, which descend from the cerebrum into the cord, and which are the paths along which the mandates of the will travel, myelinate at an early period; whilst in the human infant the corresponding fibres do not obtain their medullary sheaths until after birth. The study of the dates, therefore, at which the various strands of nerve-fibres myelinate not only gives the anatomist a means of locating their position in the white matter of the cord, but it also affords the physiologist most important information regarding their functions, and also the periods at which these functions are called into play.

It is a matter of interest to note that influences which either accelerate or retard the periods at which nerve fibres are brought into functional activity have also an effect in determining the dates at which these fibres assume their sheaths of myelin. Thus, when a child is prematurely born the whole process of myelinisation is, as it were, hurried up; and further, when in new born animals light is freely admitted to one eye whilst it is carefully excluded from the other, the fibres of the optic nerve of the former myelinate more rapidly than those of the opposite nerve.

Posterior Column of the Cord and the Posterior Roots of the Spinal Nerves.—In the cervical and upper dorsal regions of the cord the posterior column is divided by the posterior paramedian septum into the **tract of Burdach**, which lies externally and next the posterior horn of gray matter, and the **tract of Goll**, which lies internally and next the postero-median septum. The tract of Burdach is composed of nerve-fibres, which are for the most part larger than those entering into the formation of Goll's tract, and both tracts have a most intimate relation to the posterior nerve-roots; indeed, they are both almost entirely composed of fibres which enter the cord by these roots and then pursue a longitudinal course.

The nerve-fibres which form the posterior nerve-roots, on entering the cord along the postero-lateral groove, divide within the tract of Burdach into ascending and descending branches. These branches diverge abruptly from each other; and the former take an upward course, whilst the latter proceed downwards. The **descending fibres** are as a rule short, and soon end in the gray matter of the cord. These descending fibres occupy an area in the posterior column near to the place of entrance of the nerve-root. This area, when the spinal cord is divided, undergoes descending degeneration and then presents a comma-shaped outline. The fibres in question are included under the name of the **comma tract of Schultze**.

The **ascending fibres** vary greatly in length, and at varying distances from the point where the parent fibres enter the cord they end in the gray matter. A small contribution of ascending fibres, however, from each posterior nerve-root, extends upwards to the upper end of the cord, to end in the medulla oblongata.

As each posterior nerve-root enters, its fibres range themselves in the outer part of

of Burdach close up against the posterior horn of gray matter. The nerve-

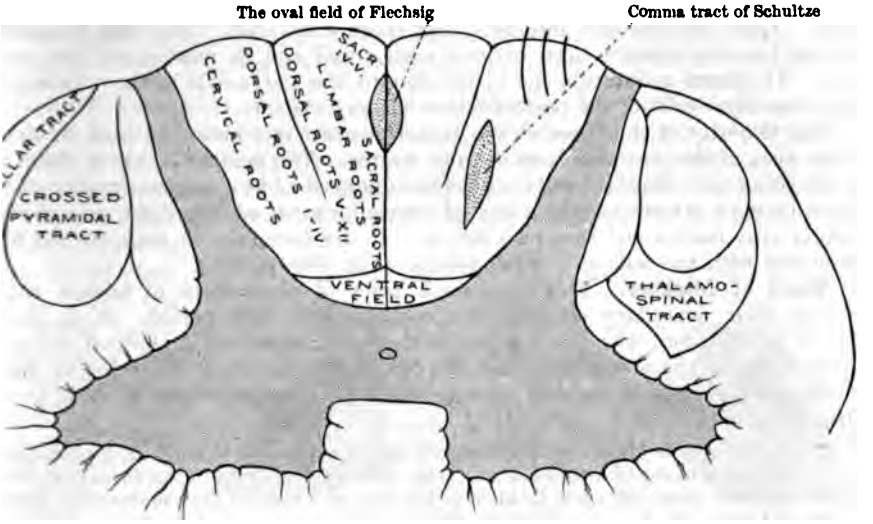

DIAGRAM TO SHOW THE ARRANGEMENT OF THE FIBRES OF THE POSTERIOR NERVE-ROOTS IN POSTERIOR COLUMNS OF THE CORD. The oval field of Flechsig is present in the lumbar region is composed of fibres which degenerate in a downward direction, and which are not derived from posterior nerve-roots. In all probability they are commissural fibres (from Edinger, modified).

he nerve-root next above take the same position, and consequently those which om the nerve immediately below are displaced nd come to lie in the tract of Burdach nearer esial plane. This process goes on as each enters, and the result is that the fibres of nerves are gradually pushed nearer and nearer stero-median septum in a successive series of tracts. Of course the greater proportion of s, which are thus carried upwards from the nerve-roots, sooner or later leave the posterior id enter the gray matter, to end there in relation f its cells; but, as we have said, every posterior sends a few fibres up the whole length of that the cord which lies above, and thus the posterior adually increases in bulk as it is traced upwards, he upper reaches of the cord a tract of Goll vident. This tract of Goll is composed of the nding fibres of the posterior nerve-roots, which ered the lower segments of the cord. To put er differently, the fibres of the sacral roots aced inwards by the entering lumbar fibres, fibres of the lumbar roots are in their turn wards by the entering dorsal fibres, and, lastly, of the cervical roots displace the dorsal fibres. ence between the tract of Goll and the tract of simply consists in this, that the former is com- the fibres of posterior nerve-roots which have he cord at a lower level than those which enter formation of the column of Burdach. The Goll's tract, taking them as a whole, must there- ssarily run a very much longer course.

nowledge of the constitution of the posterior of the cord is largely derived from studying e of degeneration in monkeys, in which the cord cut across—either partially or completely. It pear, from the examination of the human cord been injured or compressed, that the lamination es entering from the series of posterior nerve-roots *rly so complete as in the case of the monkey.*

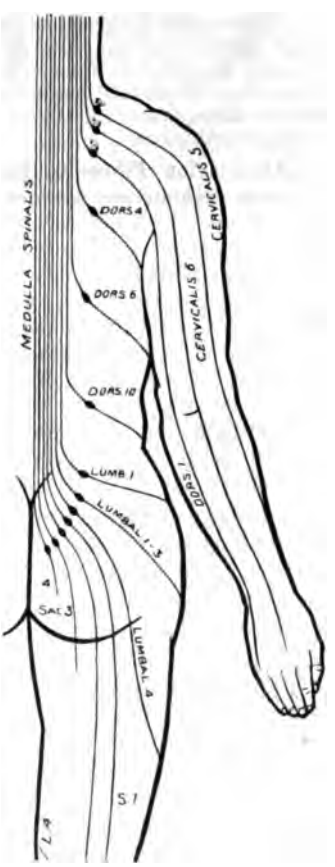

FIG. 376.—DIAGRAM TO SHOW THE MANNER IN WHICH THE FIBRES OF THE POSTERIOR NERVE-ROOTS ENTER AND ASCEND IN THE POSTERIOR COLUMN OF THE CORD (from Edinger).

Numerous collateral fibrils stream into the gray matter of the **posterior horn** from the ascending and descending branches of the entering fibres of the **posterior** roots. These are classified into long and short collaterals. The **long collaterals** end forward into the anterior horn of gray matter and end in relation to the **ventral** cells. The **short collaterals** end in relation to the nerve-cells in the **substantia Ro** and other nerve-cells of the posterior horn of gray matter.

The majority of the fibres of the posterior nerve-root enter the cord on the inner of the apex of the posterior horn of gray matter. The manner in which these are re to the columns of Burdach and Goll has been noticed; but a certain number of those fi which lie most externally take a curved course forwards on the inner side of the post horn of gray matter and then pass into it. In the dorsal region these curved fibres en connexion with the cells of Clarke's column (Fig. 369, p. 458).

Tract of Lissauer.—This is a small tract of nerve-fibres of minute calibre w assume their medullary sheaths at a comparatively late period. It is placed at surface of the cord close to the postero-lateral furrow. It is formed by some of outer fibres of the posterior nerve-roots, which do not enter the tract of Burdach, which pass upwards in the cord close to the substantia gelatinosa Rolandi, in which ultimately end.

It must now be evident that the fibres which enter the cord through each posterior nerve have three main modes of distribution: (1) the majority take part in the formation of the col of Burdach and Goll; (2) a few lie close to the posterior horn of gray matter and describe a s of graceful curves as they pass forwards prior to turning outwards into the gray matter, to en the dorsal region, in Clarke's vesicular column; (3) a third series form Lissauer's tract and en connexion with the cells of the substantia gelatinosa Rolandi and other cells in the posterior anterior horns of gray matter.

The fibres derived from the posterior nerve-roots which ascend in the posterior columns of cord to the medulla oblongata of the brain constitute a direct sensory tract; other fibres described which give rise to a crossed sensory tract termed the **spino-thalamic tract.** T latter fibres arise as the axons of certain of the cells in the posterior horn in connexion w which fibres from the posterior nerve-roots have ended, and crossing to the opposite sid the cord through the anterior commissure they ascend in the anterolateral column to the b where they ultimately reach the optic thalamus. As the spino-thalamic tract ascends in cord its fibres are not gathered into a compact strand, but are more or less loosely scatt in the lateral column.

Association Fibres in the Posterior Column.—But the whole of the fibres of posterior column are not derived from the posterior nerve-roots. A few fibres exis this column which have a different origin. They are derived from certain of the cell the gray matter of the cord, and entering the posterior column divide into ascending descending branches which pass upwards and downwards in the column for a var distance before they finally turn in to end in the gray matter at a higher and a lower l These fibres, therefore, constitute links of connexion between different cord segments, thus they are termed **association** or **longitudinal commissural fibres.** Our informa regarding these fibres at present is somewhat defective; but it is believed that the de part of the column, *i.e.* the part next the posterior gray commissure and termed **ventral field,** and also the **descending septo-marginal tract** of Bruce, placed in appos with the postero-median septum and in the adjoining part of the surface, belong mainl this category.

Lateral Column of the Cord.—In the lateral column of the cord the v established tracts are:—

1. The direct cerebellar tract.
2. The tract of Gowers.
3. The crossed pyramidal tract.

The remainder of the column goes under the name of the **lateral basis-bundl**

The **direct cerebellar tract** (fasciculus cerebello-spinalis) is a band-like st which lies in relation to the surface of the cord immediately in front of the post lateral groove. It is an ascending tract, and is composed for the most pa coarse, large nerve-fibres, which are derived from the nerve-cells of the post vesicular column (Clarke's column) in the posterior horn of gray matter. I therefore, not found throughout the whole length of the cord. It first appea the lower part of the dorsal region; and as it ascends it gradually increases in as it is joined by the axons of the cells of Clarke's column, which lie at hi levels. It finally enters the medulla oblongata, and through this proceeds to cerebellum, in which it ends.

It must not be forgotten that each posterior nerve-root in the dorsal region of the cord gives ntribution of fibres to the posterior vesicular column of cells from which the fibres of the direct ebellar tract arise (see p. 468). In this way a connexion is established between the posterior ts of the dorsal nerves and the cortex of the cerebellum. It is believed that the direct cerebellar t is an important factor in bringing about a proper co-ordination of muscular movements.

Gowers's tract (fasciculus antero-lateralis superficialis) lies in front of the direct rebellar tract, and, like it, next the surface of the lateral column. It is also an ending tract, and it likewise (in part at least) ultimately reaches the cerebellum, though after leaving the cord it takes a different route to gain its destination. transverse sections of the cord it presents a comma-shaped appearance, the ick part abutting inst the direct cere-llar tract, and the rrower portion taper-g forwards into the ion of the emerging terior nerve-roots. e tract of Gowers ins at a lower level the cord than the ect cerebellar tract d it increases in vol-e as it is traced up-rds. The fibres of s tract have probably ir origin in the cells the posterior horn of y matter, but on this nt there is at present precise information.

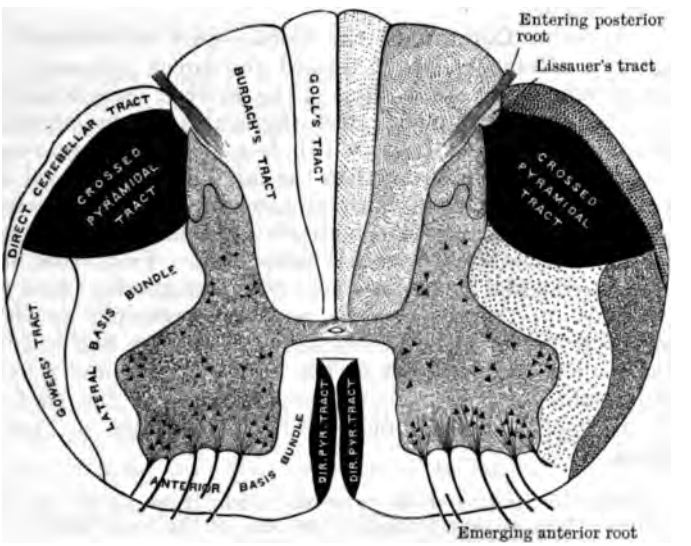

FIG. 377.—DIAGRAMMATIC REPRESENTATION OF A TRANSVERSE SECTION THROUGH THE SPINAL CORD.

The nerve tracts in the white matter and the clusters of nerve-cells in the gray matter are shown.

The **crossed pyramidal** ct (fasciculus cerebro-nalis lateralis) is a ge well-defined de-ending tract, which lies immediately in front of the posterior horn of gray atter and subjacent to the direct cerebellar tract, which shuts it out from e surface of the cord. Below the point where the direct cerebellar tract begins e crossed pyramidal tract becomes superficial, and in this position it can be aced as low as the fourth sacral nerve, at which level it ceases to exist as a stinct strand. The crossed pyramidal tract is composed of an admixture of both rge and small fibres. These arise in the brain from the large pyramidal cells the motor or Rolandic area of the cerebral cortex, and pass downwards through rious subdivisions of the brain to gain the spinal cord. As they enter the cord ey cross the mesial plane from one side to the other, and it thus happens that e crossed pyramidal tract in the right lateral column of the cord has its origin the cortex of the left cerebral hemisphere, and *vice versa*. As the tract descends the cord it gradually diminishes in size; and this is due to the fact that, as it averses each spinal segment, numerous fibres leave it to enter the anterior horn gray matter, and end in connexion with the ventral motor cells from which the bres of the anterior nerve-roots arise. The entire strand is ultimately exhausted this way. Numerous collateral fibrils spring from the pyramidal fibres, and, ntering the gray matter, end in a similar manner, and in this way a single pyra-idal fibre may be connected with several spinal segments before it finally ends. he crossed pyramidal tract must be regarded as a great motor strand which rings the spinal motor apparatus under the control of the will.

Schäfer believes that many of the pyramidal fibres end in connexion with the cells Clarke's column.

In the rat, mouse, guinea-pig, squirrel, sheep, kangaroo, etc., the pyramidal tract lies the posterior column of the cord.

The **lateral basis-bundle** (fasciculus lateralis proprius) represents the remain of the lateral column. Our information regarding it is still imperfect; but would appear that its fibres are largely derived from the cells situated in all p of the gray matter, and also from the nerve-cells of the opposite side of the c After a course of very varying length in the basis-bundle, these fibres turn inw and re-enter the gray matter. Such fibres may thus be regarded as **inter-segm association fibres** binding two or more segments of the cord together. It may mentioned that the association fibres which link together segments of the c which are near to each other lie close to the gray matter, whilst those wh connect the more distant segments are situated further out in the late basis-bundle.

Anterior Column of the Cord.—One well-defined tract is situated in t anterior column. This is termed the direct pyramidal tract. The remainder the column receives the name of the anterior basis-bundle.

The **direct pyramidal tract** (fasciculus cerebro-spinalis anterior) is usually nerve-strand of small size which lies next the antero-median fissure. As a ru it cannot be traced lower than the middle of the dorsal region of the cord. It a descending tract and must be associated with the crossed pyramidal tract of t opposite side, seeing that both of these strands arise from the motor area of t cortex of the same cerebral hemisphere. From this, it must be clear that t direct pyramidal tract does not cross the mesial plane as it enters the cord, b descends on the side of the cord corresponding to the cerebral hemisphere which it arises. All the same its fibres do not end in the same side of t cord, but at every step along the path of the strand they make use of the anter commissure and cross to the opposite side of the cord, to terminate in relati to the opposite ventral motor cells in the same manner as the crossed pyramid fibres.

From this crossing of the pyramidal tracts, it results that the destruction of the fibres wh compose them as they descend in one side of the brain must result in paralysis of the mus supplied by the efferent nerves of the opposite side of the cord.

In cases of old brain lesion it is sometimes possible to detect some degenerated fibres in t crossed pyramidal tract of the sound side of the spinal cord, and from this it is supposed that th tract contains a few uncrossed fibres. If this be the case, each side of the cord stands connexion with the motor area of both cerebral hemispheres.

It is well to note that the fibres of both pyramidal tracts are not medullated until the time birth. They are the latest of all the cord-tracts to myelinate.

The **anterior basis-bundle** (fasciculus anterior proprius), like the lateral basis bundle, is composed largely of fibres which arise from the cells of the gray matte of the cord, and act the part of **intersegmental association fibres.**

Summary of the Constitution of the White Matter of the Cord.—Th white columns of the cord are formed of two kinds of nerve-fibres :—

1. Those which enter the cord from without.
2. Those which take their origin from the cells within the gray matter of the cord itself.

Under the first category we include (*a*) the greater part of the fibres of the posterior column (columns of Burdach and Goll), which arise from the cells of the spinal ganglia, and which enter the cord as the posterior nerve-roots; and (*b*) the crossed and direct pyramidal tracts which come from the motor cells of the cerebral cortex.

The fibres which arise within the gray matter of the cord may be classified thus: (*a*) Fibres which pass out from the cord as efferent nerves (anterior nerve-roots); (*b*) fibres which form long tracts and pass up the cord to enter the brain (direct cerebellar tract and the tract of Gowers); (*c*) fibres which form short tracts, linking together different segments of the cord (intersegmental association fibres in each of the three columns of the cord).

Anterior White Commissure.—The anterior commissure is composed of medullated nerve-fibres passing from one side of the cord to the other and entering the anterior horn of gray matter, and also the anterior column of white matter. It is to be regarded more as a decussation than as a commissure, and its width, which

es somewhat in different regions, fluctuates in correspondence with the diameter he cord.

Amongst the fibres which cross in the anterior commissure may be mentioned: (1) The fibres he direct pyramidal tract; (2) collaterals from both the ventral and lateral columns; (3) axons any of the cells of the gray matter; (4) the dendritic processes of some of the mesial ventral a.

Posterior Gray Commissure.—Although this is composed of gray matter with arge admixture of neuroglia, numerous transverse nerve-fibres pass through it, so to bind the cells of one side of the cord to those of the other.

Development of the Spinal Cord.

In the chapter upon General Embryology it has been pointed out (p. 21) that the in and cord first take shape in the form of a tube of ectoderm, which receives the name he **neural tube**. Three expansions, placed one behind the other at the cephalic end of tube, represent the early brain; whilst behind these primitive cerebral vesicles comes elongated narrower part of the tube, which at this stage represents the spinal cord. developmental process, which we now have to study, the walls of this portion of the al canal give rise to the various elements which build up the substance of the cord, st a portion, if not the whole, of the primitive cavity is preserved as the central canal he cord. The account which is here given of the development of the cord is taken st entirely from the writings of Professor His.

When first formed, the neural tube is compressed from side to side and presents an oval ine in transverse section (Fig. 16, p. 21). The two lateral walls are very thick, whilst narrow dorsal and ventral portions of the wall are thin, and are termed the **mid-dorsal** **mid-ventral laminæ** (Fig. 378). The cavity of the tube in transverse section appears as rrow slit. At this stage the wall of the neural tube is formed of a series of elongated ro-epithelial columnar cells, closely applied to each other and extending throughout the le thickness of the wall. The r ends of these long columnar s unite to form a delicate mem- ne termed the **internal limiting nbrane**, which lines the lumen of tube, whilst their outer ends sent a similar relation to an **ex- nal limiting membrane**, which sts the outer surface of the tube. e name of **spongioblasts** is given hese cells, and they soon develop such a manner as to form the tentacular framework of the wing cord. Between their inner ts, immediately subjacent to the ernal limiting membrane, a series clefts or open spaces are formed, which appear large numbers of nd cells called **germinal cells.** e precise origin of these germinal ls is not at present satisfactorily ablished; but they rapidly in- ase in number, and in the human bryo of four weeks they are seen form an almost continuous layer neath the internal limiting mem- ane. It is well to note, however, at in the thin mid-dorsal and mid- ntral laminæ no germinal cells are rmed. Here the wall remains rely spongioblastic. The peri- eral portions of the spongioblasts likewise undergo a marked transformation. They ve off branches or processes, and by the interlacement of these a sponge-like network ith irregular meshes is formed in the outer portion of the wall of the neural tube. The

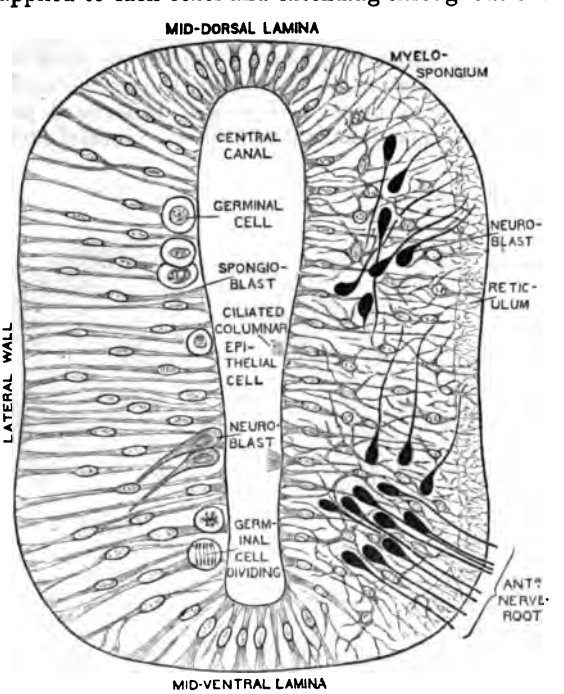

Fig. 378.—Schema of a Transverse Section through the Early Neural Tube (Young).

The left side of the section shows an earlier stage than the right side.

entire sustentacular framework into which the spongioblasts are developed is term the **myelosponge.**

The numerous germinal cells which are placed in the clefts between the in columnar portion of the myelosponge are the progenitors of the nerve-cells. Many them show karyokinetic stages, and by their division they give rise to the **neuroblasts** young nerve-cells. A neuroblast presents a very characteristic pear-shaped appearan From the body of the cell a tapering process grows out, and this represents the early a cylinder process or axon of the cell. But the crowds of neuroblasts which are thus form do not remain in their early primitive position beneath the internal limiting membra They migrate outwards, and in the course of time they come to lie in the part of t myelosponge immediately adjoining the reticular meshwork, which is formed by the out parts of the spongioblasts. Here their further outward migration is arrested. Th reticular meshwork would almost appear to act as a sieve or a filter, which prevents the progress towards the periphery of the wall of the tube. It offers no impediment to th actively growing axons of the neuroblasts, however, which freely enter it and thread the way through it. At this stage the thick lateral wall of the neural tube presents thre layers, viz. :—

1. An inner layer, formed by the columnar part of the myelosponge forsaken by th neuroblasts. This is termed the **ependymal layer,** and it ultimately resolves itself in the layer of columnar ciliated epithelial cells which lines the central canal of the cord.

2. An intermediate layer, in which the neuroblasts are present, and which is afterwa converted into the gray matter of the cord. This is called the **mantle layer.**

3. An outer layer, formed of the sponge-like meshwork of the outer parts of t original spongioblasts. Into this the axons of many of the neuroblasts are seen threadi their way. This layer is ultimately transformed into the white matter of the cord, a at this stage it may be termed the **peripheral reticular layer.**

Alar and Basal Laminæ of the Lateral Wall of the Neural Tube.—Fr what has been said, it must be evident that the changes detailed above are confined the thick lateral walls of the neural tube. In these alone do neuroblastic cells ar whilst the thin mid-dorsal and mid-ventral laminæ remain spongioblastic throughc But whilst these changes are going on, the thick lateral wall begins to bulge outwards an angular fashion, so as to widen the central cavity of the tube and become itself, al the line where the cavity is widest, demarcated into two portions—a narrow dorsal st termed the **alar lamina,** and a broader ventral strip called the **basal lamina.** The cav

of the tube now appears on transverse section more or less lozenge-shaped, and it is at t lateral angles of the lozenge that this subdivision of the lateral wall becomes evident.

This subdivision is a fundamental one, being present in the brain-part as well as t

art of the neural tube. By it the thick lateral wall is resolved into two longitudinal (the alar and basal laminæ), which extend along the whole length of the tube, and present definite and precise relations with the entering and emerging roots of the ıs cranial and spinal nerves. Confining our attention to the spinal cord, the posterior ·root is seen to enter the alar lamina, whilst the anterior nerve-root takes origin ı and emerges from the basal lamina.

urther Development of the Gray and White Matter of the Cord.—In the ıl part of the basal lamina the mantle layer thickens into a mass, which is readily ıised as the rudiment of the anterior horn of gray matter, and in this neuroblastic ;ongregate in much larger numbers than elsewhere. Further, these neuroblastic ıegin to arrange themselves into groups, and the axis-cylinder processes of a large rtion of them converge and form bundles of fibres, which penetrate into the peri- l layer, and finally pierce the external limiting membrane, to emerge as the fascicles anterior nerve-roots. Behind the anterior horn the mantle layer still remains very ınd the neuroblasts are few in number. There is, therefore, at this stage no appear- ›f the posterior horn of gray matter. Many of the axons of the neuroblasts which y this region are seen curving forwards, and, after traversing the anterior horn, they heir way across the middle line in the mid-ventral lamina. In this manner is laid at a very early stage, the rudiment of the anterior white commissure of the cord.

ıe white matter of the anterior and lateral columns is gradually established by axons various neuroblasts in different parts of the mantle layer, entering the peripheral lar layer and taking a longitudinal course within it. The anterior horn is well l with white matter, however, before the lateral column takes definite shape.

ıe posterior columns of white matter are formed in a totally different manner, viz. ; introduction into the cord of nerve-fibres from without. The fibres of the posterior ·roots coming from the spinal ganglia strike the outer surface of the alar lamina of teral wall of the neural tube, and, piercing the external limiting membrane, take a udinal course in the peripheral reticular layer. On cross section these fibres first r as an oval bundle, which lies in the outer part of the alar lamina (Fig. 379 PC). ›undle is the rudiment of Burdach's column, and at first it has a somewhat loose xion with the cord; but as the posterior horn of gray matter gradually takes , the bundle in question increases in volume, and, changing its position, comes to lie e inner aspect of the posterior horn. The column of Goll gradually assumes form ;en the tract of Burdach and the postero-median septum. Later on the lateral and ior columns are increased in bulk by the descent into them of the pyramidal tracts the brain.

he gray matter, in the first instance, is chiefly massed in the basal lamina; but as osterior columns of white matter begin to take shape it extends backward, and in ›urse of time the posterior horns are developed.

he manner in which the dendritic processes of the neuroblasts are developed has sufficiently described (p. 447). The ensheathment, also, of the axons by medulla ;een referred to, and the fact that the different tracts of fibres receive their medullary hs at different periods mentioned. It is now only necessary to state that the order ;elinisation of the several tracts is as follows:—(1) Fibres of the anterior nerve-roots; ract of Burdach; (3) fibres in the basis-bundles; (4) tract of Goll; (5) direct cere- r tract; (6) tract of Gowers; (7) pyramidal tracts (Kahler).

)evelopment of the Median Fissures and of the Central Canal.—As the ior horns of gray matter covered by the anterior columns of white matter increase in the anterior surface of the cord on either side of the mesial plane bulges forwards, :he antero-median fissure is produced as the natural result.

'he manner in which the postero-median fissure comes into existence is not fully rstood, but the majority of embryologists believe that it is produced by the approxi- ›n and fusion of the walls of the posterior part of the primitive cavity of the neural

The postero-median septum would thus appear to be formed of spongioblastic tissue. f the above view of the formation of the postero-median fissure be correct, it must ident that the central canal of the cord does not represent the whole of the primitive y of the early neural tube, but only the anterior portion of it.

among those observers who do not hold that the central canal and posterior fissure have this : of origin the most prominent is Professor A. W. Robinson, of Birmingham; and he has ght forward evidence which seems to indicate that it is doubtful if the fusion of the walls e posterior part of the canal, referred to above, takes place. Certainly the arrangement of ependymal elements of the postero-median septum, as seen in the preparations of Cajal v. Lenhossek, are extremely difficult to understand on the fusion theory. They run in the

antero-posterior direction, whereas, if fusion has taken place, most of them would present a transverse arrangement, and thus lie at right angles to the postero-median septum.

THE BRAIN OR ENCEPHALON.

The **brain** is the enlarged and greatly modified upper part of the cerebrospinal nervous axis. It is surrounded by the same membranes that envelop the spinal cord (viz. the dura mater, the arachnoid mater, and the pia mater), and it almost completely fills up the cavity of the cranium. So closely, indeed, is the skull capsule moulded upon the brain that the impress of the latter is almost everywhere evident upon the deep surface of the cranial wall. The relations, therefore, of cranium to brain are totally different from those presented by the vertebral canal

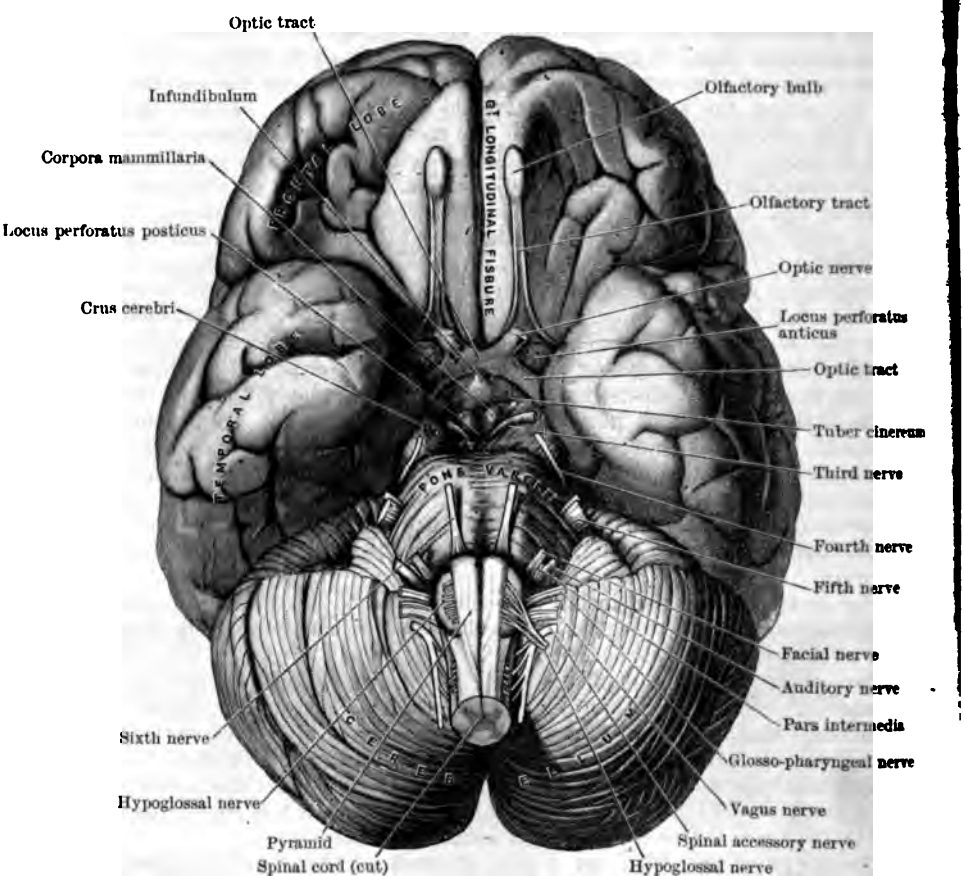

FIG. 380.—THE BASE OF THE BRAIN WITH THE CRANIAL NERVES ATTACHED.

to the spinal cord. As we have noted, the cord occupies only a part of its bony case; and there is not only a wide and roomy space between the arachnoid mater and pia mater, but also an interval of some width between the dura mater and the walls of the vertebral canal.

General Appearance of the Brain.—When viewed from above the brain presents an ovoid figure, the broad end of which is directed backwards. Its greatest transverse diameter is usually found in the neighbourhood of that part which lies between the two parietal eminences of the cranium. The only parts which are visible when the brain is inspected from this point of view are the two convoluted **cerebral hemispheres.** These present an extensive convex surface, which is closely applied to the deep aspect of the cranial vault, and are separated from each other by a deep median cleft, termed the **great longitudinal fissure,** which extends from the front to the back of the brain.

The inferior aspect of the brain is usually termed the "base." It presents an even and irregular surface, which is more or less accurately adapted to the qualities on the floor of the cranium. Upon this aspect of the brain some of main subdivisions may be recognised. Thus behind is seen the short cylindrical rtion, called the **bulb** or **medulla oblongata**, through which, at the foramen magnum, e brain becomes continuous with the spinal cord. The bulb lies on the ventral pect of the cerebellum, and occupies the vallecula or hollow which intervenes tween the two cerebellar hemispheres. The **cerebellum** is a mass of considerable e which is placed below the hinder portions of the two cerebral hemispheres. It easily recognised on account of the closely-set, curved, and parallel fissures which nverse its surface and give it a foliated appearance. Above the medulla, and in se connexion with it, is a prominent white elevation called the **pons Varolii**. Imediately in front of the pons there is a deep hollow or recess. This is bounded hind by the pons Varolii, on either side by the projecting temporal lobe of the ebral hemisphere, and in front by the orbital portions of the frontal lobes of the ebral hemispheres. Passing out from either side of the fore-part of this recess is deep Sylvian fissure which intervenes between the pointed and projecting remity of the temporal lobe and the frontal lobe of the cerebrum, whilst in the ddle line in front the great longitudinal fissure, which separates the frontal tions of the cerebral hemispheres, opens into it.

Within the limits of this deep hollow, in the base of the brain, two large rope- strands, the **crura cerebri**, may be seen issuing from the upper aspect of the is Varolii. Placed close together as they emerge from the pons, these crura erge as they proceed upwards and forwards, and finally each disappears by nging into the corresponding side of the cerebrum. Turning round the outer e of each crus, where it enters the cerebrum, a flattened band termed the **optic ct** may be observed. These bands converge in the fore-part of the hollow, and finally joined together by a short commissural portion, termed the **optic chiasma**. e **optic nerve** is continued forwards and outwards, on either side, from the chiasma d tract.

The crura cerebri, the optic tracts, and the optic chiasma enclose a deep omboidal or lozenge-shaped interval on the base of the brain, which is termed e **interpeduncular space**. Within the limits of this area the following parts may seen as we pass from behind forwards: (1) the locus perforatus posticus; (2) the rpora mammillaria: (3) the tuber cinereum and the stalk of the pituitary body.

At its posterior angle, immediately in front of the pons Varolii, the interduncular space is very deep and is floored by a layer of gray matter, which is erforated by numerous small apertures. This is the **locus perforatus posticus**. hrough the apertures which are dotted over its surface the small postero-mesial asal branches of the posterior cerebral artery enter the brain.

The **corpora mammillaria** are two small white pea-like eminences placed side by ide in front of the locus perforatus posticus.

The **tuber cinereum** is a slightly raised field of gray matter, which occupies the nterval between the anterior portions of the optic tracts in front of the corpora mammillaria. Springing from the fore-part of the tuber cinereum, immediately ehind the optic chiasma, is the **infundibulum**, or the stalk which connects the ituitary body with the base of the brain.

Outside the limits of the fore-part of the interpeduncular space there is on ither side a small depressed triangular field of gray matter, which leads outwards nto the Sylvian fissure. It is perforated by the antero-mesial and the anterolateral groups of basal arteries, and receives the name of the **locus perforatus nticus**.

General Connexions of the Several Parts of the Brain.—The medulla blongata, the pons Varolii, and the cerebellum occupy the posterior cranial fossa, nd they are separated from the cerebral hemispheres which lie above them by a artition of dura mater, termed the tentorium cerebelli. Further, they surround cavity, a portion of the primitive cavity of the early neural tube, which is termed he **fourth ventricle** of the brain, and they all stand in intimate connexion with ach other. The medulla is for the most part carried upwards into the pons

Varolii; but at the same time two large strands from its dorsal aspect, termed restiform bodies, are prolonged into the cerebellum, and constitute its in peduncles, or the chief bonds of u between the medulla and the bellum. The pons Varolii has numbers of transverse fibres e ing into its composition, and great majority of these are gath together on either side in the of a large rope-like strand. plunges into the corresponding h sphere of the cerebellum, and stitutes its middle peduncle.

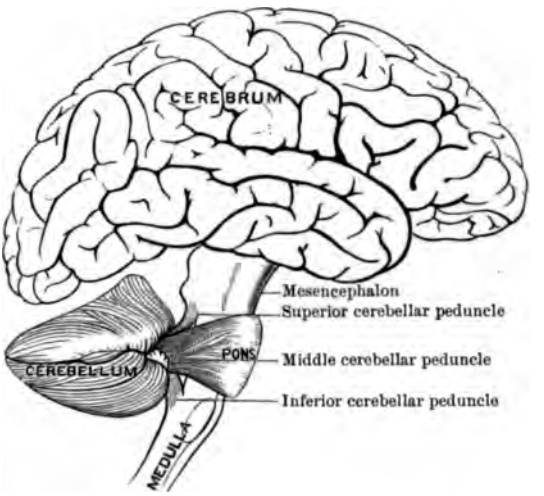

FIG. 381.—SCHEMA, showing the connexions of the several parts of the brain.

The cerebrum, which form great mass of the brain, occupie anterior and middle cranial f and extends backwards into th cipital region above the tento and the cerebellum. The greate of the cerebrum is formed b cerebral hemispheres, which separated from each other i mesial plane by the great l tudinal fissure. At the bottom of this fissure is the **corpus callosum**, a commissural band which connects the two hemispheres with each other. hemisphere is hollow, the cavity in its interior being termed the **lateral ven** of the brain. Between and below the cerebral hemispheres, and almost pletely concealed by them, is the **inter-brain** or **diencephalon**. The principal forming this portion of the brain are two large masses of gray matter, te the **optic thalami**. Between these is the **third ventricle** of the brain—a deep n cavity occupying the mesial plane. The third ventricle communicates wit lateral ventricles by two small apertures, called the **foramina of Monro**.

The cerebrum is connected with the parts in the posterior cranial fossa Varolii, cerebellum, and bulb) by a narrow stalk called the **mid-brai mesencephalon**. The mid-brain is built up of the **crura cerebri**, passing fro pons Varolii to the cerebrum; the **corpora quadrigemina**, forming its dorsal part the **superior cerebellar peduncles**, proceeding from the cerebellum to the cere It is tunnelled by a narrow passage, the **aqueduct of Sylvius**, which extends be the fourth and third ventricles.

GENERAL OUTLINE OF THE DEVELOPMENT OF THE BRAIN.

The brain is developed from the expanded anterior portion of the prin neural tube. In the section dealing with the general principles of Embryol has been pointed out that this part of the neural tube is marked off by tw strictions into three primitive cerebral vesicles, which are termed respectivel hind-brain or rhombencephalon, the mid-brain or mesencephalon, and the brain or prosencephalon.

Hind-brain or Rhombencephalon.—The hind-brain is the largest of the primary expansions of the neural tube: indeed, it may be said that in the e stages of brain development it is larger than both of the other primary subdiv taken together. The portion immediately adjoining the mid-brain is consti and is termed the **isthmus rhombencephali**. This is a very small part, formin extreme upper end of the vesicle, and from its walls are developed the su cerebellar peduncles and a thin lamina, which is stretched across the middl between them, called the valve of Vieussens or the superior medullary v Immediately behind the isthmus the hind-brain expands suddenly, and then s and gradually tapers as it passes downwards towards the spinal cord part c neural tube. Its junction with the latter is very early indicated by a sharp

the tube, which is termed the **cervical flexure**. The large portion of hind-brain ich extends from the isthmus to the cervical flexure is usually considered as ng composed of two parts, viz. an upper portion, termed the metencephalon, and inferior portion, called the myelencephalon.

From the metencephalon are derived the cerebellum and pons Varolii. The ebellum arises by a thickening of the dorsal wall of this portion of the vesicle, ilst the pons is formed by a thickening of the lateral and ventral walls. The

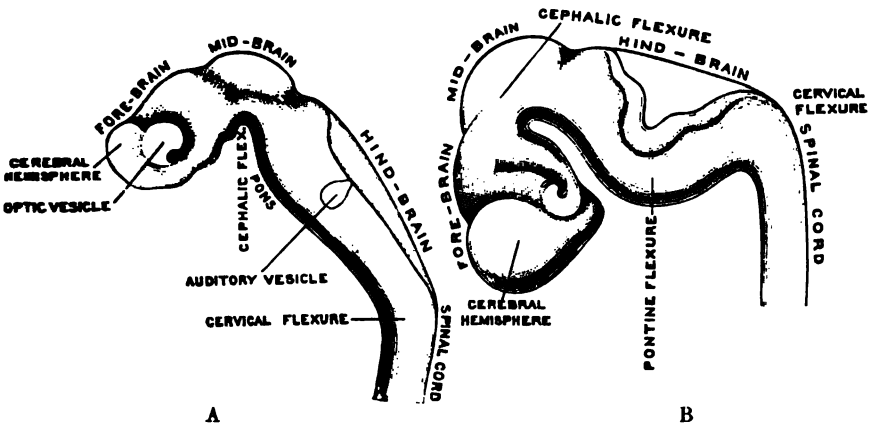

FIG. 382.—TWO STAGES IN THE DEVELOPMENT OF THE HUMAN BRAIN (after His).
A. Brain of an embryo of the third week. B. Brain of an embryo of five weeks.

elencephalon gives origin to the bulb or medulla oblongata. This is chiefly med by a thickening of the lateral walls of this part of the vesicle. These fall ay from each other in an outward direction, and thus the ventral angle between em becomes greatly opened up. The growth which leads to the formation of the lb appears, therefore, to take place chiefly on the ventral aspect of the vesicle. ie dorsal wall remains thin and epithelial, and undergoes little or no development to nervous elements.

The cavity of the original hind-brain is retained in the adult brain as the fourth ntricle; and from what has been said regarding the development of the different ortions of the wall of the rimitive hind-brain, it will e seen that in its lower or nedullary part its dorsal all or roof, to a large xtent, remains epithelial.

The parts of the adult rain which are derived rom the rhombencephalon r hind-brain are those hich lie below the ten- orium cerebelli in the osterior cranial fossa of he skull.

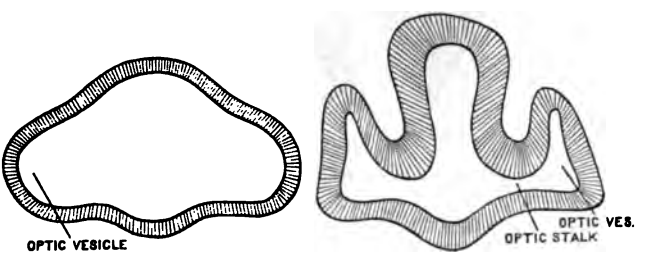

FIG. 383.—TWO CROSS SECTIONS THROUGH THE FORE-BRAIN.
A. Through the fore-brain of the early human embryo. B. Through the fore-brain and optic vesicles of a Lepidosteus embryo of eight days (after Balfour and Parker, modified).

Mesencephalon or id-brain.—The mid-brain takes a much more prominent part in the forma- ion of the early primitive brain than it does in the construction of the adult rain. It forms a very small part of the adult brain, and constitutes a stalk of onnexion between the parts which are developed from the walls of the rhomben- ephalon and those which are developed from the walls of the prosencephalon r fore-brain. The entire wall of the mid-brain is transformed into nervous tissue. Thus, by the special development of the dorsal section of the wall, the corpora quadrigemina are formed. The lateral and ventral sections of the wall undergo a still more marked degree of growth-thickening, and the result is the

formation of the two crura cerebri. The cavity of the mid-brain is retained narrow passage termed the aqueduct of Sylvius, which connects the third v of the brain with the fourth ventricle.

Prosencephalon or Fore-brain.—In its early condition one of the peculiarities of the fore-brain is its great width. It extends outwards on side for a considerable distance beyond the lateral walls of the mid-brain. lateral expansions of the fore-brain are the **optic vesicles**, and at this stage the no way constricted off from the central part of the cavity (Fig. 383). Soon, h the central portion of the fore-brain begins to expand upwards and forwards the terminal portions of the optic vesicles likewise undergo enlargement; a result is, that the originally single chamber shows subdivision into three viz. a central portion or fore-brain proper, and two expanded optic vesicles, are joined to the parts of the lateral of the fore-brain pr two short const tubular passages the **optic stalks**.

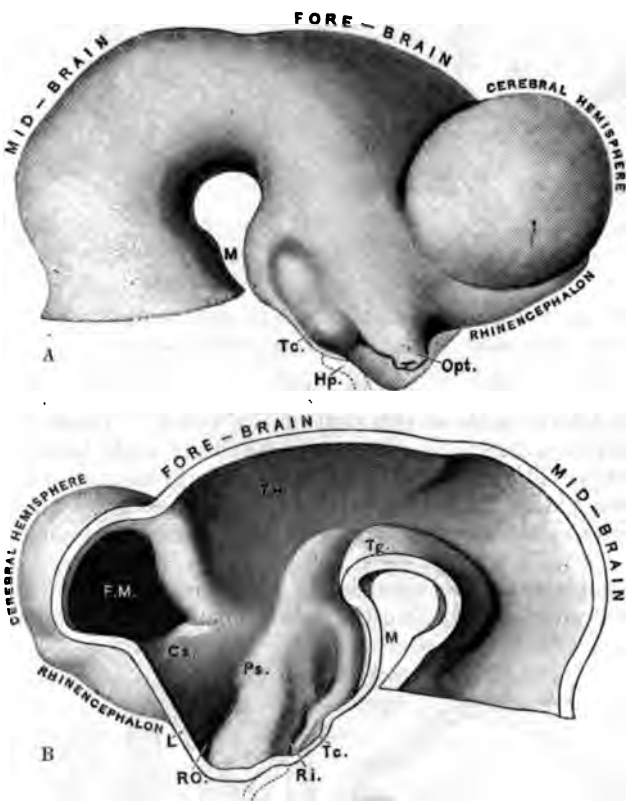

FIG. 384.—THE BRAIN OF A HUMAN EMBRYO IN THE FIFTH WEEK (from His).

The optic vesicl the optic stalk becon mately transformed i retina of the eye-b the optic nerve. changes which lead result are detailed section dealing wi anatomy of the or vision.

The fore-brain goes a series of rem developmental chan most striking of w the formation of th bral hemispheres terminal or fore-por the fore-brain, in t instance, expands i ward and downwar tion, and from the and lateral aspects new portion of the thus formed the c hemispheres bulge ou in the form of two pouches. The original part of th brain is termed th **mamencephalon** or **cephalon**, whilst t terior part with the cerebral hemispheres, which protrude out from it, rece name of **telencephalon**.

The side walls of the diencephalon become thickened into the two large of gray matter termed the optic thalami; the floor or ventral wall develc those structures which occupy the interpeduncular space in the base of th (viz. the posterior perforated spot, the corpora mammillaria, and the tuber cine whilst the roof or dorsal wall remains thin and epithelial, and under nervous development.

The hollow cerebral hemispheres soon outstrip all the other parts of th in their development. They expand not only in an upward and forward di

ly in a backward direction; and by their excessive growth backwards dually come to overlie the diencephalon, the mesencephalon, and at parts derived from the rhombencephalon. It thus comes about that, adult brain is viewed from above nothing but the cerebral hemispheres e—all the other parts of the brain lie under cover of them.

rst the cavity of each cerebral hemisphere is connected with the cavity nt portion of the fore-brain by an exceedingly short but relatively wide This is the early condition of the **foramen of Monro**. The fore-part of rain is now seen to be bounded in front between the two hollow cerebral re-pouches by a narrow thin strip, which represents the extreme anterior ie neural tube, and consequently it receives the name of **lamina terminalis**. y of the fore-brain not only in its hinder diencephalic part, but also in or telencephalic part (*i.e.* the part from which the cerebral hemispheres , persists as the third ventricle of the brain, whilst the cavities of the cerebral hemispheres are ed in the adult by the ntricles of the brain. The of Monro, relatively much in size, are preserved as throats of communication the lateral ventricles and l ventricle. The olfactory e formed as hollow out- from the cerebral hemi-

ures of the Brain-tube.— r early period, and while the detailed above are being n, the cerebral portion of the ube becomes sharply bent elf at certain points. The ture which occurs is the **cephalic flexure**. It occurs egion of the mesencephalon, olves the entire head. The n becomes bent in a ventral round the fore-end of the l and the fore-gut, until the s of the fore-brain forms an gle with the long axis of -brain and the ventral wall ne comes to lie nearly parallel with the corresponding wall of the other. this curvature the mid-brain is considerably modified in form, and for a mes to occupy the most prominent and foremost part of the embryonic head. primary cephalic flexure is soon followed by the **cervical flexure**. This the junction of the hind-brain with the spinal cord. Here the entire ent in a ventral direction, and at the end of the fifth week the flexure is nced that the cerebral and spinal cord portions of the neural tube meet er at a right angle (Fig. 385). In the later stages of development the lexure becomes obliterated by the elevation of the head and the straighten- e neck of the embryo.

third bend takes place in the region of the future pons Varolii (meten-), and is consequently termed the **pontine flexure**. It differs from the tures in being confined to the brain tube and in not in any way involving e head. Further, the bend is much more marked in the thick ventral n in the thin dorsal wall of the tube. The neural tube is doubled forwards and the pons Varolii becomes developed in connexion with the summit of ature. In the further growth of the brain the pontine flexure becomes mpletely obliterated.

By reason of these curvatures the early brain assumes a sinuous, zig S-shaped outline when viewed from the side, and the relationship of its parts becomes materially altered. The essential factor at work in the prod of the brain flexures is clearly the very unequal growth which takes pl different parts of the cerebral wall.

Basal and Alar Laminæ of His.—It has been pointed out that, i development of the spinal cord, each of the thick lateral walls of the neur is marked off into a dorsal or alar and a ventral or basal lamina. This subd is also noticeable in the cerebral part of the neural tube, and the furrow inner aspect of the lateral wall, which indicates this subdivision, can be even in the adult brain throughout a considerable part of its length.

In the spinal cord the motor cells are gathered in the basal lamina in m less conti columns. brain the sponding from whic efferent fil the cranial are given also placed the basal but they ranged diffe They are co together i connected termed the nuclei, an do not e higher up the mid- No motor occur in th brain. I the import the basal diminishes pass fro lower to the parts of the

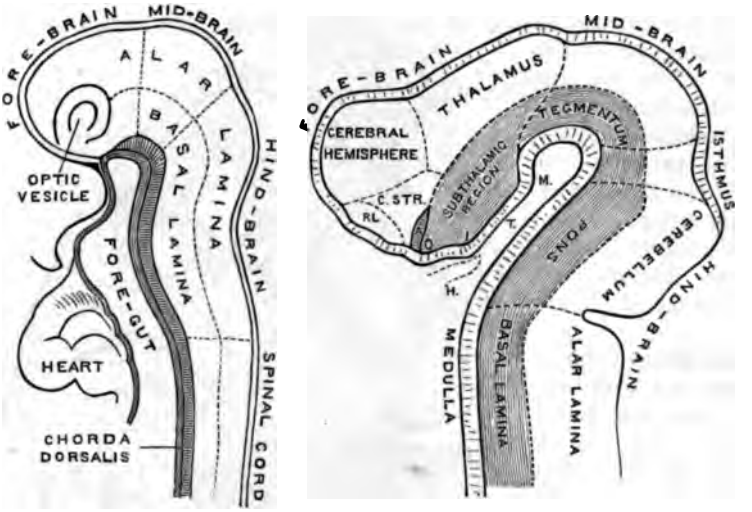

FIG. 386.—DIAGRAMS TO ILLUSTRATE THE ALAR AND BASAL LAMINÆ. In both cases the embryonic brain is represented in mesial section (His).

A. The different subdivisions of the brain are marked off from each other by dotted lines, and the dotted line running in the long axis of the neural tube indicates the separation of the alar from the basal lamima of the lateral wall.

B. Mesial section through the brain of a human embryo at the end of the first month. Dotted lines mark off the different regions and also the alar and basal laminæ from each other.

H, Buccal part of pituitary body; RL, Olfactory lobe; C.STR, Corpus striatum; A, Entrance to optic stalk; O, Optic recess; I, Infundibular recess; T, Tuber cinereum; M. Mammillary eminence.

In the rhombic or hind-brain the greater part of the medulla oblongata the pons Varolii is formed from the basal laminæ, whilst the cerebellum, w superior and inferior cerebellar peduncles, is derived from the alar lamin the mid-brain the crura cerebri are the derivatives of the basal laminæ, whi corpora quadrigemina are developed from the alar laminæ. In the fore-br subthalamic region and the optic vesicles are products of the growth of th laminæ, whilst the optic thalami and cerebral hemispheres spring from tl laminæ.

The fact that the cerebellum and the cerebral hemispheres owe their to the alar laminæ is sufficient to show the predominant part which these l play in brain development, and the higher we ascend in the animal scale th pronounced does this predominance become.

The following table gives a summary of the various developmental pr which have been described in the foregoing pages:—

Rhombencephalon or Hind-brain (posterior cerebral vesicle)	Myelencephalon	Bulb or medulla oblongata	
		Lower part of the fourth ventricle	
	Metencephalon	Cerebellum	
		Pons Varolii	
		Upper part of the fourth ventricle	
	Isthmus rhombencephali (narrow constricted part immediately adjoining the mesencephalon)	Superior cerebellar peduncles	
		Valve of Vieussens	
Mesencephalon or Mid-brain (middle cerebral vesicle)	Mesencephalon or Mid-brain	Corpora quadrigemina	
		Crura cerebri	
		Aqueduct of Sylvius	
Prosencephalon or Fore-brain (anterior cerebral vesicle)	Thalamencephalon or Diencephalon	Optic thalami	
		Subthalamic tegmental regions	
		Pituitary and pineal bodies	
		Structures in interpeduncular space	
		Optic nerve and retina	
		Hinder part of the third ventricle	
	Telencephalon	Cerebral hemispheres	
		Olfactory lobes	
		Lateral ventricles	
		Foramina of Monro	
		Anterior portion of the third ventricle	

THE PARTS OF THE ENCEPHALON DERIVED FROM THE HIND-BRAIN.

MEDULLA OBLONGATA OR BULB.

he medulla oblongata or **bulb** is the continuation upwards of the spinal cord. not more than one inch in length, and it may be regarded as beginning at the ssation of the midal tracts, h takes place t the level of oramen magnum. a this it proceeds ards in a very ly vertical direc- and ends at the r border of the Varolii. At first irth is similar to of the cord, but pidly expands as pproaches the s, and conse- ntly it presents a e or less conical . Its ventral ace lies behind grooved surface ne basilar portion he occipital bone, lst its dorsal sur-

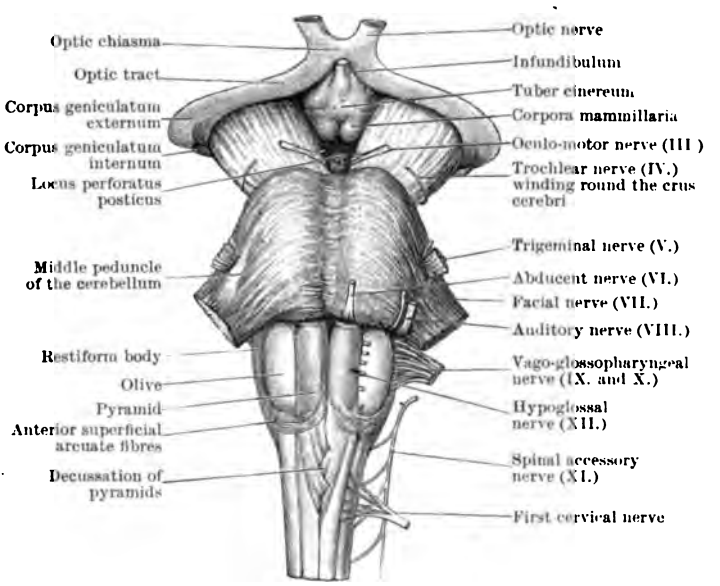

FIG. 387.—FRONT VIEW OF THE MEDULLA, PONS, AND MESENCEPHALON OF A FULL-TIME HUMAN FŒTUS.

is sunk into the vallecula of the cerebellum. The medulla oblongata is a teral structure, and this is indicated on the surface by a continuation upwards he **antero-median** and postero-median fissures of the cord on the ventral and **al aspects** of the medulla.

The **antero-median groove** (fissura mediana anterior), as it passes from the c on to the medulla, is interrupted at the level of the foramen magnum by seve strands of fibres, which cross the mesial plane from one side to the other. T intercrossing is termed the decussation of the pyramids. Above this level t furrow is carried upwards to the lower border of the pons, but is often rende very shallow by numerous superficial arcuate fibres which emerge upon the surf between its lips and then curve outwards to reach the hinder part of the medu At the lower margin of the pons Varolii it expands slightly and ends in a blind which receives the name of the **foramen cæcum** of Vicq d'Azyr. The **postero-me fissure** (fissura mediana posterior) is only carried up on the lower half of medulla. As it ascends it rapidly becomes shallower, and, halfway up, the cent canal of the cord opens on the dorsal surface of the medulla. At this point lips of the postero-median fissure are thrust apart from each other and constit the boundaries of a triangular field, which is thus opened up on the dorsal aspe of the medulla. This triangular field is the lower part of the **fossa rhomboidal** or the floor of the fourth ventricle of the brain. The lower half of the medul containing as it does the continuation of the central canal of the cord, is frequent termed the **closed part of the medulla**; the upper half, above the opening of t canal, which by its dorsal surface forms the lower part of the floor of the fou ventricle, is then called the **open part of the medulla.**

Deferring for the present the examination of the medullary part of the flo of the fourth ventricle, the appearance presented by the surface of each side the medulla, from the antero-median fissure in front to the postero-median fissu and the lateral limit of the floor of the fourth ventricle behind, may now engag our attention. In the spinal cord the corresponding surface area is divided int three districts or columns by the emerging motor roots and the entering sensor roots of the spinal nerves. Of these the latter enter along the bottom of t postero-lateral groove, whilst the motor fascicles are spread over a relatively bro surface area and hav no groove in connexio with their emergen from the cord. In th case of the medul corresponding rows o nerve-fascicles ente and emerge from th surface of each side. The efferent fascicles are the root-bundles of the hypoglossal nerve, and they carry up the line of the anterior nerve-roots of the cord. In one respect, however, they differ: they emerge in linear order and along the bottom of a distinct furrow, termed the **antero-lateral furrow**, which proceeds upwards on the surface of the medulla. The fascicles which carry up the line of the posterior nerve-roots on the surface of the medulla are the root-bundles of the spinal accessory, the vagus, and the glosso-pharyngeal nerves. These are attached along the bottom of a furrow which is the direct continuation upwards of the postero-lateral furrow of the cord, and therefore receives the name of the **postero-lateral furrow** of the medulla. The root-bundles

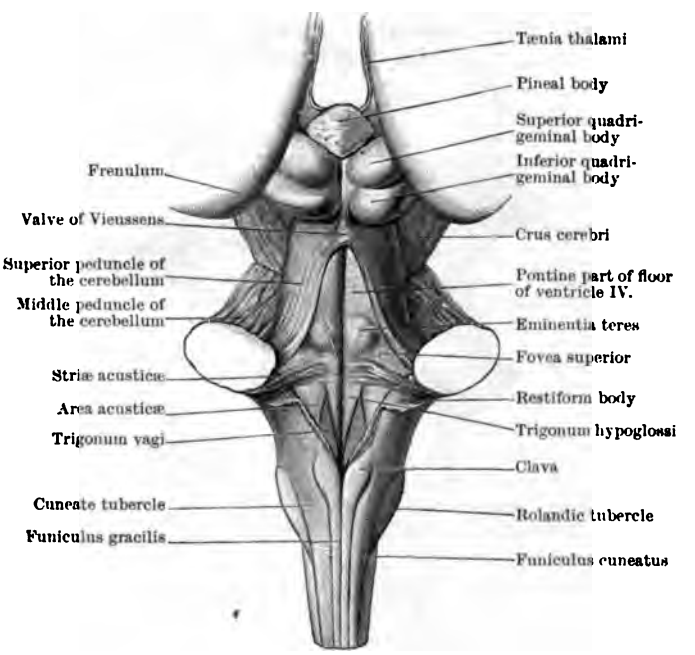

FIG. 388.—BACK VIEW OF THE MEDULLA, PONS, AND MESENCEPHALON OF A FULL-TIME HUMAN FŒTUS.

these nerves differ, however, in so far that they are not all composed of afferent res springing from ganglionic cells placed without and entering the medulla. rtain of them are purely efferent (spinal accessory roots), whilst others likewise ntain a considerable number of efferent fibres, and are therefore to be regarded mixed roots.

By the postero-lateral and the antero-lateral grooves, and also by the two rows nerve fascicles attached along the bottom of these furrows, the surface of the edulla on each side is divided into three districts, viz. an anterior, a lateral, and a sterior, similar to the surface areas of the three columns on the side of the cord. ndeed, at first sight, they appear to be a direct continuation upwards of these three rtions of the cord; this is not the case, however, because the fibres of the three lumns of the cord undergo a rearrangement as they proceed upwards into the edulla.

Anterior Area of the Medulla—Pyramid (pyramis).—The district between e antero-median fissure and the antero-lateral furrow, along the bottom of hich the root-fascicles of the hypoglossal nerve issue from the medulla, receives e name of the pyramid. An inspection of the surface is sufficient to show at the pyramid is composed of a compact strand of longitudinally directed rve-fibres. Tapering below, it expands and assumes a prominent appearance it is traced upwards, and, finally reaching the lower border of the pons Varolii, becomes slightly constricted and disappears from view by plunging into that rtion of the brain. The two pyramids, separated from each other by the antero-edian furrow, are the great motor strands of the medulla.

Although the pyramid at first sight appears to be continuous with the anterior lumn of the cord, only a very small pro-portion of the fibres contained in the latter re derived from the pyramid. This at once ecomes manifest when the lips of the ntero-median fissure are thrust apart at the lace of junction between the cord and the edulla. The pyramid is then seen to divide t this level into two parts, viz. a small ortion composed of a variable number of he outermost fibres of the pyramid, termed he **direct pyramidal tract**, and a much larger portion situated next the antero-median issure, called the **crossed pyramidal tract**. The direct pyramidal tract is continued down into the anterior column of the cord, and in this it takes up a mesial position next the antero-median fissure. The crossed pyramidal tract is broken up into three or more coarse bundles, which sink backwards and at the same time cross the mesial plane, to take up a position in the posterior part of the opposite lateral column of the cord. The term **decussation of the pyramids** (decussatio pyramidum) is applied to the intercrossing of the corresponding bundles of the crossed pyramidal tracts of opposite sides.

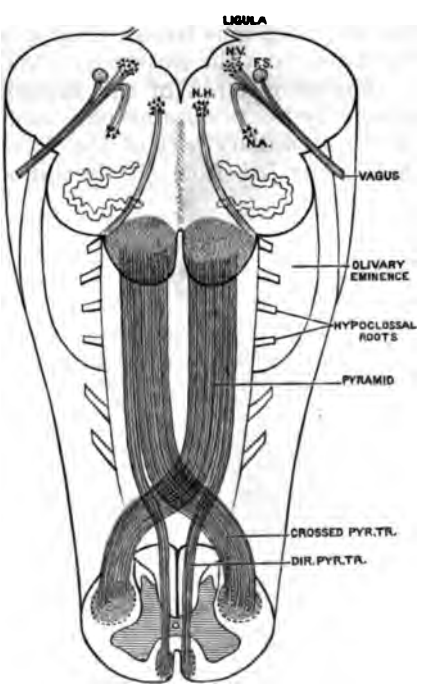

FIG. 389.—DIAGRAM OF THE DECUSSATION OF THE PYRAMIDS (modified from van Gehuchten).

NH, Nucleus hypoglossi; NV, Vago-glosso-pharyngeal nucleus; FS, Fasciculus solitarius; NA, Nucleus ambiguus.

The direct pyramidal tract is, therefore, the only part of the pyramid which has a place in the anterior column of the cord. The much larger part of this column, termed the anterior basis-bundle, as it is traced up into the medulla is seen to be thrust aside by the decussating bundles of the crossed pyramidal tract. It thus comes to occupy a deep position in the substance of the medulla behind and to the outer side of the pyramid.

Lateral Area of the Medulla.—This is the district on the surface of the medulla

which is included between the two rows of nerve-roots, viz. the **hypoglossal roots** front, and the root-bundles of the spinal accessory, the vagus, and the glo pharyngeal nerves behind. It presents a very different appearance in its upper lower parts. In its lower portion it simply appears to be a continuation upw of the lateral area of the cord; in its upper part a striking oval prominence bu out on the surface of the medulla, and receives the name of the **olivary eminence**

The lower part of this district, however, is very far from being an exact coun part of the lateral column of the cord. The large crossed pyramidal tract is longer present, seeing that it forms in the medulla the greater part of the pyr of the opposite side. Another strand of fibres, viz. the direct cerebellar tr prolonged upwards in the lateral column of the cord, gradually leaves t portion of the medulla. This tract lies on the surface, and is frequently visi to the naked eye as a white band, which inclines obliquely backwards in the posterior district of the medulla to join its upper part, or in other words t restiform body. The remainder of the fibres of the lateral column of the co comprising the lateral basis-bundle and the tract of Gowers, are continued upwa in the lateral area of the medulla, and at the lower border of the olive the majori of these fibres disappear from the surface by dipping into the substance of t medulla under cover of that projection. A small proportion of the fibres, ho ever, are retained on the surface and travel upwards towards the pons in the interv which exists between the hinder border of the olive and the roots of the vagus a glosso-pharyngeal nerves.

The **olivary eminence** (oliva) is a smooth oval projection which bulges out fro the upper part of the lateral area of the medulla. Its long axis is vertical and about half an inch long. It marks the position of the subjacent **inferior oliva nucleus**, a flexuous lamina of gray matter (nucleus olivaris inferior), which is co separated from the surface by a very thin layer of superficial white matter.

Posterior Area of the Medulla.—In its lower half, this district is bound behind by the postero-median fissure, and in its upper half by the lateral mar of the medullary part of the floor of the fourth ventricle of the brain. In fr it is separated from the lateral area by the row of root-fascicles belonging the spinal accessory, vagus, and glos pharyngeal nerves. As in the late area, we recognise a lower portion and upper portion, which appear continu but in reality are almost quite disti from each other.

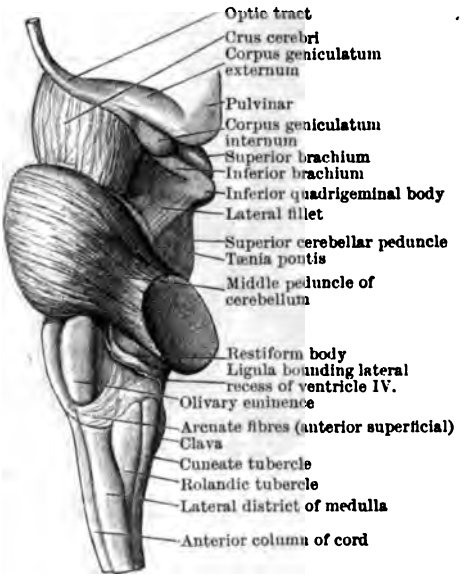

FIG. 390.—LATERAL VIEW OF THE MEDULLA, PONS, AND MESENCEPHALON OF A FULL-TIME HUMAN FŒTUS.

The lower part of the posterior a corresponds more or less closely with t posterior column of the cord. In t cervical part of the cord the poster column is divided by the paramedi septum of pia mater into an inner colu of Goll and an outer column of Burda These are prolonged upwards into t medulla, and in the lower part of t posterior area they stand out distinct and are separated from each other by continuation upwards from the cord of t paramedian groove. In the medulla t inner of these strands is called the **funicu gracilis**, whilst the outer one is designa the **funiculus cuneatus**. Each of th strands, when it reaches the level the lower part of the floor of the fou ventricle, ends in a slightly expan bulbous prominence. The swollen extremity of the funiculus gracilis is called **clava**. This is thrust aside from its neighbour of the opposite side by the open up of the medulla to form the floor of the fourth ventricle, and the central cana

opens on the surface in the angle between the two clavæ. The bulbous he fasciculus cuneatus receives the name of the **cuneate tubercle** (tuberculum m), but it is only in the fœtal or very young brain that it is well marked. e elongated prominences formed on the surface of the medulla by these two s and their enlarged extremities are, in a great measure, due to the presence elongated nuclei or collections of gray matter which make their appearance cent to the strands, and which gradually increase in bulk as they are traced rds. These are termed respectively the **gracile** (nucleus funiculi gracilis) and ate (nucleus funiculi cuneati) **nuclei**, and it can be easily shown that as the matter increases in quantity the fibres of the two corresponding strands inish in number by coming to an end in connexion with the cells of the jacent nuclei. Indeed, it is doubtful if any of the fibres of the gracile and eate strands extend upwards beyond these nuclei.

But a third longitudinal elevation is also apparent on the surface of the lower rt of the posterior area of the medulla. This is placed on the outer side of the niculus cuneatus—between it and the posterior row of nerve-roots—and it has counterpart in the posterior column of the cord. It is called the **funiculus of olando**, because it is produced by the substantia gelatinosa Rolandi, which caps the osterior horn, coming close to the surface and forming a bulging in this situation. he funiculus of Rolando is wedge-shaped in outline. Extremely narrow below, it idens as it is traced upwards, and finally ends in an expanded extremity called he **tubercle of Rolando** (tuberculum Rolandi). A thin layer of white matter, composed of longitudinally arranged fibres, is spread over this district, and separates the substantia Rolandi from the surface. These fibres constitute the spinal root of the fifth or trigeminal nerve, which here assumes a superficial position as it descends in the medulla.

The **restiform body** (corpus restiforme) forms the upper part of the posterior area of the medulla. It lies between the floor of the fourth ventricle and the roots of the vagus and glosso-pharyngeal nerves. It is a large and prominent rope-like strand, which inclines upwards and outwards, and then finally takes a turn backwards and enters the cerebellum. It forms the great link of connexion between the cerebellum on the one hand and the medulla and spinal cord on the other, and consequently it also receives the name of the **inferior cerebellar peduncle**. At the same time it must be understood that it is not formed by fibres which are prolonged into it from the funiculus cuneatus and funiculus gracilis of the medulla. It is true that a surface inspection of the medulla might very naturally lead the observer to this supposition, because there is no sharp line of demarcation marking it off from the tubercles of these strands. Such a conclusion, however, would be altogether erroneous, because it would appear that none of the fibres of the posterior columns of the cord are carried beyond the gracile and cuneate nuclei of the medulla. A study of the surface of the medulla yields some important information regarding the constitution of the restiform body. Thus the direct cerebellar tract from the lateral column of the cord can be traced into it, and large numbers of fibres which take a curved course on the surface of the medulla may likewise be followed into it. These are the superficial arcuate fibres. Numerous other fibres enter the restiform body on its deep aspect, but these will be studied at a later stage.

Superficial Arcuate Fibres (fibræ arcuatæ externæ).—These fibres enter into the constitution of the restiform body, and they may be regarded as consisting of two sets, viz. the anterior superficial arcuate fibres and the posterior superficial arcuate fibres, both of which present this feature in common that they run on the surface of the medulla.

The **anterior superficial arcuate fibres** are more particularly seen in the neighbourhood of the olivary eminence, round the lower border of which, and also over the surface of which, they may be observed coursing in the form of a number of coarse curved bundles. They vary greatly in number and in distinctness, and they are sometimes so numerous as to cover over almost entirely the eminence. An attentive examination will show that they come to the surface in the antero-median fissure between the pyramids, and also not unfrequently in the groove between

pyramid and olive, or through the substance of the pyramid itself. The an median fissure in its upper part is often almost completely blocked up by t emerging fibres. The anterior superficial arcuate fibres reaching the surface of medulla in this manner turn backwards, and the great majority enter the resti body and form a considerable part of its outer portion.

The **posterior superficial arcuate fibres** arise in the cuneate and gracile nuclei, enter the restiform body of the same side.

THE PONS VAROLII.

The **pons Varolii** is a marked white prominence on the basal aspect of the h which is interposed between the medulla and the crura cerebri, and which lie front of the cerebellum. It is convex from side to side, as well as from al downwards, and transverse streaks on its surface show that, superficially at leas is composed of bundles of nerve-fibres which course transversely over it. On ei side these transverse fibres are collected together in the form of a large com strand, which sinks in a backward and outward direction into the white matte the corresponding hemisphere of the cerebellum. This strand is termed the mi **peduncle of the cerebellum**, and the term "pons," applied to the entire struct expresses in an admirable way the arch-like manner in which this portion of brain bridges across between the two cerebellar hemispheres.

The *ventral surface* of the pons is in relation to the basilar process of occipital bone and the dorsum sellæ of the sphenoid bone. It presents a m groove (sulcus basilaris), which gradually widens as it is traced upwards, an which the basilar artery lies. This mesial depression is produced by the promin which is caused on either side by the passage of the pyramidal tract of fi downwards through the pons. The **trigeminal** or fifth cranial nerve, with its l entering sensory root and its small emerging motor root, is attached to the sid the ventral aspect of the pons, nearer its upper than its lower border. It is u to restrict the term "pons" to that portion of the structure which lies between two trigeminal nerves, and to apply the designation of middle cerebellar pedu to the part which extends beyond the nerve into the hemisphere of the cerebel The sixth or **abducent nerve**, the seventh or **facial nerve**, and the eighth or **audi nerve** are attached to the brain at the lower border of the pons. The sixth eme at the outer border of the pyramid, the seventh immediately in front of the r form body, whilst the auditory nerve reaches the brain close to the facial nerve the ventral aspect of the restiform body.

The whole of the medulla enters the *lower aspect* of the pons, and, with exception of the restiform bodies, its constituent parts are, to a large extent, car up within it. The crura cerebri emerge from its *upper aspect.*

The *dorsal surface* of the pons looks backwards towards the cerebellum, presents a triangular area covered with gray matter, which forms the upper pa the anterior wall or floor of the fourth ventricle. This area is directly contin below with the medullary part of the floor of the fourth ventricle, and is bou on either side by a band of white matter termed the **superior peduncle of cerebellum.**

Superior Cerebellar Peduncles (brachia conjunctiva).—These are hidden f view by the upper part of the cerebellum, under cover of which they lie. T emerge from the lateral hemispheres of the cerebellum, and, as they pro upwards on the dorsal aspect of the pons, they converge towards each other u at the level of the inferior corpora quadrigemina, the inner margins of the peduncles almost become contiguous (Fig. 388, p. 482). At first they form lateral boundaries of the upper part of the fourth ventricle; but, as they as and approach closer to each other, they gradually come to overhang that ca and thus enter into the formation of its roof. They disappear from the sur by dipping under cover of the quadrigeminal bodies and entering the substanc the mesencephalon.

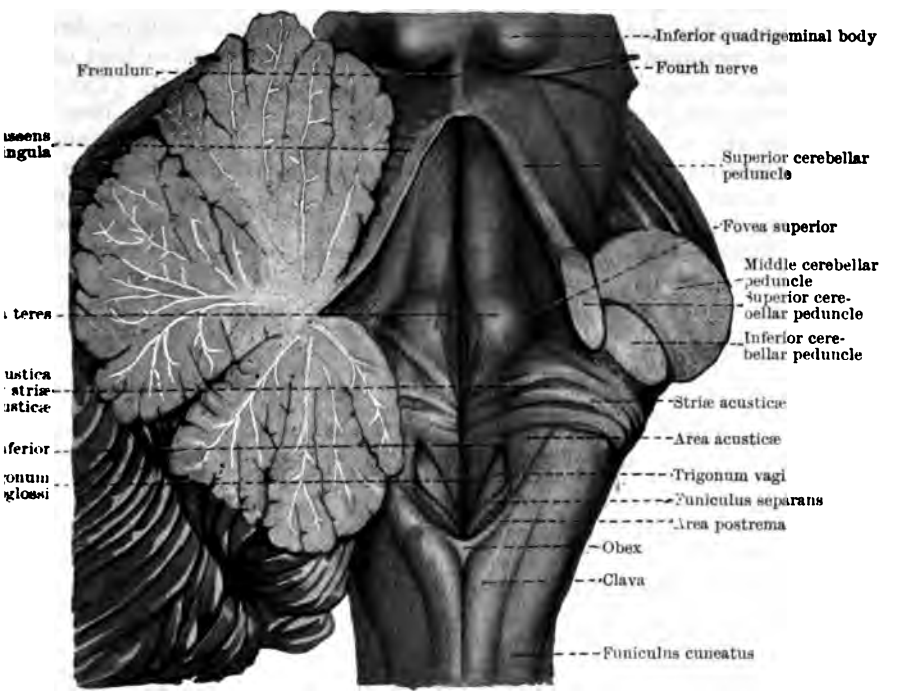
Valve of Vieussens or the Superior Medullary Velum (velum medu anterius).—Filling up the triangular interval between the two superior c

duncles, and stretching across from the inner and free margin of the one ›rresponding margin of the other, is a thin layer of white matter which **s the roof** or dorsal wall of the upper part of the fourth ventricle, and **the name** of the superior medullary velum. When traced downwards, it › **be carried** with the superior peduncles into the white matter of the cere-

Spread out on its dorsal surface is a small, thin, tongue-shaped prolongation **matter** from the cortex of the cerebellum, which is termed the **lingula**, **suing** from its substance close to the inferior quadrigeminal bodies are the **th or trochlear cranial nerves.**

·th Ventricle of the Brain (ventriculus quartus).—The fourth ventricle is **ıt** rhomboidal in form. Below, it tapers to a point and becomes continuous **ə central canal** of the cord; above, it narrows in a similar manner and is **›d into the aqueduct** of Sylvius, which tunnels the mesencephalon. The **· wall is termed the roof** and is concealed by the cerebellum. The anterior **called the floor** and is formed by the dorsal surfaces of the medulla and **)n** either side a long, curved and narrow prolongation of the ventricular **ı carried** outwards from its widest part and curves round the upper part **orresponding** restiform body. This is termed the **lateral recess.** The roof **:avity** is very thin and intimately connected with the cerebellum. It **·**, therefore, to defer its description until that part of the brain has been

r of the Fourth Ventricle (fossa rhomboidea).—In its lower part the **he** fourth ventricle is formed by the dorsal surface of the open part of the



-FLOOR OF THE FOURTH VENTRICLE. On the right side the right half of the cerebellum has been oved by cutting through its three peduncles and dividing it in the mesial plane. On the left side left half of the cerebellum is drawn over to the left so as to expose fully the floor of the ventricle.

, whilst in its upper part it is formed by the dorsal surface of the pons (Fig. 388, p. 482). The area thus constituted is lozenge-shaped, its widest ng opposite the upper ends of the restiform bodies or inferior peduncles :erebellum. A thick layer of gray matter, continuous with that which ls the central canal of the cord, is spread out like a carpet over the lar floor, and covering this is the usual ependymal layer, which lines all ricles of the brain. The area is circumscribed by definite lateral boundaries.

Thus, *below* it is bounded on either side by the clava, the **cuneate tubercle**, the restiform body; whilst *above* the lateral limits are formed by the superior cerebellar peduncles.

The floor of the fourth ventricle is divided into two lateral and symmetrical portions by a median groove. Its lower narrow pointed portion between the two clavæ receives the name of the **calamus scriptorius**, from its fancied resemblance to the point of a pen. Crossing each half of the floor, at its widest part, are seven or more or less conspicuous bundles of fibres termed the **striæ acusticæ**. They appear to emerge from the mesial groove and they are carried outwards over the floor of the ventricle in the region between its upper pontine and lower medullary portions. The striæ acusticæ exhibit a large amount of variation in different individuals both in their degree of prominence and also in the direction which they pursue. As a general rule they proceed towards the upper part of the restiform body, where they are connected with the cochlear nuclei. Except for this break on the surface, the medullary and pontine portions of the floor of the fourth ventricle are quite continuous with each other.

On the lower medullary district of the ventricular floor a small triangular depression, placed immediately below the striæ acusticæ, catches the eye. This is termed the **fovea inferior**. It is shaped somewhat like an arrow-head. The apex or point looks towards the striæ, whilst the lateral angles of the base are prolonged downwards in the form of diverging grooves (Fig. 391, p. 487). Of these, the inner groove runs towards the opening of the central canal at the calamus scriptorius, whilst the outer groove runs towards the lateral boundary of the floor. In this manner the portion of the floor which lies below the striæ acusticæ is mapped out into three triangular areas. The mesial subdivision is slightly elevated and is termed the **trigonum hypoglossi**, because subjacent to the inner part of this area is the nucleus of origin of the hypoglossal or twelfth cranial nerve. The intermediate area between the two diverging grooves which proceed from the base of the fovea inferior is the **trigonum vagi** (ala cinerea), so called because the nucleus of the vagus or tenth and the glosso-pharyngeal or ninth cranial nerves lies subjacent to it. The external area is the **trigonum acustici**. The base of this area is directed upwards and runs continuously into an eminence—the **acustic area** (area acustica)—over which the striæ acusticæ pass. Subjacent to this district of the floor of the ventricle lies the large terminal chief nucleus of the vestibular division of the auditory or eighth cranial nerve.

A close inspection of the medullary part of the floor of the fourth ventricle in the region of the calamus scriptorius will show that the base of the trigonum vagi is separated from the inner margin of the clava by a narrow lanceolate strip of the ventricular floor, to which Retzius has given the name of **area postrema**. Beneath this area is some vascular tissue (Streeter), and marking it off on its upper and inner aspect from the base of the trigonum vagi there is a translucent cord-like ridge called the **funiculus separans**.

When the floor of the ventricle is examined under water with a magnifying glass, the trigonum hypoglossi is seen to consist of a narrow inner strip which corresponds to the hypoglossal nucleus, and a wider lateral part which has been shown to be the surface representation of another nucleus termed the nucleus intercalatus (Streeter).

On the part of the floor of the ventricle which lies above the striæ acusticæ, and which corresponds to the dorsal surface of the pons, there is also a slight depression termed the **fovea superior**. Between it and the median groove is a marked prominence called the **eminentia teres**. Inferiorly this elevation passes downwards and becomes continuous with the trigonum hypoglossi, whilst above it is carried upwards towards the opening of the aqueduct of Sylvius. In both directions it becomes gradually less prominent, but still it forms a distinct elongated elevation, which stretches along the whole length of the median groove. As already stated, the **area acustica** extends upwards into the pontine part of the ventricular floor and forms an elevated region in the outermost part of its widest portion, below and to the outer side of the fovea superior. Proceeding upwards from the fovea superior to the opening of the Sylvian aqueduct there is a shallow depression termed the **locus cæruleus**, seeing that it usually presents a faint slate-gray colour. When the ependyma is scraped away from the surface of this part of the floor, the colour is seen to be due to the **substantia ferruginea**,—a name applied to a linear group of

ongly pigmented cells, which lies in the lateral part of the gray matter covering is portion of the ventricular floor. When transverse sections are made through e upper part of the pons, the substantia ferruginea appears on the cut surface a small black spot or dot.

INTERNAL STRUCTURE OF THE MEDULLA.

The internal structure of the medulla differs in a marked degree from that of e spinal cord; indeed, in its upper part it presents very little in common with the tter. The various strands of the cord either come to an end within the medulla undergo changes in their relative position, whilst the gray matter is much modi- d and new masses are added. Like the cord, however, the medulla consists of ro nearly symmetrical right and left halves. When transverse sections are made rough it at different levels each lateral half is seen to be partly marked off from e other in the lower closed part of the medulla by the anterior and posterior edian fissures, whilst in the upper open part of the medulla the subdivision is ndered evident in transverse sections by the presence of a distinct median

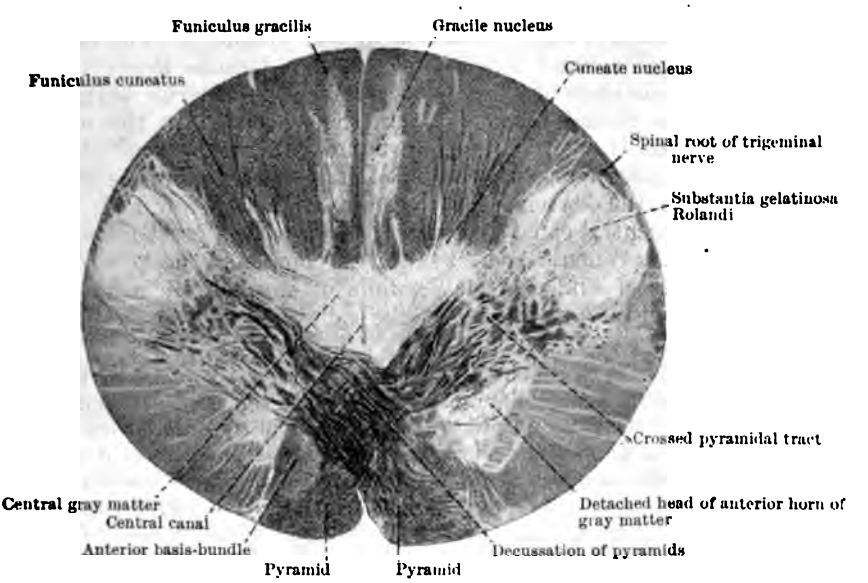


FIG. 392.—SECTION THROUGH THE LOWER END OF THE MEDULLA OBLONGATA OF A CHIMPANZEE TO SHOW THE DECUSSATION OF THE PYRAMIDS.

line, called the **raphe**, which occupies the mesial plane. The raphe is formed by the close intersection of fibres running in different directions and crossing from one side to the other.

Each half of the medulla is composed of: (*a*) strands of white matter; (*b*) gray matter; and (*c*) the formatio reticularis.

The **white matter**, as in the cord, is to a large extent disposed on the surface, and the gray matter in the interior; but in the upper open part of the medulla the gray matter comes to the surface on the dorsal aspect, and is spread out over that area which forms the medullary part of the floor of the fourth ventricle. In the cord the white matter, in the shape of massive longitudinal strands of fibres, forms a thick coating round the central gray matter. In the medulla the only massive longitudinal strands which are seen on the surface are the gracile and cuneate strands (until they become absorbed by the subjacent nuclei), the inferior cerebellar peduncles or restiform bodies and the pyramidal tracts. Elsewhere the coating of white matter is thin, and in certain places is composed chiefly of the superficial arcuate fibres. New longitudinal strands, however, take shape within the medulla, and two of the most important are placed on either side of the median raphe.

The **gray matter** of the cord, as it is continued upwards into the medulla,

becomes greatly modified. A considerable part of it is broken up in the form reticularis, whilst the only portions which remain as compact masses in di continuity with the gray matter of the cord are: (1) the thick layer wh surrounds the central canal, and which, in the open part of the medulla, becc spread out on the floor of the fourth ventricle; and (2) the substantia gelatin Rolandi. New masses of gray matter, which are not represented in the cord, a which in some cases appear in isolated clumps, are also added. The chief of th are the gracile and cuneate nuclei, the inferior olivary nuclei, and the arcuate pyramidal nuclei.

The **formatio reticularis** is only feebly represented in the cord, but in t medulla it forms a very considerable part of its bulk. It is composed of gr matter coarsely broken up by fibres, which traverse it in different directions.

In the following detailed account of the internal structure of the medulla must be understood that the appearances described are such as are seen wh successive transverse sections through the bulb are examined.

Decussation of the Pyramids and the Changes produced thereby.—As pass under the microscope a series of successive transverse sections through t upper end of the cord and the lower end of the medulla, the most striking cha which meets the eye is the decussation of the pyramids. The crossed pyrami tract in the lateral column of the cord is seen to become looser in its formati then coarse strands leave it, pass right through the anterior horn of gray mat and, crossing the mesial plane, take up their position in the other side of medulla, close to the antero-median fissure. Strands from the right cro pyramidal tract alternate with corresponding strands from the left side, and interval between the bottom of the antero-median furrow and the gray ma surrounding the central canal becomes filled up with a great mass of intercros bundles of fibres. When the decussation is completed the pyramid is seen t composed of a solid and compact bundle of fibres, well marked off from surrounding structures, which lies at the side of the antero-median fissure of medulla.

As a rule the inner three-fourths of the pyramid is composed of fibres which, l down in the opposite lateral column of the cord, form the crossed pyramidal tract, w the outer fourth of the pyramid proceeds downwards in the anterior column of the co the same side as the direct pyramidal tract. A considerable amount of variation, how occurs in the proportion of fibres which is allotted to the formation of these two trac the cord. Sometimes the crossed pyramidal tract is much larger than usual, and the direct pyramidal tract suffers a corresponding diminution in size. Cases indeed c in which the entire pyramid enters into the decussation, and in these there is no d pyramidal tract in the cord. Further, it is not uncommon to meet with variations c opposite kind which lead to an increase of the direct pyramidal tract at the expense o crossed tract. In the majority of cases the decussation appears to be symmetrical- division of the pyramid at the lower end of the medulla being into parts of correspor size on the two sides; in certain instances, however, the decussation is asymmetrical the corresponding pyramidal tracts on opposite sides of the cord are then unequal in Seeing that the direct pyramidal tracts undergo a gradual decussation in the ant commissure, as they descend in the cord, the final result is the same, no matter variations occur in the decussation at the lower part of the medulla.

The variations indicated above receive an additional interest when viewed in the of comparative anatomy. It would appear that only in man and the anthropoid ap the decussation of the pyramids in the lower part of the medulla incomplete. Acco to Sherrington, a direct pyramidal tract in the cord of the anthropoid apes stands in nexion with the arm-centre in the cerebral cortex. If this be the case in man it must wise have other connexions as well, seeing that it is carried down the cord for a conside distance beyond the level of the cord-segments which give motor fibres to the arm the lower apes a direct pyramidal tract does not seem to exist: the whole pyramid cr over to the opposite side of the cord in the shape of the crossed pyramidal tract.

As we have noted, the decussating pyramidal bundles pass through the ant horn of gray matter of the cord, and cut it into two portions (Figs. 392 and The basal part remains in position on the anterior and lateral aspect of the ce canal, and forms part of the thick layer of gray matter which surrounds it.

ched head of the anterior horn is set free; and from the large multipolar cells h lie in its midst some of the fibres of the anterior root of the first cervical e, and also some of the root fibres of the spinal accessory nerve, take origin.

On proceeding up into the medulla another effect of the decussation of the mids is seen in the submergence from the surface of the strand of fibres which, e anterior column of the cord, lies to the outer side of the direct pyramidal , and which receives the name of the anterior basis-bundle. While the decus- n is going on the anterior basis-bundle is thrust aside, and, sinking from the ce, it takes up its ion as a flattened -like strand on uter side of the ually increasing mid (Fig. 393). n the decussation ompleted, this d is seen to lie to the median e on the dorsal et of the pyramid, e it is separated its fellow of the site side by the an raphe alone 394). In the r part of the lla it approaches nearer to the

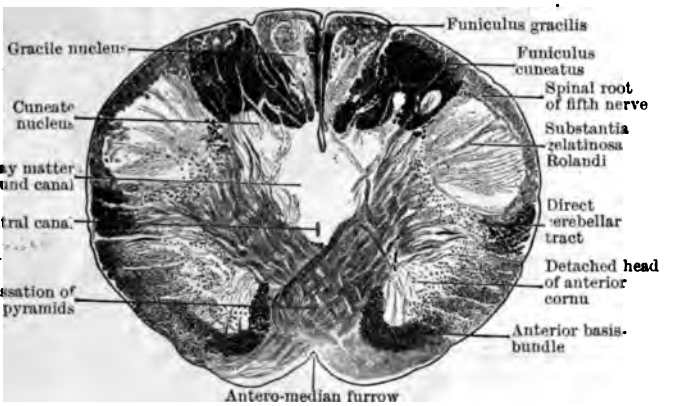

FIG. 393.—TRANSVERSE SECTION THROUGH LOWER END OF THE MEDULLA OF A FULL-TIME FŒTUS,

Treated by the Weigert-Pal method. The gray matter is bleached white, and the medullated tracts of fibres are black.

l surface and appears to form the greater part of a strand, which is ed the **posterior longitudinal bundle** (Figs. 397 and 398). The detached head e anterior horn of gray matter of the cord, as it is traced upwards, is observed ing closely to its original relationship with the anterior basis-bundle. It is ied to the outer side of this strand, and, gradually becoming smaller, finally ppears at the level of the lower part of the inferior olivary nucleus.

Cuneate and Gracile Strands, with their Nuclei.—As the funiculus gracilis the funiculus cuneatus of the posterior column of the cord are traced up the medulla they seem to increase in bulk, and in transverse sections they me the form of massive wedge-shaped strands, quite distinct from each other. n the decussation of the pyramids is fully established they change their shape. y increase in width and lose considerably in depth, and consequently the sverse diameter of the area which they occupy becomes greater. As a result his, and also owing to the removal of the crossed pyramidal tract from the al region of the cord immediately in front, the posterior horn of gray matter adually rotated forwards and comes to lie transversely and in the same straight with its fellow of the opposite side (Figs. 393 and 395). The substantia tinosa Rolandi, at the same time, becomes increased in quantity and presents rseshoe-shaped outline in transverse section. It clasps within its concavity the ewhat reduced head of the posterior horn, and forms with it a conspicuous ular mass of gray matter which lies close to the surface, and produces upon it bulging termed the funiculus and tubercle of Rolando. The basal portion of posterior horn of gray matter remains upon the dorsal and lateral aspect of the ral canal, and forms a portion of the central gray mass of the closed part of medulla; but very soon the neck of the horn, which at this level is greatly ced owing to the absence of entering posterior nerve-roots, is invaded by dles of fibres which traverse it in different directions and convert it into a natio reticularis. By this means the rounded head of the posterior horn becomes off from the central gray matter, and from this point upwards it remains as solated gray column intimately associated with the spinal root of the trigeminal re.

The **gracile** and **cuneate nuclei** take shape before the decussation of the pyram is fully completed (Fig. 395). The **gracile nucleus** appears in the form of a irregular mass of gray matter in the interior of the funiculus gracilis, wh

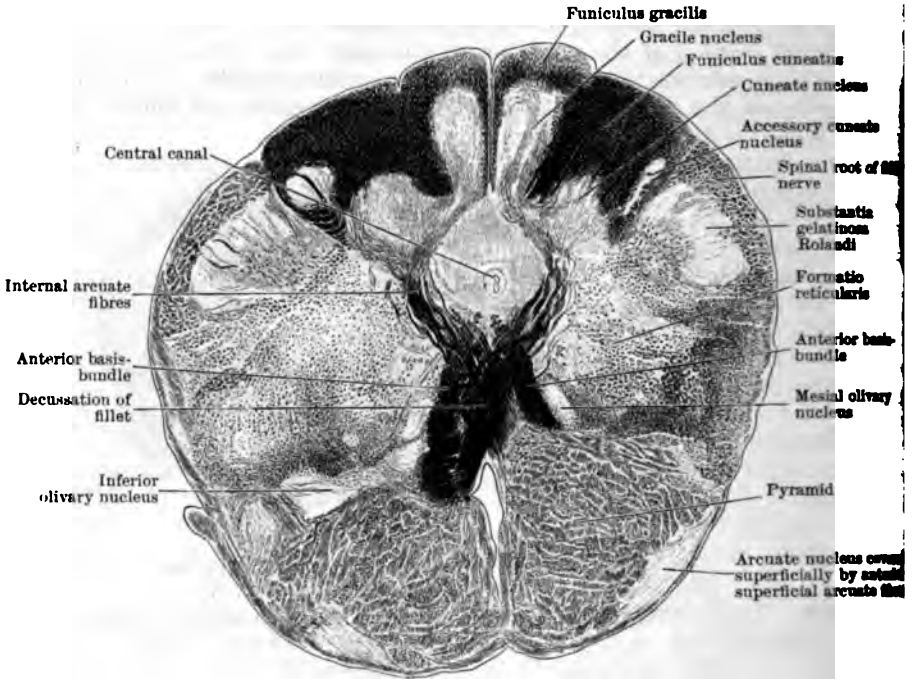

FIG. 394.—SECTION THROUGH THE CLOSED PART OF HUMAN MEDULLA IMMEDIATELY ABOVE THE DECUSSATION OF THE PYRAMIDS (Weigert-Pal Specimen).

gradually infiltrates the entire strand. At first it is not directly connected wi the gray matter which surrounds the central canal; but as it is traced upwar it increases in bulk, absorbs more of the strand in which it lies, and such a co nexion becomes established (Figs. 393 and 394).

The **cuneate nucleus**, from the first, is a direct offshoot from that part of the b of the posterior horn of gr matter which is preserved as portion of the central gray ma In transverse section it is seen invade the funiculus cuneat upon its deep aspect, and gradually grows backwards i its substance. It presents a v different appearance from t gracile nucleus, because throu out its whole length the gr nucleus and the fibres of t strand are separated from e other by a sharp line of demar tion. A second and much smal mass of gray matter appears the funiculus cuneatus, sup ficial to the main nucleus, soon after the region of the decussation of the pyram is left. This is termed the **accessory** or the **external cuneate nucleus** (Fig. 394).

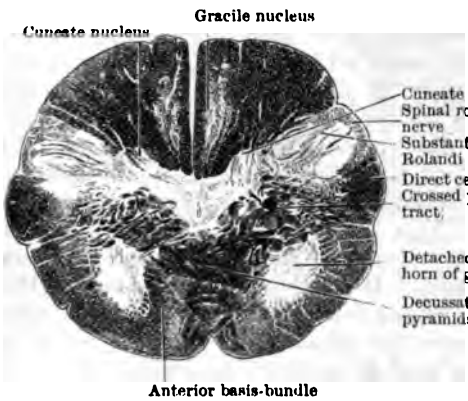

FIG. 395.—SECTION THROUGH THE LOWER PART OF THE MEDULLA OF THE ORANG.

Gradually the fibres of the gracile and cuneate strands become absorbed in th nuclei. As the gray masses gain in size a corresponding diminution in the num of fibres composing the corresponding tracts is observed, until, at the level of clava and cuneate tubercles, it is seen that these eminences are composed alm

of the gray nuclei, covered by a thin skin of the few remaining fibres of strands involved. It would appear that no fibres belonging to the funiculus and funiculus cuneatus get beyond these nuclei. They all end in fine l ramifications around the cells of the nuclei. In the case of the funiculus s the bundles es, as they om the sur- to the sub- gray nucleus, y distinctly transverse through the en the med- ongata opens the fourth e the gracile neate nuclei ied outwards expanding ular floor, and cile nucleus omes to an t the cuneate

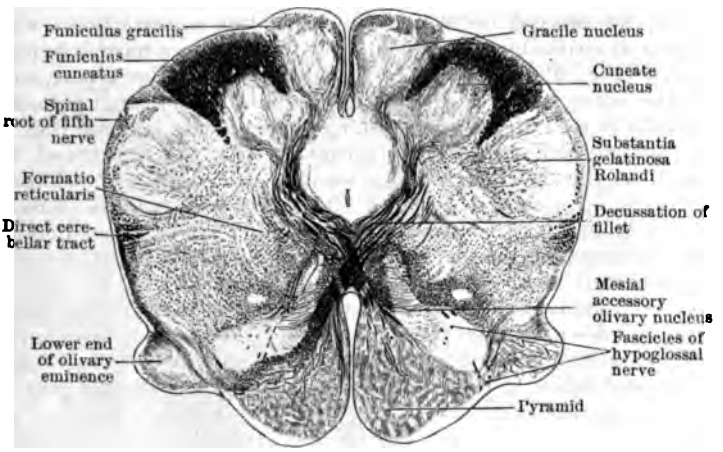

FIG. 396.—TRANSVERSE SECTION THROUGH THE CLOSED PART OF A FŒTAL MEDULLA, IMMEDIATELY ABOVE THE DECUSSATION OF THE PYRAMIDS.

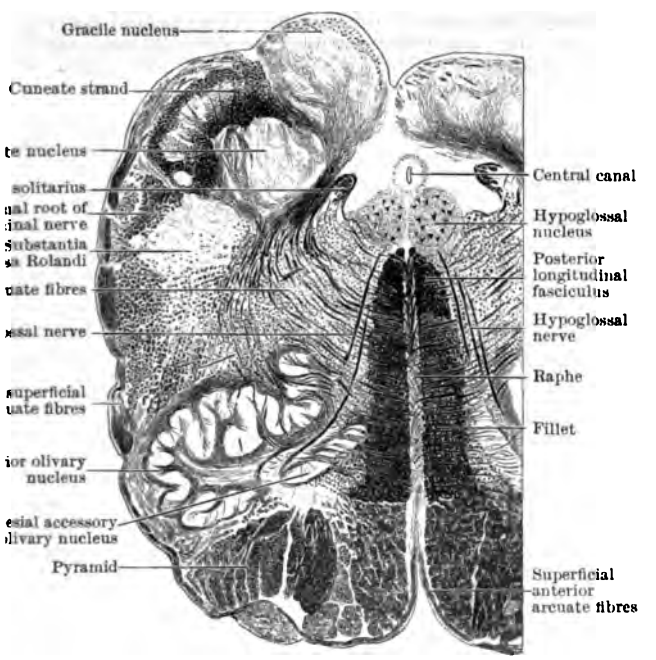
extends upwards for a short distance farther, and only terminates when iform body begins to take definite shape on its outer aspect.

ussation of the Fillet (decussatio lemniscorum).—Immediately above the the decussation of the pyramids another decussation of fibres in the median nd upon the dorsal aspect of the pyramids, takes place in the substance of the medulla. This is termed the **decussation of the fillet**, or the **sensory decussation**, in contradistinction to the term "motor decussation," which is sometimes applied to the decussation of the pyramids. The fibres which take part in this decussation are called **deep arcuate fibres** (fibræ arcuatæ internæ), and they are derived from the cells of the gracile and cuneate nuclei. From the deep aspects of these nuclei these fibres stream forwards and inwards towards the median raphe, forming a series of con-



97.—TRANSVERSE SECTION THROUGH THE HUMAN MEDULLA IN THE LOWER OLIVARY REGION.

curves in the substance of the medulla. They cross the mesial plane cussate with the corresponding fibres of the opposite side, upon the dorsal of the pyramids. Having thus gained the opposite side of the medulla they

immediately turn upwards and form a conspicuous strand of longitudina which ascends close to the mesial plane and is separated from its fellow opposite side by the median raphe alone. This strand is termed the **lemniscus.**

As we proceed up the medulla the deep arcuate fibres which first come in appear as coarse bundles which curve forwards in a narrow group around the cent matter (Figs. 394 and 396). Soon other finer bundles appear, which describe wide on the outer side of the coarser group until a very large part of each lateral hal medulla is seen to be traversed by these arcuate fasciculi (Fig. 397). As they a the mesial plane they come in contact with the remains of the anterior basis which at this level, as already mentioned, lies upon the dorsal aspect of the p flattened up against the raphe. The deep arcuate fibres pierce the anterior basis obliquely, and in the interval between it and the corresponding strand of the oppo they decussate in the middle line with the deep arcuate fibres of the opposite side. then change their direction and turn upwards, and the fillet, as already state form and gradually increases in volume as it ascends. This great and important thus laid down between the pyramid and the anterior basis-bundle; and the cons of this is that the latter tract is pushed still farther backwards, and, when the fully established, it comes to lie immediately beneath the gray matter of the floo fourth ventricle (Fig. 398).

It is important that we should realise at this stage the full significance of the de of the fillet and have a clear conception of the connexions of the fibres which take pa The columns of Burdach and Goll, which end in the cuneate and gracile nuclei, are deri the posterior roots of the spinal nerves. The fillet fibres therefore carry on the continui posterior columns of the cord, the gracile and cuneate nuclei, which are thrown across th in the lower part of the medulla, merely constituting an internodal interruption. At tl the fillet strand is transferred to the opposite side of the medulla. But it will be rem that a large proportion of the fibres of the entering posterior nerve-roots of the spinal ne in connexion with the cells of the posterior horn of gray matter of the cord. It mu supposed that the path represented by these latter fibres comes to a termination theret these posterior horn cells other fibres arise which cross to the opposite side of the cor anterior white commissure and proceed up the cord to the lateral part of the medulla fibres constitute the **spino-thalamic tract** already referred to. The practical bearing c that owing to the crossing of the fillet and lower down of the spino-thalamic tract u lesions of the medulla are apt to produce complete hemi-anæsthesia; whilst unilateral l the cord produce only partial hemi-anæsthesia.

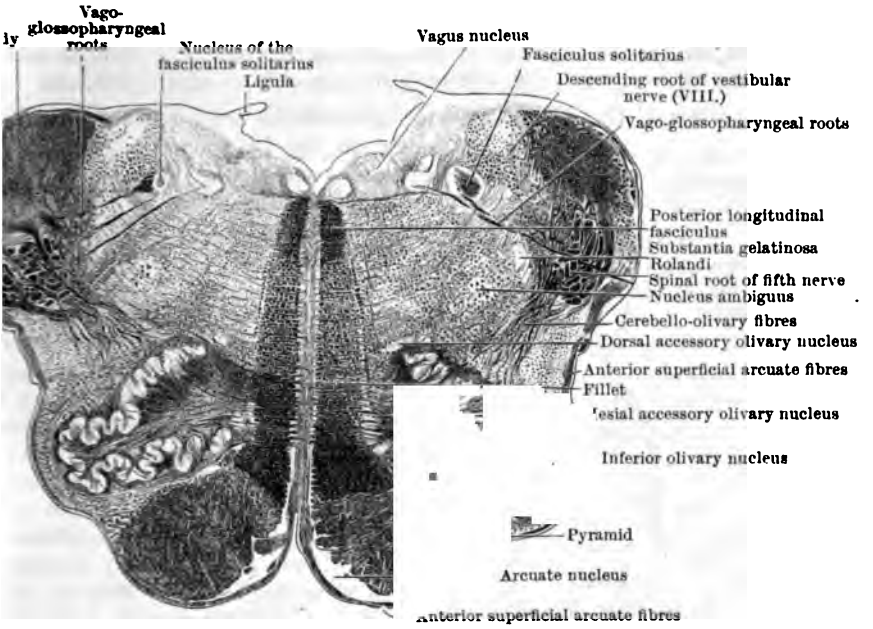
When the fillet is fully formed three longitudinal strands are observed ing the medulla, close to the mesial plane. From before backwards these a the pyramid, (2) the fillet, and (3) the posterior longitudinal bundle.

The pyramid forms a massive tract in front of and quite distinct fr fillet. The fillet and the posterior longitudinal bundle are, in the first in not marked off from each other. They appear as a broad flattened band to the raphe. One edge of this band is directed backwards and reaches tl matter on the floor of the fourth ventricle, while the other edge looks fc and is in contact with the pyramid. In the upper part of the medulla tl and the posterior longitudinal fasciculus begin to draw asunder from eacl The intermediate longitudinal fibres become reduced in number and t strands grow denser—the one on the dorsal aspect of pyramid, and th immediately beneath the gray matter of the floor of the fourth ventricle (Fi

The **posterior longitudinal bundle** (fasciculus longitudinalis medialis) largely formed out of fibres, which in the cord constitute the anterior basis- These fibres are thrust back by the two decussations: the first decussation them behind the pyramids, and the second decussation displacing them still backwards to a position behind the fillet.

Olivary Nuclei.—The most conspicuous of the isolated clumps of gray in the medulla are the inferior olivary nucleus and the two accessory nuclei. The **inferior olivary nucleus** (nucleus olivaris inferior) lies subjacent olivary eminence, and constitutes a very striking object in transverse s through this region. It presents the appearance of a thick wavy or undulati of gray matter, folded on itself, so as to enclose a space filled with white It is in reality a crumpled lamina arranged in a purse-like manner, with a

slit, which is called the **hilum** (hilum nuclei olivaris), directed towards the ane. The hilum does not reach either extremity, so that in transverse



TRANSVERSE SECTION THROUGH THE MIDDLE OF THE OLIVARY REGION OF THE HUMAN MEDULLA OR BULB.

r of the fourth ventricle is seen, and it will be noticed that the restiform body on each side has now taken definite shape.

through each end of the nucleus the gray lamina is seen in the form of a ly closed capsule. Into and out of the open mouth of the olivary capsule a dense crowd of fibres. These constitute what is called the **olivary peduncle.**

-THE INFERIOR OLIVARY NUCLEUS, as reconstructed and figured by Miss Florence R. Sabin.

View of the dorso-lateral and lateral surfaces.

The **accessory olivary nuclei** are two band-like laminæ of gray matter, which are respectively placed on the dorsal and mesial aspects of the main nucleus. In transverse section each of these nuclei presents a rod-like appearance (Fig. 398).

The **mesial accessory olivary nucleus** (nucleus olivaris accessorius mesialis) extends lower down in the medulla than the main nucleus, and it is much larger in its lower than its upper part. It begins immediately above the decussation of the pyramids, where it is seen lying ıter side of the pyramidal tract and the anterior basis-bundle (Figs. 394 and 396). ıp it lies across the mouth of the main nucleus and on the outer side of the fillet **ıal accessory olivary nucleus** (nucleus olivaris accessorius dorsalis) is placed the dorsal aspect of the main nucleus. The two accessory nuclei fuse together ıey finally disappear.

gray matter forming the three inferior olivary nuclei consists of a close feltwork ıglia in which are interspersed numerous small round cells, each of which is with one axon and numerous dendrites. It is traversed by fibres, some of which

pass straight through the gray lamina, whilst others end in connexion with the c
is only in man and the higher apes that the inferior olivary nuclei are found
developed. In other mammals they are much smaller. The size of the olive ap
be correlated with that of the lateral hemisphere of the cerebellum and not in an
be dependent on the development of the cerebral hemisphere. Thus in cetace
very extensive cerebral cortex the inferior olivary nuclei are small (Edinger).

As the fibres of the fillet decussate and assume a longitudinal directi
come to lie between the olivary nu
opposite sides, and hence the tern
olivary stratum (stratum interolivar
nisci) is frequently applied to them.

THE CORD AND MEDULLA OF THE ORANG.
The direct cerebellar tract is well seen, especially on the

Bruce has shown that the fibres of the direct cerebellar tract ultimately lie in the cent
restiform body, forming as it were its central core, and that in the cerebellum they can
to the superior vermis.

The **posterior superficial arcuate fibres** take origin from the gracile and
nuclei, and enter the superficial part of the restiform body of the same side.

The **anterior superficial arcuate fibres** proceed from the lower portions
gracile and cuneate nuclei of the opposite side. After decussating in the
line, it can easily be determined that all the deep arcuate fibres which ari
these nuclei do not enter the fillet. A large proportion of them gain the sur
sweeping round the inner aspect of the pyramid in the antero-mesial fissure.

ı likewise gain the surface by piercing the pyramid or by passing out ı it and the olive. These fibres constitute the anterior superficial arcuate and on the surface of the medulla they sweep backwards around it, forming layer over the olivary eminence and ultimately reaching the restiform body. terior superficial arcuate fibres, as well as the direct cerebellar tract-fibres, ver the trigeminal spinal root, which thus comes to take up a deeper posi- the substance of the medulla (Figs. 397 and 398).

ngst the fibres which reach the surface of the medulla in this way Kölliker includes om the striæ acusticæ. If this be the case, these fibres connect the cochlear nucleus e cerebellum, the path being striæ acusticæ, superficial arcuate fibres, and restiform *de* p. 522).

fibres of the direct cerebellar tract, which come from the cells of the posterior vesicular of the cord, and the superficial posterior arcuate fibres, which are derived from the cells gracile and cuneate nuclei, do not cross the mesial plane, but enter the restiform body of e side. The anterior superficial arcuate fibres arise from the cells of the cuneate and nuclei, and cross the mesial plane so as to gain the restiform body of the opposite side.

e cerebello-olivary fibres are only seen in the upper part of the medulla. They he deep part of the restiform body and constitute its chief bulk. Streaming

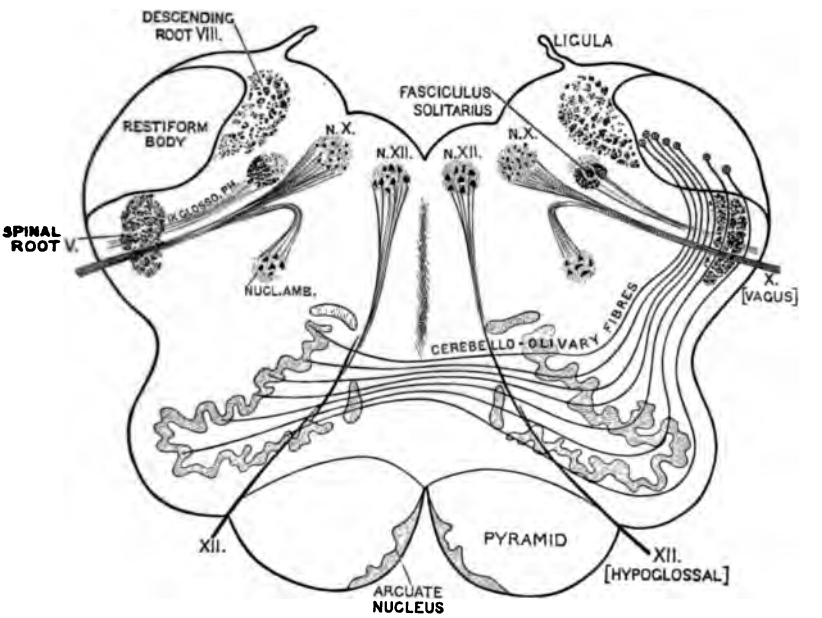

FIG. 402.—DIAGRAM OF THE CEREBELLO-OLIVARY FIBRES.

(This diagram has been constructed from the specimen figured on p. 495.)

N.X., Vago-glossopharyngeal nucleus. N.XII., Hypoglossal nucleus.

ɔm the hilum of the inferior olivary nucleus, they cross the mesial plane, and ; opposite side of the medulla they either pass through the inferior olivary ıs of that side or sweep around it. Ultimately, on the dorsal aspect of the y nucleus, they are gathered together in the form of a conspicuous group of ;e fibres, which curve backwards to take up a position in the deep part of the ɔrm body. In passing back, they traverse the spinal root of the trigeminal and break it up into several separate bundles. The cerebello-olivary fibres ;onnect the inferior olivary nucleus of one side with the opposite side of the ıllum.

hough we have traced the cerebello-olivary tract in an upward direction from the olive to ebellum, and have thus inferred that it is composed of fibres which proceed from the cells inferior olivary nucleus of the opposite side, it is right to state that this view is not uni- y accepted. There are some who regard these fibres as constituting an efferent tract from ebellum, or, in other words, as arising in the cerebellar cortex (probably as the axons of ls of Purkinje), and descending in the inferior cerebellar peduncle to establish connexions he cells of the inferior olivary nucleus of the opposite side. If this view be correct, the

destination of the axons of the cells of the inferior olivary nucleus becomes a difficu Kölliker considers that they enter the lateral column of the cord.

Arcuate Nucleus (nucleus arcuatus).—Immediately above the decussa the pyramids, a small flattened mass of gray matter, covered by superficial fibres, makes its appearance on the ventral or superficial aspect of the p (Fig. 393). At a higher level, when the open part of the medulla is reach gray mass shifts its position and comes to lie upon the mesial aspect pyramid, and thus constitutes the immediate boundary of the antero-fissure (Fig. 398). From its intimate connexion with the anterior sup arcuate fibres, as they sweep out from the antero-median fissure, it recei name of the **arcuate nucleus.**

The nerve-cells which lie in its midst are smaller than those of the inferior olivary and are fusiform in shape. It would appear that large numbers of the anterior superficial fibres end in this nucleus, whilst others take origin within it. Many of the anterior fibres, however, sweep continuously over its surface and bind it down to the pyramid. upper end of the medulla the arcuate nucleus increases in size, and ultimately it becon tinuous with the gray matter of the ventral part of the pons.

Formatio Reticularis.—Behind the olive and the pyramid is the fo reticularis. In the medulla it occupies a position which, to a large extent, sponds with that of the lateral column in the spinal cord. In transverse sec appears as an extensive area, which is divided into a lateral and a mesial fi the root fascicles of the hypoglossal nerve as they traverse the substance medulla to reach the surface. In the lateral portion which lies behind th there is a considerable quantity of gray matter, continuous with that in th present in the reticular formation; it is, therefore, called the **formatio ret grisea.** In the mesial part which lies behind the pyramid the gray ma extremely scanty, and the reticular matter here is termed the **formatio ret alba.**

In the **formatio grisea** many of the cells which are scattered thickly amongst the inte bundles of fibres are to be regarded as association cells. They possess short axons, which serv different levels of the medulla to each other, and therefore constitute association fibres. F the combined and harmonious activity exhibited by the nuclei of the vagus, facial and nerves in the process of respiration, is attained through the nuclear connexions establi these fibres (Edinger). Certain compact masses of gray matter are also seen in the grisea. Of these may be mentioned (*a*) the dorsal accessory olivary nucleus, which already described, and (*b*) the nucleus lateralis. The **nucleus lateralis** is seen in th between the olive and the substantia gelatinosa Rolandi. In the upper part of the me gradually becomes diffuse and disappears.

Except in the immediate vicinity of the raphe, the **formatio alba** may be said to be d cells. The mesial accessory olive, however, forms an isolated compact mass of gray matte its limits.

The nerve fibres which traverse the formatio reticularis run both in a tra and a longitudinal direction. The **transverse fibres** are the deep arcuate The **longitudinal fibres** are derived from different sources in the two fields. formatio grisea they represent to a large extent the fibres of the lateral col the cord, after the removal of the direct cerebellar and the crossed pyramidal They consist, therefore, of the fibres of the tract of Gowers and of fibres corre ing to the lateral basis-bundle of the cord. In the formatio alba the longit fibres are the tract of the fillet and the posterior longitudinal bundle, both o have already been sufficiently described.

Central Canal and the Gray Matter which surrounds it.—The centra as it proceeds upwards through the closed part of the medulla, is gradually to assume a more dorsal position, owing to the accumulation of fibres on its aspect. First the decussation of the pyramids, and then the decussation fillet, both of which take place in front of the canal, tend to push it back and the formation of the longitudinal strands in which these intercrossings (viz. the pyramid and the fillet), together with the continuation upwards anterior basis-bundle, lead to a great increase in the amount of tissue separates it from the anterior surface of the medulla. In the closed part medulla it is surrounded by a thick layer of gray matter, which is continuo

agus, glosso-pharyngeal, and auditory nerves lie in the lateral part of the The gray matter of the ventricular floor is covered by ependyma.

Areas of Flechsig.—In transverse sections, through the upper open part of the the root fibres of the hypoglossal and vagus nerves are seen traversing the substance of lla. The nucleus of origin of the hypoglossal is placed in the gray matter of the floor urth ventricle close to the mesial plane; the nucleus of the vagus is situated in the er of the ventricular floor immediately to the outer side of the hypoglossal nucleus. se nuclei the root-bundles of the two nerves diverge from each other as they are traced face and subdivide the substance of the medulla, as seen in transverse section, into the s of Flechsig, viz. an anterior, a lateral, and a posterior.

nterior area, which is bounded internally by the median raphe and externally by the al roots, presents within its limits: (*a*) the formatio alba; (*b*) the pyramid; (*c*) the the posterior longitudinal fasciculus; (*e*) the mesial accessory olivary nucleus; (*f*) the ucleus.

ateral area lies between the root fibres of the hypoglossal and those of the vagus. It (*a*) the inferior olivary nucleus; (*b*) the dorsal accessory olivary nucleus; (*c*) the nucleus (*d*) the nucleus ambiguus, or the motor nucleus of the vagus and glosso-pharyngeal *e*) the formatio reticularis grisea.

osterior area is situated behind the vagus roots, and within its limits are seen: (1) the body; (2) the upper part of the cuneate nucleus; (3) to the inner side of this a crowd ersely-cut bundles of fibres, loosely arranged and forming the descending root of the r part of the auditory nerve; (4) close to these, but placed more deeply, a round, com- l very conspicuous bundle of transversely-cut fibres, viz. the fasciculus solitarius, or ıg root of the vagus and glosso-pharyngeal nerves; (5) the substantia gelatinosa Rolandi, luced, with the large spinal root of the trigeminal nerve close to its outer side.

INTERNAL STRUCTURE OF THE PONS VAROLII.

en transverse sections are made through the pons, it is seen to be composed ıtral part and a dorsal or tegmental part. The **ventral part** is much the f the two, and, broadly speaking, it corresponds to the pyramidal portions nedulla and the pedal portions of the two crura cerebri, which lie above it and to issue from it. The dorsal **tegmental part** may be regarded as the con- on upwards of the formatio reticularis grisea and the formatio reticularis As these parts are traced upwards into the pons they become much modified, w constituents are added.

ntral Part of the Pons (pars basilaris pontis).—This constitutes the chief f the pons. It is composed of: (1) transverse fibres arranged in coarse s; (2) longitudinal fibres, gathered together in massive bundles; and (3) a mount of gray matter termed the **nucleus pontis**, which fills up the inter-

passing across upon the dorsal aspect of the latter. Laterally these trans fibres are collected together into one compact mass, which enters the white co core of the cerebellum and constitutes the **middle cerebellar peduncle.** A mesial plane the transverse fibres of the two sides of the ventral portion o pons intercross and form a coarse decussation.

The **gray matter** (the nucleus pontis) forms a considerable part of the b the ventral portion of the pons. It is packed into the intervals between the i secting transverse and longitudinal bundles.

There is a close analogy between the pyramidal portions of the medulla and the v part of the pons. In the medulla fine arcuate fibres on their way to the surface pass th the pyramids. Other superficial arcuate fibres sweep over the surface of the pyramids present a strong resemblance to the transverse fibres of the pons. They likewise the cerebellum, although by a different route, viz. the inferior cerebellar peduncle. nucleus pontis is also represented in the pyramidal part of the medulla by the a

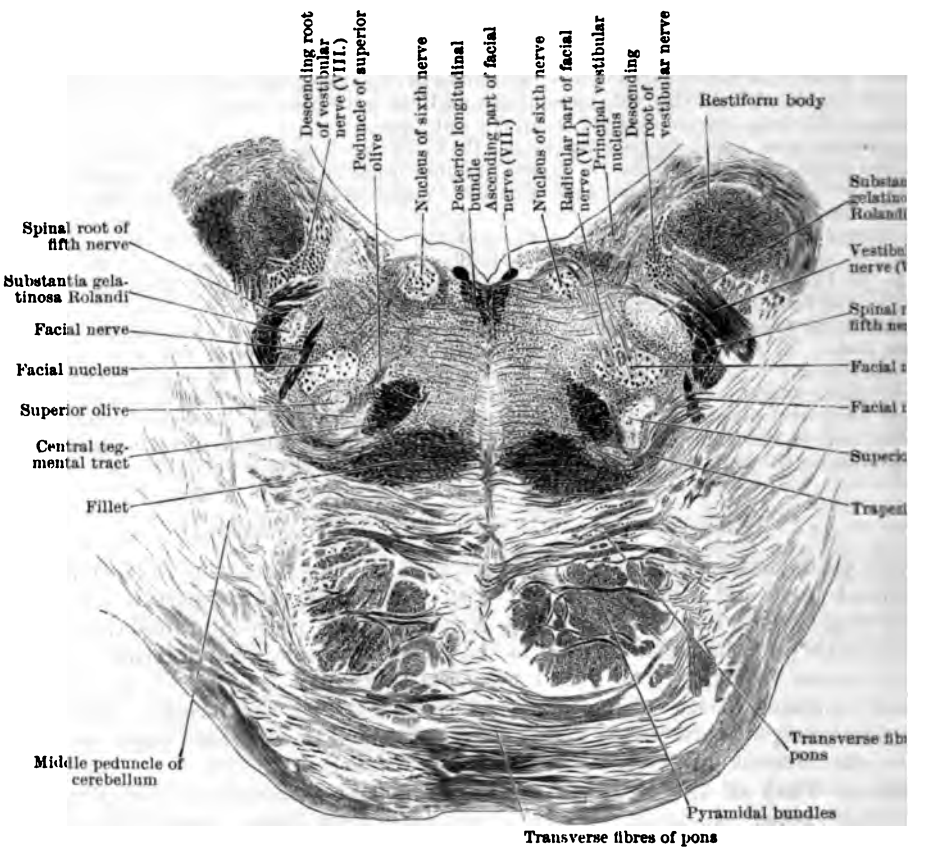

FIG. 403.—SECTION THROUGH THE LOWER PART OF THE HUMAN PONS VAROLII IMMEDIATELY A THE MEDULLA.

nuclei, which are covered over by the superficial arcuate fibres, and even tend to pen to a slight extent, into the pyramidal tracts. These arcuate nuclei, as already point are continuous with the nucleus pontis.

Connexions of the Longitudinal and Transverse Fibres.—Our knowle the connexions of the longitudinal and transverse fibres of the ventral part of the very far from being complete. When a transverse section through the upper part pons is compared with one close to its lower border, it becomes at once apparent th numerous scattered bundles of longitudinal fibres which enter the ventral part of th from above, if brought together into one tract, would form a strand very much large the two pyramids which leave its lower aspect and enter the medulla. It is clear, fore, that many of the longitudinal fibres which pass into the pons from above do n

t below into the medulla. What becomes of these fibres that are thus absorbed in

It is known that the pyramidal bundles suffer a small loss by the fibres which to the nuclei of origin of the efferent nerves which arise within the pons (viz. the t of the fifth, the sixth, and seventh nerve nuclei); but this loss is, comparatively trifling. It is clear, therefore, that other longitudinal bundles enter the pons e than those which form the pyramidal tracts. These bundles occupy a lateral l position in the ventral part of the pons, and may be termed the **cortico-pontine** ing that they come from the cerebral cortex and end in fine ramifications around of the nucleus pontis.

ansverse fibres are of two kinds, viz.: (1) those which arise in the cortex of the a; and (2) those which in in the nucleus pontis. er are the axons of certain ls of the cortex of the cere- ells of Purkinje). us Trapezoides.—This name is applied to a group of transverse fibres averse the lower part of the pons (Fig. 405). They are quite distinct from hich have been just described as entering the middle peduncle of the m, and they lie in the boundary between the dorsal and ventral parts of , but encroaching considerably into the ground of the former. They arise cells of the terminal nucleus of the cochlear division of the auditory nerve, stitute a tract which establishes certain central connexions for that nerve. ll be more fully described when we treat of the cerebral connexions of the nerve.

al or Tegmental Part of the Pons (pars dorsalis pontis).—On the dorsal of the tegmental part of the pons there is spread a thick layer of gray

matter, covered by ependyma, which forms the floor of the upper or po part of the fourth ventricle. Beneath this the mesial raphe of the medu continued up into the pons, so as to divide its tegmental part into two symme halves.

In the *lower part of the pons*, immediately beyond the medulla, the rest body is placed on the outer side of the tegmental part (Fig. 403). In trans sections through the pons it appears as a large, massive oval strand of fibres w gradually inclines backwards into the cerebellum, and thus leaves the Between the restiform body and the median raphe the tegmental part of the is composed of formatio reticularis, continuous with the same material in medulla. Thus arcuate or transverse fibres, curving in towards the raphe, and longitudinal fibres, are seen breaking through a mass of gray matter which occ the interstices of the intersecting fibres. To the naked eye the formatio reticu presents a uniform gray appearance, but its constituent parts are revealed by powers of the microscope in properly-stained and prepared specimens. Embed in this formatio reticularis are various clumps of compact gray matter and cer definite strands of fibres. These we shall describe as we pass from the restif body inwards towards the median raphe.

(1) **Spinal root of the trigeminal nerve and the substantia gelatinosa Rolandi.** Close to the inner side of the restiform body, but separated from it by the ve bular root of the auditory nerve as it proceeds backwards through the pons, is s a large crescentic group of coarse transversely-divided bundles of fibres. This is spinal root of the fifth nerve, and applied to its inner concave side is a small m of gray matter, which is the direct continuation upwards of the substantia gelatin Rolandi.

(2) The **nucleus of the facial or seventh nerve** comes next. It is sunk dee in the tegmental part of the pons and lies close to the transverse fibres of corpus trapezoides. It is a conspicuous, obliquely placed, ovoid clump of g matter. From its outer and dorsal aspect the root-fibres of the facial ne stream backwards and inwards towards the gray matter on the floor of the fou ventricle. Passing forwards between this nucleus and the substantia Rolandi solid nerve-bundle may be observed. This is the facial nerve, traversing the p towards its place of emergence from the brain.

(3) Immediately internal to the facial nucleus, but placed more deeply in t tegmental part of the pons, is the **superior olivary nucleus** (nucleus olivaris superi It lies in a bay formed for it by the transverse fibres of the corpus trapezoid These fibres curve round its ventral aspect, and many of them may be observed pe trating into its substance. In man it is a very small mass of gray matter, a presents little resemblance to the inferior olivary nucleus, except in the size a shape of its constituent cells. In sections through the part of the pons where attains its greatest size, it appears in the form of two, or it may be three, sm isolated masses of gray matter. It is intimately connected with the trape fibres, many of which end in it, whilst others take origin within it.

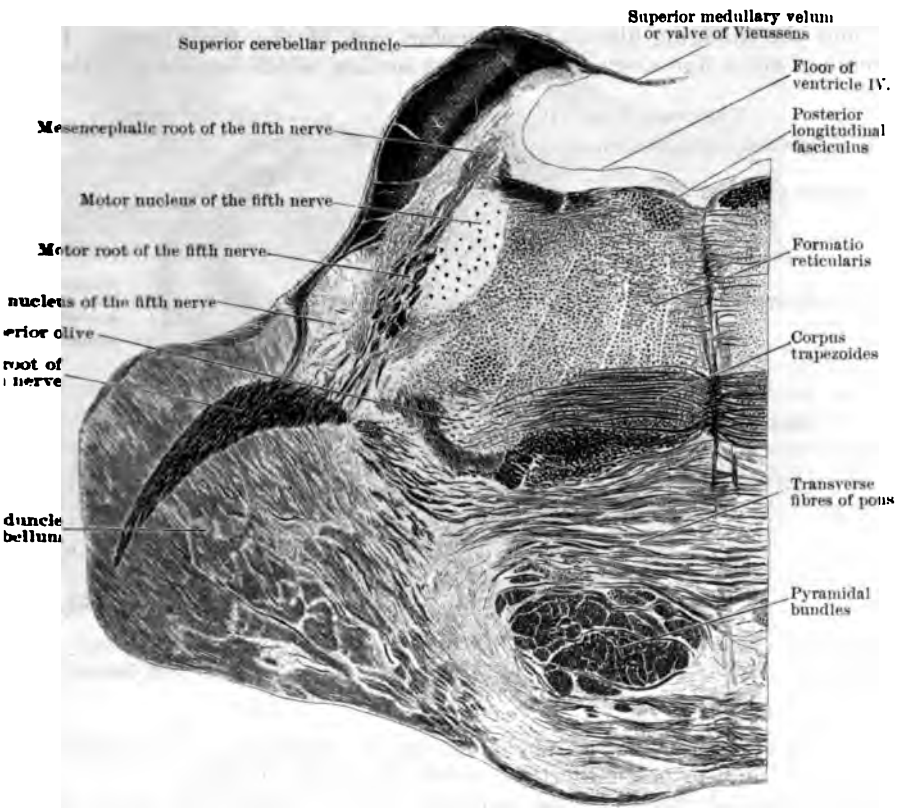
Upon the inner and dorsal aspect of the superior olive there is a dense group of longitudi fibres. These constitute the **central tegmental tract**; but as precise information in regard its connexions is still to a large extent wanting, it is not necessary to do more than indicate position.

(4) The **posterior longitudinal bundle** and the **fillet** come next. As they proce upwards through the tegmental part of the pons, these longitudinal tracts occu the same relative position as in the medulla. They are placed close to the medi raphe: but they have drawn further apart from each other, and their fibres more distinctly concentrated into separate strands, with an interval of some lit width between them. The **posterior longitudinal bundle** lies immediately und cover of the gray matter of the floor of the fourth ventricle. The **fillet** is plac close to the trapezial fibres, many of which traverse it as they pass towards t mesial plane.

(5) The **nucleus of the sixth nerve** also forms a conspicuous object in sectio through the lower part of the pons. It is a round mass of gray matter, which situated close to the outer side of the posterior longitudinal bundle, and immediate

over of the gray matter of the floor of the fourth ventricle. From its inner merous root-bundles of the sixth nerve pass out and proceed forwards the fillet and the superior olivary nucleus. They occupy in the pons, re, a position similar to that occupied by the hypoglossal root-fibres in the a.

to the present only the lower part of the tegmental portion of the pons en described, *i.e.* the portion immediately adjoining the medulla. As we upwards and gain a point *above the level of the trapezial fibres*, many of uctures which have attracted attention lower down gradually disappear ne formatio reticularis. The posterior longitudinal bundle, the fillet, and nal root of the fifth nerve, however, are still carried upwards. Further, the



405.—Transverse Section through the Pons Varolii at the Level of the Nuclei of the Trigeminal Nerve (Orang).

of the fourth ventricle becomes narrower, and other objects appear in the ental substance.

ne **superior cerebellar peduncle** (brachium conjunctivum) is a very con- ous object, in sections, through the middle and upper parts of the pons. In erse section it presents a semilunar outline, and as it emerges from the llum it lies immediately on the outer side of the fourth ventricle, towards its concave aspect is turned (Fig. 405). Its dorsal border is joined with the ponding peduncle of the opposite by the thin lamina of white matter, d the superior medullary velum, whilst its ventral border is sunk to a small t in the dorsal part of the pons. As it is traced upwards it sinks deeper and r into the pons until it becomes completely submerged, with the exception e posterior border to which the superior velum is attached. It now lies on ater side of the tegmental or reticular substance of the pons, and this position intains until the mesencephalon is reached (Fig. 406).

bout *half-way up the pons* the nuclei of the trigeminal or fifth cranial nerve a very important stage in its tegmental portion. These nuclei are two in

number on each side, viz. a large oval terminal nucleus for certain of the sen fibres of the nerve and a nucleus of origin equally conspicuous for certain of motor fibres (Fig. 405). The **sensory nucleus** lies close to the outer surface of pons, deeply sunk in its tegmental part, and in the interval between the subm anterior border of the superior cerebellar peduncle and the ventral part of the p The **motor nucleus** is placed on the inner side of the sensory nucleus, but somew nearer the dorsal surface of the pons. At this level the spinal root of the f nerve disappears by joining the fibres of the sensory portion. The sensory motor roots of the fifth nerve traverse the ventral part of the pons on their to and from the region of the nuclei.

Above the level of the nuclei of the trigeminal nerve a new tract of fi comes into view. This is the **mesencephalic root** of the fifth nerve, as it desc to join the emerging fibres of the motor part of the fifth nerve. It is a s bundle of nerve fibres, semilunar in cross section, which lies close to the inner s

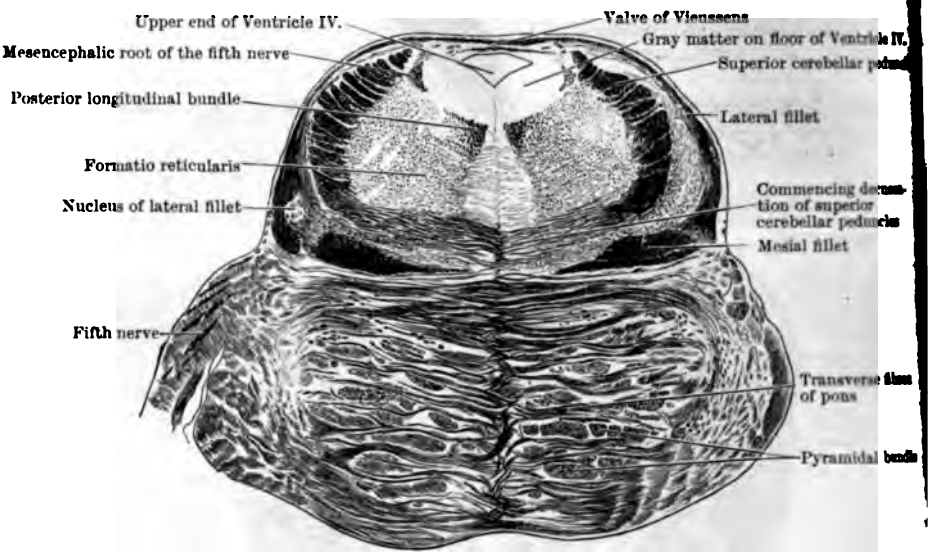


FIG. 406.—SECTION THROUGH THE UPPER PART OF THE PONS VAROLII OF THE ORANG, ABOVE THE LEVEL OF THE TRIGEMINAL NUCLEI.

of the superior cerebellar peduncle and on the outer and deep aspect of the gray matter on the floor of the fourth ventricle (Figs. 406 and 407).

On a slightly deeper plane than the mesencephalic root of the fifth nerve, between it and the posterior longitudinal bundle, and in close relation to the gray matter of the floor of the ventricle, is the collection of pigmented cells which constitutes the **substantia ferruginea.**

The **posterior longitudinal bundle,** as it is traced upwards through the tegmental part of the pons, maintains the same position throughout, and as it ascends it becomes more clearly mapped out as a definite and distinct tract. It lies close to the mesial raphe, and immediately subjacent to the gray matter of the floor of the fourth ventricle.

The **fillet** as it ascends through the tegmental part of the pons undergoes striking changes in shape. In the lower portion of the pons its fibres, which in the medulla are spread out along the side of the median raphe, are collected together in the form of a loose bundle, which occupies a wide field, somewhat triangular in shape, on either side of the median raphe and immediately behind the ventral portion of the pons. As it proceeds up, the fibres spread out laterally until a compact ribbon-like layer is formed in the interval between the tegmental and ventral portions of the pons. This constitutes what is termed the **mesial fillet** (Figs. 406 and 407).

Above the level of the trigeminal nuclei another flattened layer of fibres comes

into view to the outer side of the mesial fillet. To this the name of **lateral fillet** is given. These fibres spread outwards and backwards, and finally take up a position on the outer surface of the superior cerebellar peduncle. In the angle between the mesial and lateral fillets a little knot of compact gray matter, termed the **lateral**

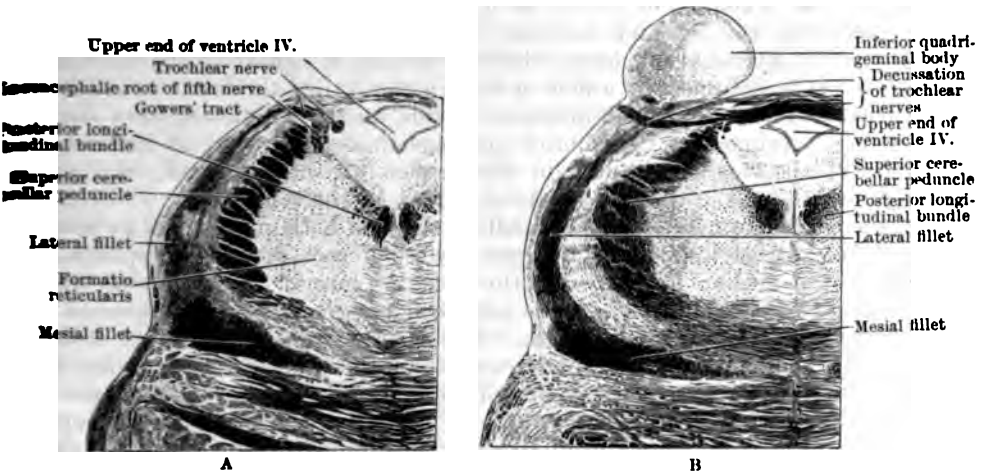

FIG. 407.—TWO SECTIONS THROUGH THE TEGMENTUM OF THE PONS AT ITS UPPER PART, CLOSE TO THE MESENCEPHALON.

A is at a slightly lower level than B.

fillet nucleus, comes into view (Fig. 406). This appears to be in more or less direct continuity with the superior olivary nucleus. Many of the fibres of the lateral fillet take origin in this nucleus. Bruce has called attention to the continuity between the superior olive and the lateral fillet nucleus in man, and the writer can confirm his statement in so far as the orang brain is concerned.

THE CEREBELLUM.

The **cerebellum** lies behind the pons Varolii and the medulla oblongata, and below the hinder portions of the cerebral hemispheres. From the latter it is

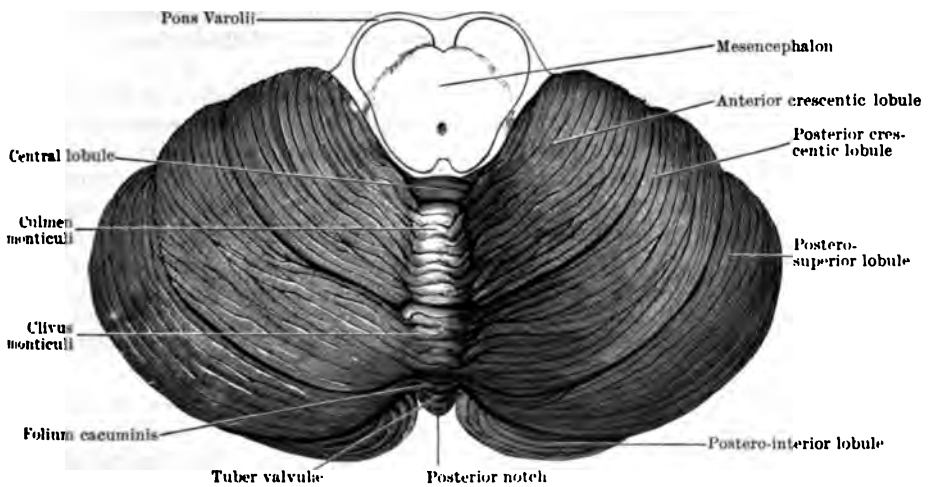

FIG. 408.—UPPER SURFACE OF THE CEREBELLUM.

separated by an intervening partition of dura mater, termed the tentorium cerebelli. It is distinguished by the numerous parallel and more or less curved sulci, which traverse its surface and give it a foliated or laminated appearance. It is composed of a cortex of gray matter (substantia corticalis) spread over its surface, with white matter in the interior, forming a central core (corpus medullare).

The cerebellum is subdivided somewhat arbitrarily into a median port termed the **vermis**, and two much larger lateral portions, called the **lateral he spheres** (hemisphæria cerebelli). The demarcation between these main subdivisi of the organ is not very evident from every point of view. In front, and s behind, there is a marked deficiency or notch. The **posterior notch** (incisura ce belli posterior) is smaller and narrower than the anterior notch. It is bound laterally by the lateral hemispheres, whilst its bottom is formed by the median l or vermis. It is occupied by a fold of dura mater, called the falx cerebelli. T **anterior notch** (incisura cerebelli anterior) is wide, and, when viewed from above, is seen to be occupied by the inferior quadrigeminal bodies and by the super peduncles of the cerebellum. As in the case of the hinder notch, its sides a formed by the lateral hemispheres and the bottom by the vermis.

On the superior surface of the cerebellum there is little distinction to be not between the median lobe and the upper surface of each lateral hemisphere. this aspect the median lobe receives the name of **superior vermis**, and it form high median elevation, from which the surface slopes gradually downwards on e side to the margin of the hemisphere. The superior vermis is highest in fr immediately behind the anterior notch, and from this it shows a somewhat sh descent towards the posterior notch. This elevation of the superior worm frequently called the monticulus cerebelli. The folia on the surface of the supe vermis are thicker and fewer in number than those on the upper surface of lateral hemisphere. It is this which gives it the worm-like appearance from wh it derives its name.

On the inferior surface of the cerebellum the distinction between the three m constituent parts of the organ is much better marked (Fig. 409). On this asp the lateral hemispheres are full, prominent, and convex, and occupy the cerebe fossæ in the floor of the cranium. They are separated by a deep mesial holl which is continued forwards from the posterior notch. This hollow is termed **vallecula cerebelli**, and in its fore-part is lodged the medulla oblongata. When medulla is raised and the lateral hemispheres are pulled apart, so as to expose bottom of the vallecula, it will be seen that this is formed by the **vermis infe** or inferior aspect of the median lobe, and, further, that the latter is separated each side from the corresponding lateral hemisphere by a distinct furrow, ter the **sulcus valleculæ**.

Sulci Cerebelli.—Certain of the fissures which traverse the surface of cerebellum are deeper and longer than the others, and they map out districts wh are termed lobes. One of the most conspicuous of these clefts is the great horizon fissure.

The **great horizontal fissure** (sulcus horizontalis cerebelli) of the cerebell begins in front and passes continuously round the circumference of the org cutting deeply into its outer and posterior margins. In front, its lips diverge enclose the three cerebellar peduncles as they pass into the interior of cerebellum. The great horizontal fissure divides the organ into an upper an lower part, which may be studied separately.

The prominence which is accorded to the great horizontal fissure in descriptive anatom not justified by its developmental history and morphological status. It is very late in mak its appearance in the fœtal cerebellum, and not infrequently the part of the fissure on the side fails to establish a continuity across the vermis with the part of the fissure on the o side of the organ.

Lobes on the Upper Surface of the Cerebellum.—When examined fr before backwards, the superior vermis presents the following subdivisions: (1) **lingula**; (2) the **central lobule** (lobulus centralis); (3) the **culmen monticuli**: (4) **clivus monticuli**: (5) the **folium cacuminis** (folium vermis). With the exception the lingula, each of these is continuous on either side, with a corresponding dist on the upper surface of the hemisphere, thereby forming a cerebellar lobe. T the central lobule is prolonged outwards on either side in the form of a sm flattened, wing-like expansion called the **ala**; the culmen constitutes the mec connecting piece between the two **anterior crescentic lobules** of the hemisphe the clivus stands in the same relation to the two **posterior crescentic lobules**;

folium cacuminis is the connecting band between the **postero-superior lobules** of the hemispheres.

It should be noted that this subdivision of the upper surface of the cerebellum is to some extent conventional, and in certain particulars receives little support from morphological data.

The lingula can only be seen when the part of the cerebellum which forms the bottom of the anterior notch is pushed backwards. It consists of four or five small flat folia continuous with the gray matter of the vermis superior, which are prolonged forwards on the upper surface of the superior medullary velum in the interval between the two superior cerebellar peduncles.

Lobus Centralis with its Alæ.—The lobulus centralis lies at the bottom of the anterior cerebellar notch, and is only seen to a very small extent on the upper surface of the organ. It is a little median mass which laterally is prolonged outwards for a short distance round the anterior notch in the form of two expansions, termed the alæ.

Lobus Culminis.—The culmen monticuli constitutes the highest part or summit of the monticulus of the vermis superior. It is bounded behind by a deep and strongly marked fissure called the **fissura prima** (Elliot Smith), and is prolonged outwards on either side into the lateral hemisphere as the **anterior crescentic lobule.** This is the most anterior subdivision on the upper surface of the hemisphere. The two anterior crescentic lobules, with the culmen monticuli, form the **lobus culminis cerebelli.**

Lobus Clivi.—The clivus monticuli lies behind the culmen, from which it is separated by the fissura prima, and it forms the sloping part or descent of the monticulus of the vermis superior. On each side it is continuous with the **posterior crescentic lobule** of the lateral hemisphere, and the three parts are included under the one name of **lobus clivi.**

The two crescentic lobules on the upper surface of the hemisphere are sometimes classed together and described as the **lobulus quadrangularis.** They are separated from each other by a lateral extension on the upper surface of the hemisphere of the fissura prima, whilst the posterior crescentic lobule is bounded behind by a curved sulcus termed by Elliot Smith the **fissura postlunata.** The union of the two postlunate furrows across the vermis separates the clivus from the folium cacuminis, but in many cases this junction fails to take place.

Lobus Cacuminis.—The folium cacuminis forms the most posterior part of the vermis superior, and when the right and left portions of the great horizontal fissure are continuous across the vermis it bounds that fissure superiorly at the posterior notch. It is a single folium, subject to considerable variation in the degree of its development, and its surface may be smooth or beset with rudimentary secondary folia. It is the median connecting link between the two **postero-superior lobules** of the hemispheres, the three parts forming the **lobus cacuminis.** As the folium cacuminis is traced outwards into the postero-superior lobule, it is found to expand greatly, and as a result of this the postero-superior lobule on each side forms an extensive foliated district bounding the great horizontal fissure above.

Lobes on the Under Surface of the Cerebellum.—The connexion between the several parts of the inferior vermis and the corresponding districts on the under surface of the two hemispheres is not so distinct as in the case of the vermis superior and the lobules on the upper surface of the hemispheres. A groove, the **sulcus vallecula**, intervenes between the vermis inferior and the hemisphere on each side.

From behind forwards the following subdivisions of the vermis inferior may be recognised: (1) the **tuber valvulæ** (tuber vermis); (2) the **pyramid** (pyramis); (3) the **uvula**; (4) the **nodule** (nodulus).

On the under surface of the hemisphere there are four main lobules mapped out by intervening fissures. From behind forwards these are: (1) the **postero-inferior lobule**, a large subdivision which bounds the great horizontal fissure on its under aspect; (2) the **biventral lobule** (lobulus biventer) which lies in front of the postero-inferior lobule, and is partially divided into two parts by a curved fissure which traverses its surface; (3) the **tonsil** or **amygdala** (tonsilla), a small rounded lobule which bounds the fore-part of the vallecula, and is lodged in a deep concavity on

the inner aspect of the biventral lobule; (4) the **flocculus**, a minute lobule situated on the middle peduncle of the cerebellum in front of, and partially overlapped by, the anterior border of the biventral lobule.

These lobules, with the corresponding portions of the vermis inferior, constitute the lobes on the under surface of the cerebellum. Still, it should be noted that, just as in the case of the upper surface of the organ, this subdivision is to some extent artificial, and is not in every particular provided with a sound morphological basis.

Lobus Tuberis.—The tuber valvulæ, which forms the most posterior part of the vermis inferior, is composed of several transversely arranged folia which, on either side, run directly into the postero-inferior lobule. The three parts of the lobus tuberis are thus linked together.

The postero-inferior lobule, which is wider towards the vallecula than it is further out, is traversed by two or it may be three curved fissures. The most anterior of these cuts off a narrow, curved strip of cerebellar surface, which presents a more or less uniform width throughout its whole length. This is the so-called **lobulus gracilis.**

Lobus Pyramidis.—The pyramid is connected with the biventral lobule on each side by an elevated ridge which crosses the sulcus valleculæ. The term lobus pyramidis is applied to the three lobules, which are thus associated with each other.

The pyramid is separated from the tuber valvulæ by a deep furrow which has been termed by Elliot Smith the **suprapyramidal fissure.** It is in a measure continuous with the curved fissure, which on the under surface of the hemisphere intervenes between the biventral lobule and the lobulus gracilis or fore part of the postero-inferior lobule. The name applied to the latter fissure by Elliot Smith is **fissura parapyramidalis.**

Lobus Uvulæ.—The uvula is a triangular elevation of the vermis inferior. It lies between the two tonsils, and is connected with each of these by a low-lying

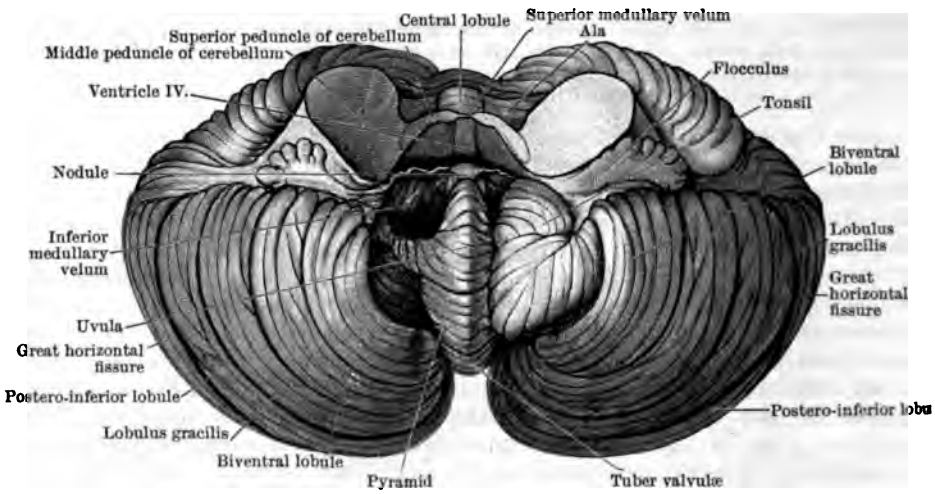

FIG. 409.—LOWER SURFACE OF THE CEREBELLUM.

The tonsil on the right side has been removed so as to display more fully the inferior medullary velum and the furrowed band.

band-like ridge of gray matter scored by a few shallow furrows, and in consequence termed the **furrowed band.** The two tonsils and the uvula form the lobus uvulæ.

Between the pyramid and the uvula there is a deep cleft which may be termed the **infra-pyramidal fissure** (the fissura secunda of Elliot Smith). This is more or less directly connected with the **retrotonsillar fissure** which curves round the tonsil. The large size of the tonsil is characteristic of the brain of man and the anthropoid apes.

Lobus Noduli.—The lobus noduli comprises the nodule and the flocculus on each side, with a delicate connecting lamina of white matter termed the **inferior medullary velum.**

The cleft between the nodule and the uvula is termed the **postnodular fissure** (Elliot Smith); that between the flocculus and the biventral lobule is called the **floccular fissure.**

The flocculus will usually be observed to be partially divided into two pieces. The smaller inferior portion, which, as a rule, is completely overlapped by the overhanging edge of the biventral lobule, is the **paraflocculus.** This assumes very large proportions in certain of the lower mammals.

Arrangement of the Gray and White Matter of the Cerebellum.—The white matter of the cerebellum forms a solid compact mass in the interior, and over this is spread a continuous and uniform layer of gray matter. In each lateral hemisphere the white central core is more bulky than in the median lobe or worm, in which the central white matter is reduced to a relatively thin bridge thrown across between the two lateral hemispheres. The white matter in the interior of the median lobe or worm is termed the **corpus trapezoides.** When sagittal sections are made through the cerebellum, the gray matter on the surface stands out clearly from the white matter in the interior. Further, from all parts of the surface of

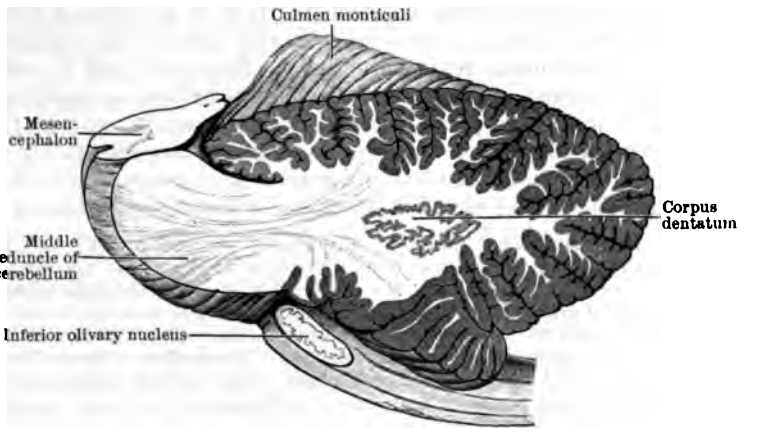

FIG. 410.—SAGITTAL SECTION THROUGH THE LEFT LATERAL HEMISPHERE OF THE CEREBELLUM,

Showing the "arbor vitæ" and the corpus dentatum.

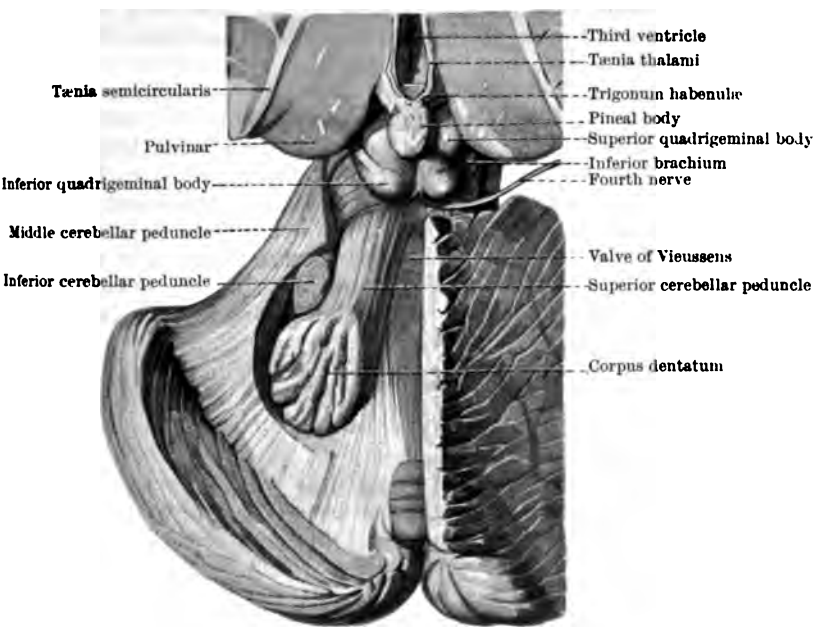

FIG. 411.—From a dissection by Dr. Edward B. Jamieson in the Anatomical Department of the University of Edinburgh. The corpus dentatum is displayed from above and the superior cerebellar peduncle has been traced from it to the mesencephalon.

the central core stout stems of white matter are seen projecting into the lobes of the cerebellum. From the sides of these white stems secondary branches proceed

at various angles, and from these again tertiary branches are given off. Over the various lamellæ of white matter thus formed the gray cortex is spread, and the fissures on the surface show a corresponding arrangement, dividing up the organ into lobes, lobules, and folia. When the cerebellum is divided at right angles to the general direction of its fissures and folia, a highly arborescent appearance is thus presented by the cut surface. To this the term **arbor vitæ cerebelli** is applied.

Corpus Dentatum and other Gray Nuclei in the White Matter of the Cerebellum.—Embedded in the midst of the mass of white matter which forms the central core of each lateral hemisphere there is an isolated nucleus of gray matter which presents a strong resemblance to the inferior olivary nucleus of the medulla. It is called the **corpus dentatum** (nucleus dentatus), and it consists of a corrugated or plicated lamina of gray matter, which is folded on itself so as to enclose, in a flask-like manner, a portion of the central white matter (Figs. 410 and 411). This gray capsule is not completely closed. It presents an open mouth, termed the hilum, which is directed inwards and upwards, and out of this stream the great majority of the fibres of the superior cerebellar peduncle.

Three small additional masses of gray matter are also present on either side of the mesial plane in the central white matter of the cerebellum. These are termed the **nucleus emboliformis**, the **nucleus globosus**, and the **nucleus fastigii**. The **nucleus emboliformis** or **embolus** is a small lamina of gray matter which lies immediately internal to the hilum of the corpus dentatum, being thus related to it somewhat in the same manner that the mesial accessory olivary nucleus is related to the main inferior olivary nucleus. The **nucleus globosus** lies internal to the embolus and on a somewhat deeper horizontal plane. The **nucleus fastigii** or **roof nucleus** is placed in the white substance of the worm (corpus trapezoides) close to the mesial plane and its fellow of the opposite side. It is, therefore, situated on the mesial aspect of the nucleus globosus.

Although isolated from the gray matter of the surface, these small nuclei and the corpus dentatum are connected at certain points with each other. The corpus dentatum and the embolus present a structure very similar to that of the inferior olivary nucleus. In the nucleus globosus and the nucleus fastigii the cells are somewhat larger in size.

Cerebellar Peduncles.—These are three in number on each side, viz. the middle, the inferior, and the superior (Fig. 391, p. 487). The fibres of which they are composed all enter or emerge from the white medullary centre of the cerebellum.

The **middle peduncle** is much the largest of the three, and has already been described on pp. 486 and 501. It is formed by the transverse fibres of the pons, and it enters the cerebellar hemisphere on the outer aspect of the other two peduncles. The lips of the anterior part of the great horizontal fissure are separated widely from each other to give it admission (Fig. 409). Within the cerebellar hemisphere its fibres are distributed in two great bundles. Of these, one, composed of the upper transverse fibres of the pons, radiates out in the lower part of the hemisphere; whilst the other, consisting of the lower transverse fibres of the pons, spreads out in the upper part of the hemisphere.

The **inferior peduncle** is simply the restiform body of the medulla. After leaving the medulla it ascends for a short distance on the dorsal surface of the pons and then turns sharply backwards, to enter the cerebellum between the other two peduncles.

The **superior peduncle**, as it issues from the cerebellum, lies close to the inner side of the middle peduncle (Fig. 409). Its further course upwards on the dorsum of the pons to the inferior quadrigeminal body has been previously described (pp. 486 and 503).

Connexions established by the Peduncular Fibres.—The fibres of the **middle peduncle** are both afferent and efferent. The connexions which they establish in the pons are described on p. 501. The efferent fibres arise from cells in the gray cortex of the lateral hemisphere (also probably to some small extent in the cortex of the vermis), and end in connexion with the cells of the nucleus pontis, and likewise in the tegmental part of the pons. The afferent fibres, arising in the pons, end in the gray cortex of the lateral hemisphere of the cerebellum, and perhaps also in the cortex of the worm.

The **inferior peduncle** is also composed of afferent and efferent fibres (see p. 496); only the more important connexions which these establish in the cerebellum can be touched on here. The principal afferent strand is the *direct cerebellar tract*. The fibres of this strand end in the cortex of the superior worm on both sides of the mesial plane, but chiefly on the opposite side. The *cerebello-olivary fibres* are also probably afferent. It

ears that they end in connexion with cells in the cortex of both the worm and hemi-ere, and also cells in the nucleus dentatus. The numerous *arcuate fibres* which enter inferior peduncle establish connexions with cells in the cortex of the lateral hemisphere of the worm.

The superior peduncle is an efferent tract. The majority of its fibres come from cells of the nucleus dentatus, whilst a small proportion appear to come from the cere-llar cortex. According to Risien Russell, the fibres which form the dorsal edge of the come from the opposite side of the cerebellum and cross the mesial plane to join the duncle.

Our knowledge of the connexions of the peduncles of the cerebellum has been greatly ended by Ferrier and Aldren Turner; and the account which is given above, and also at 501, is largely derived from their memoir on this subject.

Commissural and Association Fibres.—In addition to those fibres of the white edullary centre which belong to the system of peduncles, there are others which have clusively cerebellar connexions. Thus the various folia are bound together by numerous sociation fibres, which pass from one folium into another around the bottom of the inter-ening fissure. Tracts of transversely-directed **commissural fibres** cross the mesial plane the white centre of the vermis, connecting corresponding parts of opposite sides. These, some measure, are analogous to the corpus callosum of the cerebrum. The **roof nuclei** re also closely bound by connecting fibres with the cortex.

Medullary Vela.—The medullary vela are closely associated with the cerebellar eduncles. They consist of two thin laminæ of white matter, which are projected ut from the white central core of the cerebellum.

The **superior medullary velum** is described on p. 486. Laterally, it is continuous ith the dorsal edges of the superior cerebellar peduncles; whilst, inferiorly, it s prolonged downwards and backwards under the lingula and the central lobule of he superior worm, to become continuous with the central white matter or corpus rapezoides of the worm.

The **inferior medullary velum** is more complicated in its connexions. It presents uch the same relations to the nodule of the inferior vermiform process that the uperior velum presents to the lingula of the superior vermiform process. It is a ide thin lamina of white matter—so thin that it is translucent—which is pro-onged out from the white centre of the cerebellum above the nodule. From the nodule it stretches outwards to the flocculus on each side, thereby bringing these hree small portions of the cerebellum into association with each other (Fig. 409). Where it issues from the white matter of the cerebellum it is in contact with the uperior medullary velum, but, as the two laminæ are traced forwards, they iverge from each other. The superior velum is carried upwards between the wo superior cerebellar peduncles, whilst the inferior medullary velum is curved orwards and then downwards round the nodule, and ends at a variable point in free, slightly thickened, crescentic edge. The cavity of the fourth ventricle carried backwards into the cerebellum between the two vela, which thus form peaked and tent-like roof for it.

Relation of the Tract of Gowers to the Superior Medullary Velum.—The scending tract of Gowers has been noticed in connexion with the lateral column of the ord (p. 469). The fibres which compose it are carried upwards through the formatio eticularis grisea of the medulla and the corresponding part of the tegmental portion of he pons. In this part of its course the fibres are scattered and do not form a compact trand. Reaching the upper end of the pons the tract turns backwards, enters the uperior medullary velum, and proceeds downwards in it into the cerebellum.

Roof of the Fourth Ventricle.—In its upper part the roof of the fourth ventricle is formed by the superior medullary velum as it stretches across between the two superior cerebellar peduncles, and also, to some extent, by the approximation of these peduncles themselves as they approach the mesencephalon.

In its lower part the roof of the ventricle is exceedingly thin and is not all formed of nervous matter. The inferior medullary velum enters into its formation, and, where this fails, the epithelial lining of the cavity, supported by pia mater, is carried downwards towards the lower boundaries of the floor of the ventricle. At the lowest part of the calamus scriptorius, and also along each lateral boundary of

the floor, a thin lamina of white matter is carried for a short distance over epithelial roof. The small semilunar lamina which stretches across between lower parts of the two clavæ at the calamus scriptorius and overhangs the ope

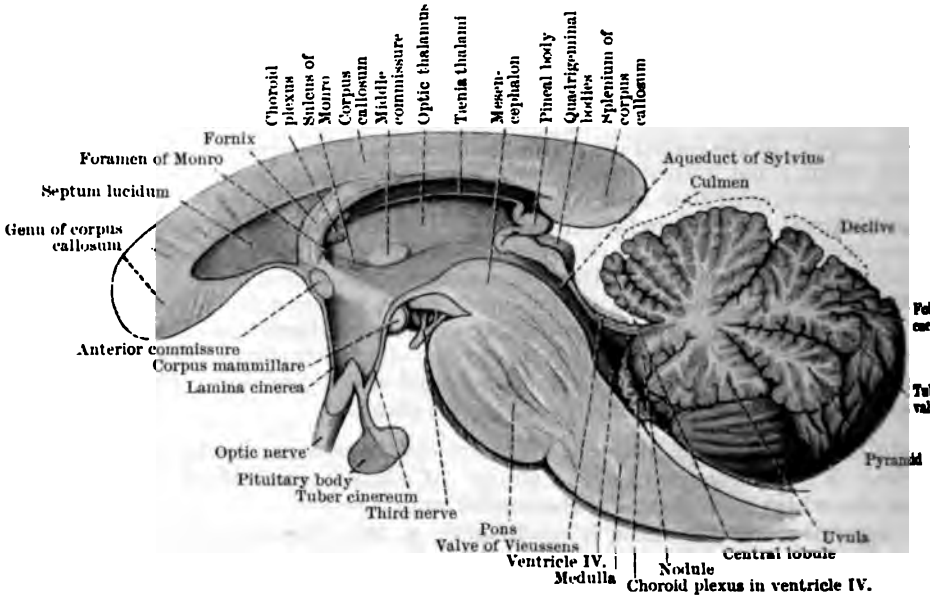

FIG. 412. - MESIAL SECTION THROUGH THE CORPUS CALLOSUM, THE MESENCEPHALON, THE PONS, MEDULLA, AND CEREBELLUM.

Showing the third and fourth ventricles joined by the aqueduct of Sylvius.

of the central canal is termed the **obex** (Fig. 391, p. 487). The lamina in connexion with the lateral boundary of the ventricular floor is more extensive, and is called the **ligula** (Figs. 388 and 390). It begins on the clava and passes upwards over the cuneate tubercle to the restiform body. On the outer surface of the restiform body it turns outwards so as to bound the lateral recess of the ventricle below, and in some cases it may be seen to become continuous around the extremity of the lateral recess with the inferior medullary velum.

A short distance above the calamus scriptorius there is, in the mesial plane, an opening in the epithelial and pial roof of the ventricle, by which the cavity of the ventricle communicates with the subarachnoid space. This opening is termed the **foramen of Majendie**. There is also an aperture of a similar nature in the epithelial and pial roof at the extremity of each lateral recess.

Two **choroid plexuses**, or highly vascular infoldings of the pia mater, invaginate the lower part of the roof of the fourth ventricle. These are placed one on either side of the mesial plane, and, although they appear to lie within the cavity, they are in reality excluded from it by the epithelial lining of the ventricle, which covers over and is adapted to every sinuosity on their surface.

Two lateral offshoots from these longitudinal choroid plexuses proceed outwards, and protrude in a similar manner into the lateral recesses.

MINUTE STRUCTURE OF A CEREBELLAR FOLIUM.

A cerebellar folium is composed of a central core of white matter, covered by a layer of gray matter. The gray cortex is arranged in two very evident layers, viz. a superficial **molecular layer** and a subjacent rust-coloured **granular layer**. Between these strata a single layer of large cells, termed the **cells of Purkinje**, are disposed in the form of a very nearly continuous sheet. The cells of Purkinje constitute the most characteristic, and probably the most essential, constituents of the cerebellar cortex.

The **cells of Purkinje** are most numerous on the summit of the folium. At the bottom of the sulci which intervene between the folia they become fewer in number, and, therefore, looser in their arrangement. Each consists of a large flask-shaped or pyriform

l body, the narrow end of which projects into the molecular layer, whilst the thicker, per end rests on the granular layer. From the latter arises a **single axon**, which passes to the granular layer and presents the peculiarity of almost immediately assuming its edullary sheath. From this axon a few collateral branches soon arise, which, taking a current course, enter the molecular layer, to end in connexion with certain of the joining cells of Purkinje. They would seem to have the function of binding together djacent cells, and thus nabling them to carry on eir operations in harmony ith each other.

The **dendritic processes** pring from the narrow end f the cell either in the form f one or perhaps two stout talks. These ascend into he molecular layer, branching and rebranching until an aborescent arrangement of extraordinary richness and extent results. The dendritic branches extend throughout the entire thickness of the molecular layer, and the branching takes place in one plane only, viz. in a plane which is transverse to the long axis of the folium. Consequently, it is only when transverse sections are made through a folium that the full dendritic effect is obtained; in sections made parallel to the long axis of the folium the cells are seen in profile, and are observed to occupy quite a narrow area (Fig. 414). The branching of the dendrites of a cell of Purkinje may, therefore, be compared to that which takes place in the case of a fruit-tree which is trained against a wall.

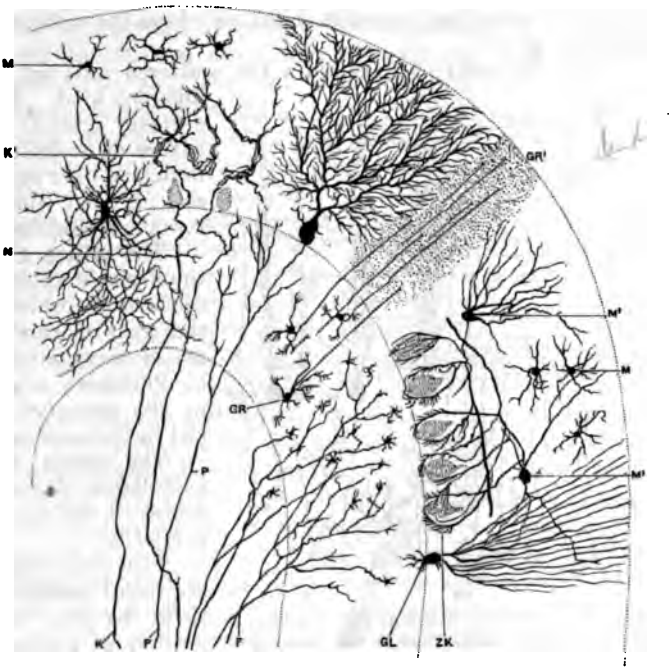

FIG. 413.—TRANSVERSE SECTION THROUGH A CEREBELLAR FOLIUM (after Kölliker).

GR¹. Axons of granule cells in molecular layer cut transversely.
M¹. Basket-cells.
ZK. Basket-work around the cells of Purkinje.
GL. Neuroglial cell.
N. Axon of an association cell.

In the **molecular layer** the cells are not particularly numerous, and of these the most characteristic are the **basket-cells** which lie in the deeper part of the layer. In addition to numerous dendrites the basket-cell gives off an axon which runs transversely, as regards the long axis of the folium, between the planes of adjacent dendritic arborisations of the cells of Purkinje. At first very fine these axons gradually become coarse and thick, and at intervals they give off collaterals which run towards the bodies of the cells of Purkinje. Reaching these, they break up into an enormous number of fine terminal branches, which enclose the cells of Purkinje, as well as the short non-medullated portions of their axons, in a close basket-work of fine filaments.

The **granular layer** is, for the most part, composed of large numbers of small granule-like bodies closely packed together. Each of these possesses a somewhat large nucleus, with a very small amount of surrounding protoplasm. From the cell body three or four, or perhaps five, dendrites and one axon proceed. The **dendrites** are short and radiate out from different aspects of the cell body. They end in tufts of claw-like twigs, which either embrace or are otherwise in contact with neighbouring granule cells. The whole multitude of granule cells, therefore, are brought into intimate connexion with each other. The **axon** passes into the molecular layer, in which it ends at a varying

distance from the surface by dividing into two branches. These diverge so sharp each other that they almost form a right angle with the parent stem, and th parallel to the long axis of the folium, threading their way between the branche various dendritic planes of the cells of Purkinje and entering into contact associati them. When the great number of granule cells is borne in mind, and the fact th sends an axon into the molecular layer, the important part which these fibres, wi longitudinal branches, take in building up the molecular layer will be understood. are found pervading its entire thickness—from the surface down to the bodies of t of Purkinje.

Near the cells of Purkinje a few scattered cells are seen in the granular la different kind. These are much larger t ordinary granule cells, and are probably nature of association cells. They are ste form, and have numerous long branching d and an axon which divides up in the g layer to a singular extent.

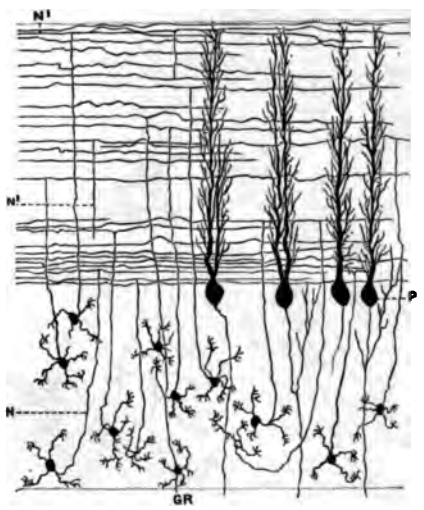

FIG. 414.—SECTION THROUGH THE MOLECULAR AND GRANULAR LAYERS IN THE LONG AXIS OF A CEREBELLAR FOLIUM (after Kölliker).

N¹. Axons of granule cells in molecular layer.

The **white centre** of the folium l thinner as it approaches the summit. Thi to the fibres which compose it gradually e the gray matter on the surface. Thes are of three kinds, viz.: (1) axons of t of Purkinje; (2) fibres which apparen in the granular layer; and (3) fibres end in the molecular layer.

The **axons of the cells of Purki** medullated fibres which, entering the centre of the folium, form a not incons part of it.

The fibres which end in the granul are called **moss-fibres.** This name is ap them because, in the granular laye present at certain points moss-like thic from which short rough twigs proceed.

The fibres which proceed into the m layer give off few or perhaps no branches traverse the granular layer. In the dee of the molecular layer they break varicose branches, which twine arou primary and secondary stems of the Purkinje dendrites.

Entering into the constitution of the **molecular layer** are the following eleme dendrites of the cells of Purkinje; (2) basket-cells and somewhat smaller cells ne surface; (3) axons of the granule cells, with their longitudinally arranged branc the terminations of certain fibres from the white core of the folium, which end in with the Purkinje dendrites.

In the **granular layer** are found: (1) granule cells; (2) larger stellate as cells; (3) axons of the cells of Purkinje; (4) moss-fibres; (5) fibres traversing th to end in the molecular layer.

THE DEEP CONNEXIONS OF THE CRANIAL NERVES ATTACHED TO MEDULLA AND PONS.

There are twelve pairs of cranial nerves, of which the lower eight are a to the medulla and pons Varolii. From above downwards these are nam fifth or trigeminal, the sixth or abducent, the seventh or facial, the ei auditory, the ninth or glossopharyngeal, the tenth or vagus, the eleventh c accessory, and the twelfth or hypoglossal. The hypoglossal, the spinal ac the greater part of the facial, the abducent, and the motor root of the tri are efferent nerves; the auditory, the pars intermedia of the facial, and the root of the trigeminal are purely afferent nerves: whilst the vagus and the pharyngeal are composed of both efferent and afferent fibres. In all cases fibres arise from ganglionic cells placed outside the brain and penetrate th *stem, to end in connexion* with the cells of certain **nuclei of termination.**

res, on the other hand, take origin within the brain as the axons of cells which grouped together in certain places in the form of **nuclei of origin.**

Nuclei of Origin, or Motor Nuclei.—In the spinal cord the nuclei of origin are presented by elongated columns of cells which run more or less continuously in anterior horn of gray matter of successive cord-segments, and from these the series efferent anterior nerve-roots take origin. In the medulla and pons the nuclei of gin, or, in other words, the motor nuclei of the individual nerves become, for the st part, discontinuous, and are represented by certain isolated clumps of compact y matter, in which are placed the clusters of cells from which the fibres of the erent nerves arise. The nucleus ambiguus, however, which consists of a column of ls from which root fibres of the medullary part of the spinal accessory, of the vagus, d possibly also of the glossopharyngeal are derived, is an exception to this rule. the decussation of the pyramids, the anterior horn of gray matter of the cord is oken up by the intercrossing bundles into a detached head and a basal part which mains in relation with the ventro-lateral aspect of the central canal. Certain the efferent or motor nuclei of the medulla and pons lie in the line of the basal rtion of the ventral horn of gray matter of the spinal cord, and thus close to e mesial plane. These are termed **mesial nuclei of origin**, and are met with at ferent levels in the brain-stem. This group comprises the hypoglossal nucleus, e dorsal motor nucleus of the vago-glossopharyngeal nerve, the abducent nucleus nd, in the mesencephalon, the trochlear nucleus and the oculo-motor nucleus). ther motor nuclei of origin are present in the form of isolated clumps or columns gray matter, which lie at different levels in the medulla and pons in the line of e detached head of the anterior horn of gray matter. They are the nucleus mbiguus of the spinal accessory, the vagus and glossopharyngeal, the facial ucleus, and the nucleus of the motor root of the trigeminal nerve. From their osition in the tegmental substance of the medulla and pons they constitute a group to which the name of **lateral motor nuclei** is applied.

The different nuclei of origin of the efferent fibres which belong to the various cranial nerves, both mesial and lateral, are connected with the motor area of the cerebral cortex by fibres from the pyramidal tract, which enter the nuclei and end in connexion with their cells.

Nuclei of Termination.—In the brain the nuclei of termination are likewise discontinuous, and are represented by more or less isolated clusters or columns of cells. Unlike the motor nuclei, however, these nuclei show no regular or definite position within the medulla and pons. Some are found in the gray matter which surrounds the central canal, and in its continuation upwards as the gray matter in the floor of the fourth ventricle; others are placed in the tegmental substance; whilst two actually lie on the surface of the brain-stem, viz. the lateral and ventral nuclei of the cochlear or outer division of the auditory nerve.

The axons of the cells of the nuclei of termination enter the reticular formation of the tegmental substance as arcuate fibres, and, crossing the mesial plane, are carried upwards in the tegmental substance of the opposite side to establish direct connexions with the optic thalamus and indirect connexions with the cerebral cortex.

Hypoglossal Nerve (nervus hypoglossus).—The nucleus of origin of the hypoglossal nerve, the motor nerve of the tongue, lies in the substance of the medulla oblongata. It is composed of several groups of large multipolar cells, which closely resemble the cells in the ventral horn of gray matter in the spinal cord, and is pervaded by an intricate network of fine fibrils. In form it is elongated and rod-like, and in length it is somewhere about 18 mm. It extends from a point immediately above the decussation of the pyramids up to the level of the striæ acusticæ. The lower portion of the nucleus is thus placed in the closed part of the medulla (Fig. 397, p. 493), whilst its upper part is situated in the open part of the medulla (Fig 402, p. 497). The former lies in that part of the central gray matter which is continuous with the basal part of the ventral horn of gray matter of the cord. It is thus placed on the ventral and lateral aspect of the central canal, close to the *mesial plane and the corresponding* nucleus of the opposite side. The *upper part of the nucleus occupies a position* in the gray matter on the floor of

the fourth ventricle, subjacent to the inner part of the surface area, which has been described under the name of the trigonum hypoglossi. Within the nucleus the axons of the cells arrange themselves in converging bundles of fine fibres, which come together and leave the ventral aspect of the nucleus as the fasciculi of the nerve. The nerve bundles thus formed traverse the entire antero-posterior thickness of the medulla between the formatio reticularis grisea and the formatio reticularis alba, and emerge on the surface in linear order at the bottom of the furrow between the olivary eminence and the pyramid. In the substance of the medulla the root-bundles of the hypoglossal pass between the main inferior olivary nucleus and the mesial accessory olivary nucleus, and many of them on their way to the surface pierce the ventral lamina of the main olivary nucleus.

No decussation between the nerves of opposite sides takes place in the medulla, but commissural fibres pass between the two nuclei (Kölliker). Further, numerous fibres from the opposite pyramidal tract enter the nucleus and end in connexion with its cells. The nucleus is thus brought into connexion with the motor area of the opposite side of the cerebral cortex.

Spinal Accessory Nerve (nervus accessorius).—The spinal accessory is likewise a motor nerve, and it is generally described as consisting of a spinal and a medullary or accessory part.

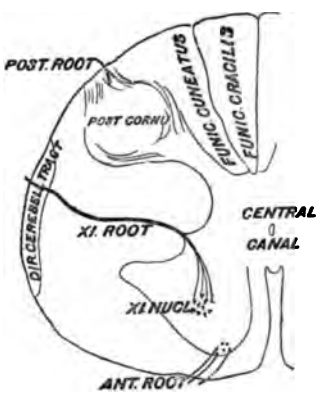

FIG. 415.—DIAGRAM OF THE SPINAL ORIGIN OF THE SPINAL ACCESSORY NERVE (after Bruce).

FIG. 416.—SECTION THROUGH THE UPPER PART OF THE CERVICAL REGION OF THE CORD (Orang), Showing the origin of the spinal part of the spinal accessory nerve.

The **spinal part** of the nerve emerges by a series of roots which issue from the surface of the lateral column of the upper part of the cord as low down as the fifth cervical nerve. These take origin in a column of cells situated in the anterior horn of gray matter of the cord close to its lateral margin, and immediately behind the nerve-cells which give rise to the fibres of the anterior roots of the upper five cervical nerves. The cells of the accessory nucleus are large, multipolar, and in every respect similar to the motor cells of the spinal nerves. The axons from these cells leave the dorsal aspect of the nucleus in converging groups to form the root-bundles of the nerve. These, in the first place, proceed straight backwards in the anterior horn of gray matter. Reaching the bay between the two horns of gray matter, they turn sharply outwards into the white matter and traverse the lateral column to gain their points of exit from the cord. At the decussation of the pyramids, root-bundles, which join the spinal accessory nerve, are seen to proceed from the detached head of the anterior horn of gray matter.

The **medullary part** of the spinal accessory nerve has its nucleus of origin in the medulla; and its root-bundles, as they proceed outwards from this, can be distin-

ished by the fact that they pursue a course on the ventral side of the spinal root the trigeminal nerve, whereas the vagus roots, with which they are apt to be infused, pass through or lie on the dorsal aspect of the trigeminal root (Kölliker). e nucleus of origin of the medullary part of the accessory nerve is formed by the ine column of cells which constitutes the **nucleus ambiguus**, and which, at a higher el, gives motor fibres to the vagus and glossopharyngeal nerves.

The part of the spinal accessory nerve which takes origin in the spinal cord supplies the sterno-mastoid and trapezius muscles. The medullary or accessory portion joins the vagus, and hrough the external and recurrent laryngeal nerves it supplies the muscles of the larynx. The rtion of the nucleus ambiguus from which it arises has thus been termed the laryngeal nucleus Ellinger).

Collaterals and fibres of the opposite pyramidal tract end in connexion with the cells of rigin of the accessory nerve, and thus bring its nucleus into connexion with the motor area of e cerebral cortex. Fibres also from the posterior roots of the spinal nerves (afferent or sensory ves) end in the nucleus.

Vagus and Glossopharyngeal Nerves (nervus vagus, nervus glossopharyngeus).—These nerves present similar connexions with the brain, and they may herefore be studied together. The greater part of both nerves is composed of fferent fibres, which arise outside the brain-stem from ganglionic cells placed in elation to the nerve-trunks. Both nerves likewise possess motor or efferent fibres, which spring from two special nuclei of origin situated within the medulla and rmed respectively the **dorsal motor nucleus** and the **nucleus ambiguus**. The afferent anglionic fibres of the vagus and glossopharyngeal enter the brain by a series of oots which penetrate the medulla along the outer or ventral side of the restiform ody. Within the medulla they separate into two sets, viz. a series of bundles chiefly composed of vagus fibres), which end in the **dorsal nucleus of termination** f the vagus and glossopharyngeal nerves, and another series of bundles (chiefly mposed of glossopharyngeal fibres), which join a conspicuous longitudinal tract f fibres called the **fasciculus solitarius**.

The **dorsal nucleus** (Figs. 398, p. 495, and 402, p. 497) of the vagus and glossopharyngeal nerves is mixed, and contains both motor cells which give origin to fferent fibres and cells around which afferent fibres of the vagus, and possibly also the glossopharyngeal nerve, break up into terminal arborisations. It very nearly uals in length the nucleus of the hypoglossal nerve, with which it is closely lated. Above, it reaches as high as the striæ acusticæ, whilst below its lower end lls slightly short of that of the hypoglossal nucleus. In specimens stained by e Weigert-Pal method the two nuclei offer a marked contrast. The hypoglossal ucleus presents a dark hue, owing to the enormous numbers of fine fibres which rine in and out amidst its cells; the vago-glossopharyngeal dorsal nucleus is pale om the scarcity of such fibres within it. In the closed part of the medulla the rsal vago-glossopharyngeal nucleus lies in the central gray matter immediately hind the hypoglossal nucleus, and upon the lateral aspect of the central canal; the open part of the medulla it lies in the gray matter of the floor of the fourth ntricle, immediately to the outer side of the hypoglossal nucleus and subjacent the surface area termed the trigonum vagi.

The cells in the portion of the dorsal nucleus which acts as a *nucleus of rmination* are spindle-shaped in form and similar to those found in the posterior orn of gray matter in the cord. In connexion with these cells, the greater umber of the afferent fibres of the vagus nerve, and a small proportion of the fferent fibres of the glossopharyngeal nerve end in fine terminal arborisations. A small part of the upper portion of the nucleus may be said to belong to the glosso-pharyngeal nerve and the remainder of the nucleus to the vagus nerve.

The cells which constitute the *dorsal motor* or *efferent nucleus* as seen in transverse section appear in a more or less compact cluster, which lies immediately to he outer side of the hypoglossal nucleus. These cells, although very conspicuous, re not so large as those in the hypoglossal nucleus, nor as those in the anterior orn of gray matter of the cord; nor do they stain so deeply.

The **fasciculus solitarius** (Figs. 397, p. 493; 398, p. 495; and 402, p. 497) is a ound bundle of longitudinal fibres which forms a very conspicuous object in transverse sections through the medulla. It begins at the upper limit of the medulla,

and can be traced downwards through its whole length. Its precise p
termination is not known, but it is believed that it is carried for some d
downwards into the upper part of the cord, viz. to the level of the fourth
nerve, according to Kölliker. The relations of the fasciculus solitarius
the same in all parts of its course. It lies immediately to the outer side
dorsal vago-glossopharyngeal nucleus; but whereas in the upper part of the

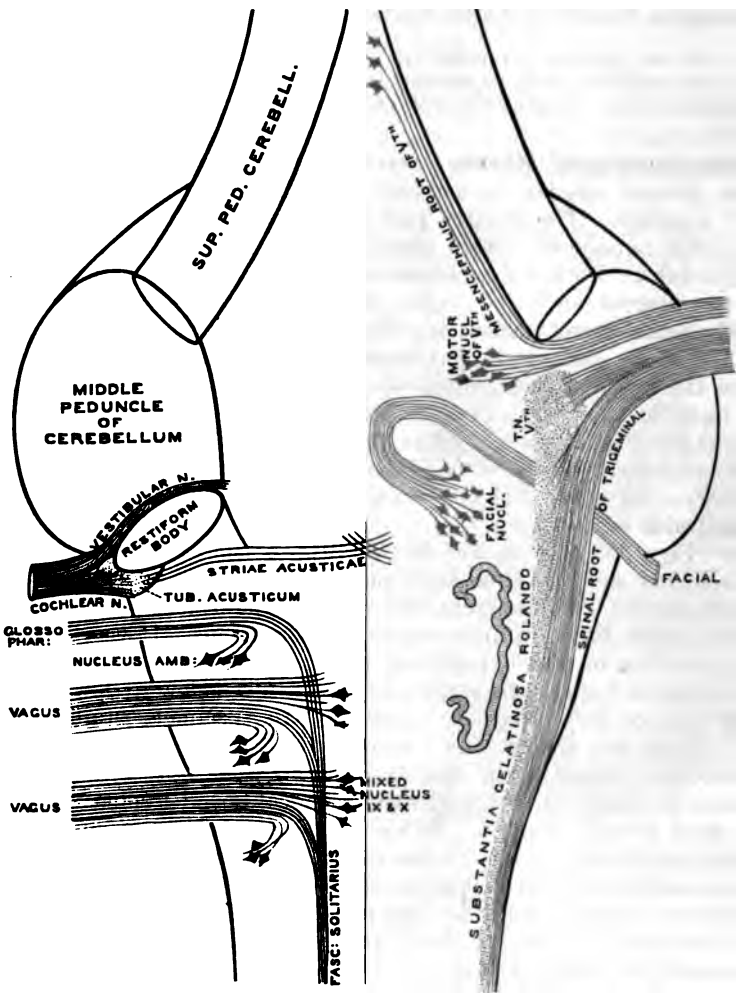

FIG. 417.—DIAGRAM, showing the brain connexions of the vagus, glosso-pharyngeal, auditory, facial, abducent, and trigeminal nerves.

As th
bundles of t
and the
pharyngeal
traverse the substance of the medulla in a backward and inward direction to r
fasciculus solitarius and the dorsal nucleus of termination, they pass through t
root of the trigeminal nerve and the substantia gelatinosa Rolandi associated
The term **ascending root** is sometimes applied to the fasciculus solitarius; but
conveys an altogether false conception of its character it should be discarde
axons of the nucleus of termination and of the nucleus of the fasciculus s
form central connexions with other parts of the brain, but these have not as
completely elucidated.

The **dorsal efferent nucleus** gives off fibres which join the afferent fibre
vago-glossopharyngeal rootlets as they traverse the medulla, and mixin
them they pass along the same path to emerge from the medulla.

The **nucleus ambiguus** (Figs. 398, p. 495, and 402, p. 497) also gives o

motor or efferent fibres which join the vagus and glossopharyngeal nerves. The cells which compose it are large, multipolar, and similar in every respect to the large cells in the ventral horn of gray matter of the spinal cord. These cells are arranged in a slender column which is best developed in the upper open part of the medulla. Here the nucleus can easily be detected in transverse sections as a small area of compact gray matter which lies in the formatio reticularis grisea, midway between the dorsal accessory olive and the substantia gelatinosa Rolandi. It therefore lies more deeply in the substance of the medulla than the mixed dorsal vago-glossopharyngeal nucleus. Kölliker states that it can be traced downwards as low as the level of the decussation of the fillet, and upwards as high as the place of entrance of the cochlear root of the auditory nerve. From its dorsal aspect the axons of the cells proceed, and in the first instance they pass backwards towards the floor of the fourth ventricle; then, bending suddenly outwards and forwards, they join the afferent roots of the vagus and possibly also of the glossopharyngeal nerves, and emerge from the brain in company with these.

Upon anatomical grounds it might be questioned whether the glossopharyngeal nerve contains any efferent fibres. It gives off, it is true, one motor branch, viz. to the stylo-pharyngeus muscle, but there are paths by means of which these fibres might enter the nerve other than by coming directly from the motor nuclei, which have been described in connexion with the vago-glossopharyngeal nerve-roots.

There is, further, some ground for the belief that all the fibres of the glossopharyngeal pass into the fasciculus solitarius. In a very instructive case described by Alexander Bruce in which the glossopharyngeal was destroyed in the jugular foramen by the pressure of a tumour, no degenerated fibres could be traced beyond the fasciculus solitarius.

Auditory Nerve (nervus acusticus).—This is a large nerve which joins the brain at the lower border of the pons Varolii and on the ventral aspect of the restiform body. It is an afferent nerve, and its fibres spring from bipolar ganglionic cells either within or in the immediate neighbourhood of the labyrinth or internal ear (see section dealing with the organs of sense). Reaching the brain the auditory nerve divides into two parts, viz. the nervus cochlearis and the nervus vestibularis, which present totally different connexions and apparently exercise absolutely distinct functions. In their further course these two divisions deviate from each other so as to embrace the restiform body—the vestibular part entering the pons on the inner or mesial aspect of the restiform body, whilst the cochlear part sweeps round its outer surface. Special nuclei of termination require to be studied in connexion with each part of the nerve.

The **cochlear nerve** is composed of finer fibres than the vestibular nerve, and these acquire their medullary sheaths at a later period. It is the true nerve of hearing, and its fibres end in a ganglion which lies in intimate relation to the restiform body, and which may be described as consisting of two parts. Of these one, called the **tuberculum acusticum** or the **lateral cochlear nucleus**, is a pyriform mass which is placed on the outer aspect of the restiform body—between it and the flocculus of the cerebellum. The second part, termed the **ventral cochlear nucleus**, does not extend so low down as the tuberculum acusticum. It is a wedge-shaped nuclear mass which is placed on the ventral aspect of the restiform body in the interval between the cochlear and vestibular divisions of the auditory nerve, after they have separated from each other. The fibres of the cochlear nerve enter these two ganglia and end around the cells in terminal arborisations, which are finer, closer, and more intricate than those met with in any other nerve nucleus in the brain.

The **vestibular nerve** enters the brain at a slightly higher level than the cochlear nerve and on the mesial aspect of the ventral cochlear nucleus. It forces its way backwards through the pons between the restiform body, which lies on its outer side, and the spinal root of the fifth nerve, which is placed on its inner side. Its fibres come to an end in three nuclei of termination, which are situated in the dorsal part of the pons and medulla, viz. (1) the principal nucleus or dorsal nucleus; (2) the nucleus of the descending root; and (3) the nucleus of Deiters.

The **principal nucleus** (Figs. 403, p. 500, and 418, p. 520) is a large diffuse nuclear mass, which lies in the floor of the fourth ventricle subjacent to the surface

district known as the *area acustica* (Fig. 391, p. 487). It is situated, therefore, both the pons and the medulla to the outer side of the fovea superior and the fo inferior. In transverse section it is prismatic in outline, and crossing the surf of its upper or pontine p immediately under t ependyma of the ventri are the striæ acusticæ.

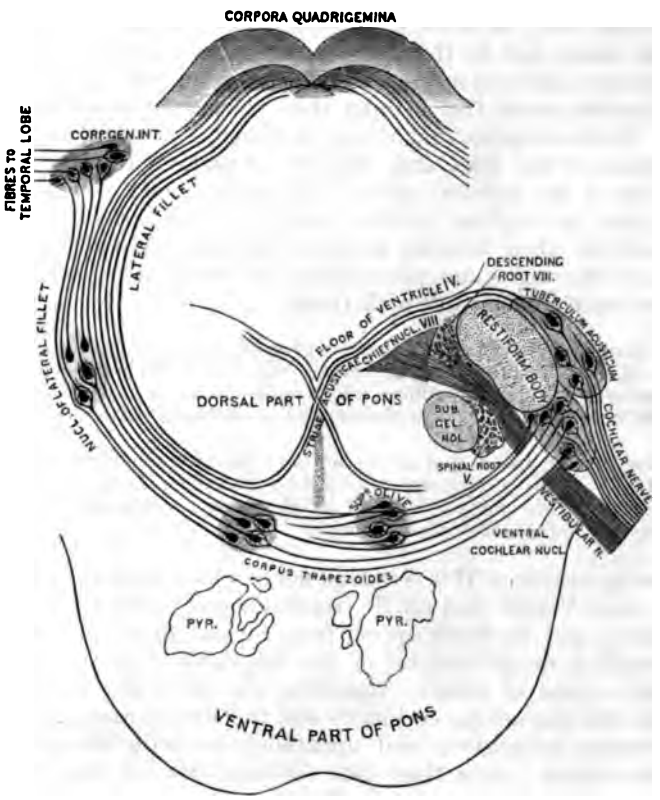

FIG. 418.—CENTRAL CONNEXIONS OF THE COCHLEAR AND VESTIBULAR DIVISIONS OF THE AUDITORY NERVE.

(Diagram founded on drawings by Edinger and Ferrier and Turner.)

When the nervus ve bularis, as it traverses brain, reaches the in aspect of the dorsal port of the restiform body very large proportion its fibres turn vertica downwards in separ bundles and form the scending root of the ve bular nerve (Figs. 398 495; 402, p. 497; 4 p. 500; 418, p. 5 This proceeds through lower part of the pons i the medulla, in which may be traced as far the level of the decu tion of the fillet. sociated with the desce ing root there is a colu of gray matter, with ne cells strewn spars throughout it. This the **nucleus of the scending root**, and fibres end in fine arbor tions around these ne cells.

The fibres of the vestibular nerve likewise end in the **nucleus of Deiters.** T nucleus is composed of a number of large and conspicuous multipolar nerve-c which are scattered amidst the bundles of the upper part of the descending r of the vestibular nerve. As it is traced upwards into the pons the nucl gradually inclines backwards, and finally it occupies a place in the lateral wal the fourth ventricle. It attains its greatest development at the level of emerging part of the facial nerve, and this upper part is sometimes termed **nucleus of Bechterew**.

Central Connexions of the Cochlear Nerve.—The cochlear nerve is brou into connexion with the inferior quadrigeminal body, and the corpus geniculat internum of the opposite side by the fibres of the corpus trapezoides and the lat fillet. But this connexion is not direct; the chain is composed of several separate l or neurons superimposed one over the other.

The fibres of the cochlear nerve end in the ventral cochlear nucleus and in the tu culum acusticum. From the cells of these nuclei two tracts arise, viz. a **ventral t** composed of the fibres of the corpus trapezoides, and a **dorsal tract**, which is represe by the striæ acusticæ.

The **corpus trapezoides** (Figs. 418 and 419) is formed of the axons of the cells o ventral cochlear nucleus, as well as certain of the axons of the cells of tuberc acusticum. In the midst of the corpus trapezoides are lodged large cells which are kn as the *nucleus trapezoideus*, and these give off axons which join the strand with w they are associated. Further, the *superior olive* forms an important internode in path of the corpus trapezoides. Many of the fibres of the corpus trapezoides end in

[illegible]node, whilst others are added to the tract from the cells of that nuclear mass. So [illegible]stituted, the trapezial fibres cross the mesial plane and decussate with the correspond-[illegible] fibres of the opposite side. Reaching the opposite superior olivary nucleus a further [illegible]change of fibres takes place, and almost immediately after this the strand turns [illegible]wards and becomes the **lateral fillet** (Figs. 405, p. 503; 406, p. 504). But still [illegible]other nucleus is interposed in its path, viz. the *nucleus of the lateral fillet*. Here [illegible]me fibres are dropped, whilst from the nuclear cells others are acquired, and the lateral [illegible]et then proceeds onwards without further interruption until it reaches the inferior [illegible]adrigeminal body and the corpus geniculatum internum, in which its fibres end. It is [illegible]obable, however, that some likewise extend into the superior quadrigeminal body.

But the lateral fillet also includes the fibres of the **striæ acusticæ** of the opposite [illegible]de. These fibres arise from the cells of the tuberculum acusticum, and arrange them-[illegible]lves in the conspicuous bundles which sweep round the dorsal aspect of the resti-[illegible]rm body and proceed inwards across the floor of the fourth ventricle, immediately [illegible]neath the ependyma (Fig. 391, p. 487). Reaching the middle line they dip forwards [illegible]to the substance of the medulla, and, crossing the mesial plane, they join the lateral [illegible]llet.

It is well to remember that the connexion between the terminal cochlear nuclei and [illegible]he inferior quadrigeminal body is not altogether with that of the opposite side, as the [illegible]regoing description and the diagram (Fig. 418) might lead one to infer. A few fibres [illegible]ass directly to the inferior quadrigeminal body of the same side, but none to the corre-[illegible]ponding corpus geniculatum internum: the connexion with the latter is entirely *crossed* [illegible]Ferrier and Turner).

From the corpus geniculatum internum there proceeds a tract to the gray cortex of [illegible]he superior convolution of the temporal lobe. The whole nervous apparatus is thus [illegible]inked on to the cerebral cortex, and the succession of neurons which build up the entire [illegible]hain are therefore: (1) the bipolar cells of the ganglion spirale; (2) the neurons of the [illegible]erminal cochlear nuclei; (3) the neurons of the superior olive and the nucleus of the [illegible]ateral fillet; (4) the neurons of the corpus geniculatum internum.

It must be borne in mind that all the axons of the cells of the superior olive do not [illegible]join the trapezoid strand. Many leave its dorsal aspect and pass backwards in a group [illegible]called the **pedicle of the superior olive**, to end in the nucleus of the sixth nerve, and, [illegible]through the posterior longitudinal bundle, in the nuclei of the fourth and third nerves. [illegible]In this way the organ of hearing is brought into connexion with the nuclei, which preside [illegible]over the movements of the eyeballs (Figs. 403, p. 500, and 420, p. 523).

Central Connexions of the Vestibular Nerve.—Although the central connexions of the vestibular nerve have been closely studied by many observers, they are still very far from being fully understood. The principal nucleus and the nucleus of Deiters both stand in intimate relation with the superior vermis of the cerebellum; and in consideration of the fact that the vestibular nerve is the nerve of equilibration, this is an important and significant circumstance. The strand which establishes this connexion has been termed by Edinger "the direct sensory cerebellar tract," and in all probability it is an efferent tract from the cerebellum. Its fibres arise to a large extent in the cerebellar **roof nuclei** of the opposite side, and, crossing the mesial plane, they sweep forwards around the outer side of the superior cerebellar peduncle as it emerges from the cerebellum to end in the nucleus of Deiters, the chief vestibular nucleus, and very possibly also in the terminal sensory nuclei of certain other cranial nerves, such as the trigeminal, vagus, and glossopharyngeal.

Until the precise nature of the nucleus of Deiters is discovered, the exact character of the central connexions of the vestibular nerve will remain more or less obscure. It cannot be regarded as a nucleus specially given over to the vestibular nerve. Composed of large cells scattered amidst the bundles of the upper part of the descending root of the vestibular nerve, it only becomes a compact nucleus above the level of that nerve, viz. at the point where the restiform body turns backwards into the cerebellum, or, in other words, at the level of the emerging facial nerve and the lower end of the abducent nucleus. Here, in the outer part of the floor of the fourth ventricle, its cells are gathered together in a crowded mass. Deiters himself considered that this nucleus should be regarded as an internode between the cerebellum and the spinal cord, and Ferrier and Turner have brought forward strong evidence in support of this view. Klimoff attaches a very high importance to the direct "sensory" tract of Edinger. From his description it would appear that he regards it as the only cerebellar efferent tract which takes a downward direction. He believes, further, that the axons of the cells of Deiters form the anterior marginal tract of Lowenthal (tractus vestibulo-spinalis of Monakow), which

descends in the antero-lateral column of the cord as far as the lumbar region. I supposed that the fibres of this tract end in the cord in arborescent terminations am the motor cells in the ventral horn of gray matter.

From what has been said it must be apparent that the nucleus of Deiters plays a q important part in connexion with the maintenance of the equilibrium of the body; the co-ordination of its muscular movements. Thus it constitutes an internode in path of those fibres which connect the cortex and roof nuclei of the cerebellum with motor apparatus of the spinal cord; it receives fibres through the vestibular nerve f the labyrinth of the ear; and it sends fibres into the posterior longitudinal bun through which it in all probability exercises some influence over the nuclei of the ca nerves.

Opinion is also divided as to the composition and nature of the so-called descend root of the vestibular nerve. After division of the eighth nerve, Ferrier and Turner w unable to detect any degeneration in this root, and they therefore are inclined to ca question its direct continuity with the nerve. They consider that in all probabilit forms an internuncial connexion between the nucleus of Deiters and the cuneate nucl in which Bruce has seen its lower end to terminate.

Facial Nerve (nervus facialis) (Figs. 419 and 420).—The facial nerve is c posed of two distinct parts, viz. a large efferent or motor portion, the **facial n proper**, and a small efferent sensory portion termed the **pars intermedia of Wris** The facial nerve emerges from the brain at the lower border of the pons, immedia in front and to the inner side of the auditory nerve, whilst the pars interm sinks into the upper part of the medulla between the facial and auditory ne The three nerves, therefore, lie in intimate relation with each other, where are attached to the surface of the brain, and they pass in company into the inte auditory meatus.

The nucleus of origin of the facial nerve is an oval mass of gray matter, about mm. in length, and containing numerous groups of large multipolar cells. It unk deeply in the dorsal or tegmental part of the lower portion of the pons rolii, and is placed close to the inner side of the spinal root of the fifth nerve. en transverse sections are made through the brain-stem, the facial nucleus is ountered the moment the boundary line between the medulla and pons is ed, and the region immediately above the inferior olivary nucleus is reached. first it lies so deeply in the tegmentum of the pons that it actually rests upon dorsal aspect of the corpus trapezoides; but a little farther up the superior e comes into view, and insinuates itself between the facial nucleus and the ezial fibres. The upper part of the nucleus is in this way tilted somewhat kwards, and thus comes to lie on the dorsal and outer aspect of the superior e.

The facial nucleus is situated close to the place where the nerve emerges from brain, but the nerve does not at once pass to this point of exit. It pursues ng and devious path within the pons before it finally reaches the surface. is intrapontine part of the nerve may be divided into three parts, viz.: (1) a icular part, (2) an ascending portion, and (3) an emergent part.

The **radicular part of the facial nerve** (Fig. 420) is composed of a large number ine loosely-arranged bundles of fibres, which issue from the outer and dorsal ct of the nucleus and proceed backwards and slightly inwards through the s. Reaching the floor of the fourth ventricle they curve inwards, and the dles which lie highest up sweep over the outer and dorsal aspect of the lower of the nucleus of the sixth nerve. Close to the mesial plane they turn ply upwards and are collected into a single solid nerve-bundle, which consti- s the **ascending part of the facial nerve** (Figs. 419 and 420). This proceeds ically upwards immediately eath the ependyma of the tricular floor, on the dorsal ct of the posterior longitudinal dle, and along the inner side he sixth or abducent nucleus a distance of about five milli- res. Suddenly the nerve bends wards at a right angle, and ves a second time over the sal aspect of the sixth or lucent nucleus. The nerve now ses straight to the place of exit m the brain, and this part of intrapontine trunk may be med the emergent portion (Figs.) and 420). The facial nerve is forms a curved loop over the sal aspect of the abducent cleus. The **emergent part** of nerve takes an oblique course ough the pons to reach the face. It inclines outwards and wnwards as it proceeds towards e ventral aspect of the pons, d on its way it passes between own nucleus and the spinal root the fifth nerve.

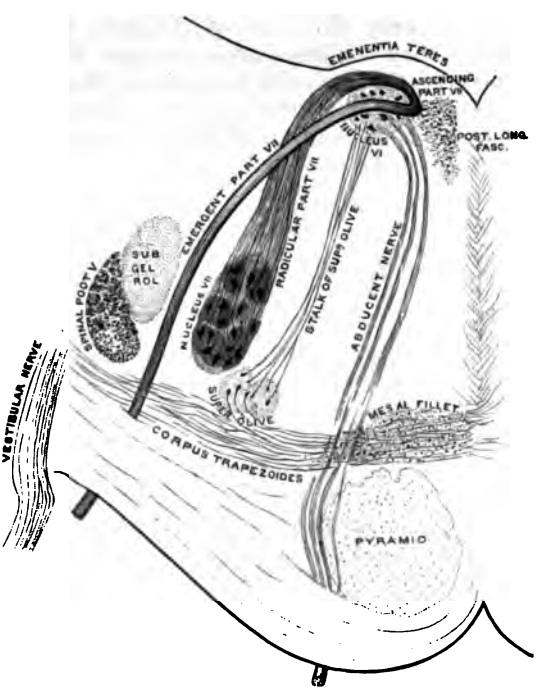

FIG. 420.—DIAGRAM OF THE INTRAPONTINE COURSE PURSUED BY THE FACIAL NERVE.

Entering the facial nucleus, and ending in fine terminal arborisations around its cells, are my fibres from the opposite pyramidal tract; fibres from the spinal root of the fifth nerve; res from the corpus trapezoides, etc. The nucleus is thus brought into connexion with the otor area of the cerebral cortex, with the trigeminal nerve or sensory nerve of the face, and th the auditory nerve, etc.

The fibres of the **pars intermedia of Wrisberg** arise from the cells of the g... culate ganglion of the facial nerve. These, like the cells of a spinal ganglion, ... unipolar, the single process in each case dividing into a peripheral and a ce... branch. The group of peripheral fibres represent the chorda tympani branc... the facial nerve, whilst the central fibres form the pars intermedia. The la... penetrate the brain, and, passing either through or on the dorsal side of the s... root of the fifth nerve, they finally reach the upper part of the column of g... matter in connexion with the fasciculus solitarius, and in this they end. The p... intermedia presents, therefore, the same terminal connexions within the brain ... the glossopharyngeal nerve.

Efferent secretory fibres are also described as being present in the pars intermedia. Th... are said to spring from cells which constitute a *salivary nucleus* placed in the pons on the dor... aspect of the facial nucleus.

Abducent or Sixth Nerve (nervus abducens) (Figs. 419 and 420).—This is ... small motor nerve which emerges from the brain at the lower border of the po... on the outer side of the pyramid of the medulla. It is the nerve of supply to ... the external rectus muscle of the eyeball. Its nucleus of origin is a smal... spherical mass of gray matter, containing large multipolar cells, which lies in ... the dorsal part of the tegmental portion of the pons, close to the mesial plane and ... immediately subjacent to the gray matter of the floor of the fourth ventricle. Its ... position can be easily indicated on the ventricular floor, seeing that it is placed ... subjacent to the eminentia teres and immediately above the level of the stri... acusticæ. Its peculiar and intimate relation to the intrapontine portion of the ... facial nerve has already been indicated. It lies on the ventral aspect of, and within ... the concavity formed by, the two limbs of the loop of that nerve.

The axons of the multipolar cells of this nucleus emerge from the inner aspect ... of the nucleus in the form of several bundles, which proceed through the whole ... antero-posterior thickness of the pons towards the place of exit. As they pass ... forwards they incline downwards and slightly outwards. In the tegmental part ... of the pons they proceed forwards on the inner side of the superior olive, whilst in ... the ventral part of the pons they keep for the most part to the outer side of ... the pyramidal bundles, although several of the nerve fasciculi pierce these on ... their way to the surface.

It would appear probable that certain of the axons of the cells of the abducent nucleus enter the posterior longitudinal fasciculus and proceed upwards in it to join the third or oculo-motor nerve of the opposite side. Further mention of these will be made later on. Fibres and collaterals from the pyramidal tract of the opposite side enter the nucleus, and, ending around the cells, bring the nucleus into connexion with the motor area of the cerebral cortex. The pedicle of the superior olive ends partly within the nucleus of the abducent nerve (p. 521).

Trigeminal or Fifth Nerve (nervus trigeminus).—The trigeminal nerve strikes its roots deeply into the brain and establishes a connexion with it which extends from the upper part of the mesencephalon above to the level of the second cervical nerve below. No other cranial nerve presents so extensive a connexion (Fig. 417, p. 518). It is composed of two roots—a large afferent or sensory root and a small efferent or motor root. Both roots appear close together on the surface of the pons, rather nearer its upper border than its lower border, and in the same line as the facial and auditory nerves.

The **sensory root of the fifth nerve** is composed of fibres which arise outside the brain from the cells of the Gasserian ganglion. They end within the brain in two nuclei of termination. One of these is situated in the pons and is termed the sensory nucleus of the trigeminal nerve, and the other is a long column of gray matter which is directly continuous below with the substantia gelatinosa Rolandi of the spinal cord.

The **sensory nucleus** (Fig. 421) is an oval mass of gray matter which is placed half-way up the pons in the outer part of its tegmental portion. It lies close to the outer surface of the pons and immediately subjacent to the ventral submerged margin of the superior cerebellar peduncle. It is directly continuous with the substantia gelatinosa Rolandi, and may be regarded as being merely the enlarged upper end of that column of gray matter.

The fibres of the sensory root of the fifth nerve, on reaching the sensory nucleus, **ide in a manner similar** to the fibres of the entering posterior roots of the spinal **ves into a system** of ascending and descending branches (Fig. 417, p. 518). **ascending fibres** are short, and almost immediately enter the sensory nucleus **l end within it**; the descending fibres turn sharply downwards and form the **spinal t** (**tractus spinalis**: the ascending root of many text-books). This root descends **the outer side** of the column of gray matter formed by the substantia gelatinosa **landi**, which constitutes its terminal nucleus. Fibres constantly leave it to **ter the nucleus**, so that the lower it gets the smaller does the spinal root become **til**, in the upper part of the spinal cord, about the level of the first or second **inal nerve**, it disappears altogether.

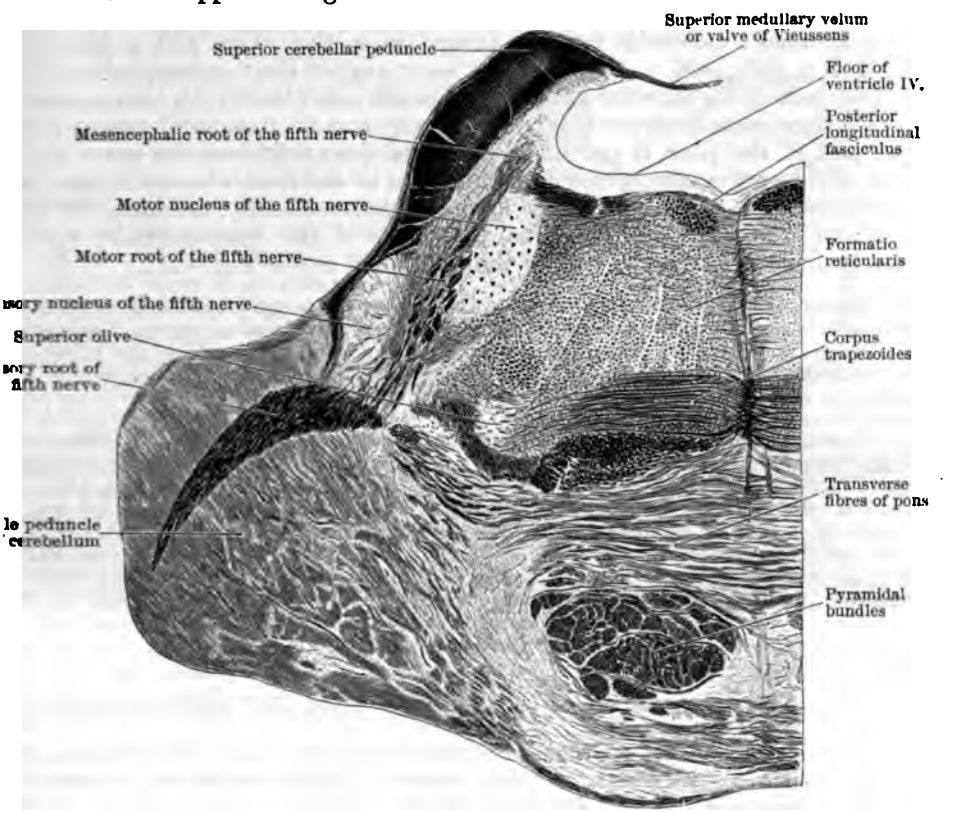

FIG. 421.—SECTION THROUGH THE PONS VAROLII OF THE ORANG, AT THE LEVEL OF THE NUCLEI OF THE TRIGEMINAL NERVE.

The large spinal root of the fifth nerve is a conspicuous object in sections through the is and medulla. In the former it traverses the tegmental part, first, between the ergent part of the facial nerve and the vestibular nerve; and then lower down, between e restiform body and the nucleus of the facial nerve (Fig. 419, A, p. 522). In cross tions it presents a well-defined semilunar or curved pyriform outline. In the upper rt of the medulla it lies on the ventral aspect of the restiform body, and therefore arer to the surface (Fig. 398, p. 495). Here it is traversed and broken up into parate bundles by the cerebello-olivary fibres and the roots of the glossopharyngeal and gus nerves. Finally, it comes to the surface and its fibres are spread over the area on e side of the medulla known as the tubercle and funiculus of Rolando (Fig. 394, 492).

The small **motor part of the trigeminal nerve** is chiefly distributed to the muscles f mastication, and derives its fibres from two sources, viz. from the motor nucleus nd from the mesencephalic root of the trigeminal nerve.

The **motor nucleus** (Fig. 421) lies in the lateral part of the tegmental portion of he pons, close to the inner side of the sensory terminal nucleus, but somewhat

nearer to the floor of the fourth ventricle. It is not placed in the exact line of the facial nucleus, as it is situated somewhat nearer the dorsal aspect of the pons; nevertheless, it may be considered as being equivalent in this region to the detached head of the anterior horn of gray matter in the lower part of the medulla. The cells of this nucleus are large and multipolar, and their axons run together to form the greater portion of the motor root of the fifth nerve.

The **mesencephalic root** takes origin in the mesencephalon from a column of large loosely-arranged cells which are placed in the extreme lateral part of the gray matter which surrounds the Sylvian aqueduct. As the lower end of this column of cells reaches the pontine part of the floor of the fourth ventricle it becomes continuous with the dark cells of the locus cœruleus. The mesencephalic root as it is traced downwards gradually gains strength by the addition of new fibres, and it assumes a crescentic form in transverse section (Figs. 430, p. 535; 432, 537; 407, p. 505; 406, p. 504). In the lower part of the mesencephalon it lies on the inner side of the superior cerebellar peduncle; and the fourth nerve, on its way to the surface, runs downwards in its concavity and on its mesial aspect. In the upper part of the pons, it continues its course downwards on the outer and dorsal aspect of the gray matter which forms the floor of the fourth ventricle, and here it stands in relation to the cells of the locus cœruleus. Finally, reaching the level of the nuclei of the trigeminal nerve, the fibres of the mesencephalic root turn forwards and join the motor part of the trigeminal nerve (Fig. 421).

S. Ramon y Cajal has shown that an intimate relationship is established between the mesencephalic nucleus and the principal motor nucleus of the trigeminal nerve. Large numbers of collaterals from the fibres of the mesencephalic root enter the latter nucleus and break up into close networks around its cells. It has been suggested that through this connexion a weak impulse proceeding from the higher nucleus may be transformed within the lower or principal nucleus into a powerful excitation.

(1) It is not known to what parts the fibres of the mesencephalic root go. Kölliker suggests that they supply the tensor veli palatini and the tensor tympani; perhaps, also, they may be distributed to the mylo-hyoid and the anterior belly of the digastric. (2) Fibres from the opposite pyramidal tract go to the motor nucleus and bring it into connexion with the motor area of the cerebral cortex. (3) By degeneration methods the root of the fifth nerve has been traced down to the level of the second cervical nerve (Ferrier and Turner). (4) The axons of the terminal nuclei emerge as arcuate fibres, and, proceeding through the raphe, assume a longitudinal course in the tegmentum of the opposite side, and thus establish connexions with parts higher up (tractus quinto-thalamicus). (5) Some of the axons of the cells of the terminal nucleus enter the motor nucleus, and thus establish a simple reflex apparatus.

The Development of the Parts derived from the Rhombencephalon.

A general sketch of the development of the medulla, pons, and cerebellum has already been given (p. 476). It is only necessary, therefore, in this section to call attention to some of the more important details connected with the process.

Medulla.—In the embryo the cervical flexure indicates in a sharp and definite manner the point of junction between the cord and the brain (Fig. 382, p. 477). In the early condition of the rhombencephalon the calamus scriptorius extends downwards to this level, so that, in the first instance, there is no part of the medulla which corresponds to the closed portion present in the adult. The lower closed part of the medulla makes its appearance at a later period, and is termed by His the **intercalated portion** (Schaltstück).

In our study of the development of that part of the neural tube which forms the spinal cord we have recognised two thick lateral walls connected in front and behind by narrow mid-ventral and mid-dorsal laminæ. The same parts are seen in the developing medulla. Owing, however, to the expansion of the cavity in this portion of the tube the mid-dorsal lamina is stretched out into an extensive and thin epithelial membrane which forms the dorsal wall or roof of the ventricle in this section of the early brain. The thick lateral walls have also fallen away from each other, and are joined in front by the narrow mid-ventral lamina. On section, therefore, the medullary part of the neural tube presents a triangular figure—the base, which is directed backwards, being formed by the thin epithelial expansion derived from the mid-dorsal lamina, the apex by the narrow mid-ventral lamina, and the sides by the thick lateral walls of the tube. Further, each lateral wall consists of an alar or dorsal and a basal or ventral lamina. This subdivision is more clearly indicated than in the cord, and on the inner surface of the lateral wall a strongly marked longitudinal furrow marks the line of junction of the two laminæ. The histo

›pment of these several parts of the wall of the medullary portion of the ›roceeds in a manner very similar to that already detailed in the case of the uroblasts are formed in the mid-ventral and mid-dorsal laminæ; the entire formation is confined to the basal and alar laminæ. Within the basal lamina, collected the neuroblasts which form the nuclei of origin of the efferent st within the alar lamina are developed the neuroblasts which constitute the mination for the fibres of the es.

›pment proceeds, the two laminæ al wall fall outwards to a still ıt, so that they come to lie very same horizontal plane. In this r originally mesial or ventricular e to form the floor of the fourth Even in the adult the groove, ıtes the basal and alar laminæ om each other in the early con- re or less distinctly perceptible on ar floor. At first the con- the fasciculus solitarius with is very loose, and it may be being the equivalent in this neural tube of the oval bundle ıal fibres which, in the early cord, the first stage of the column

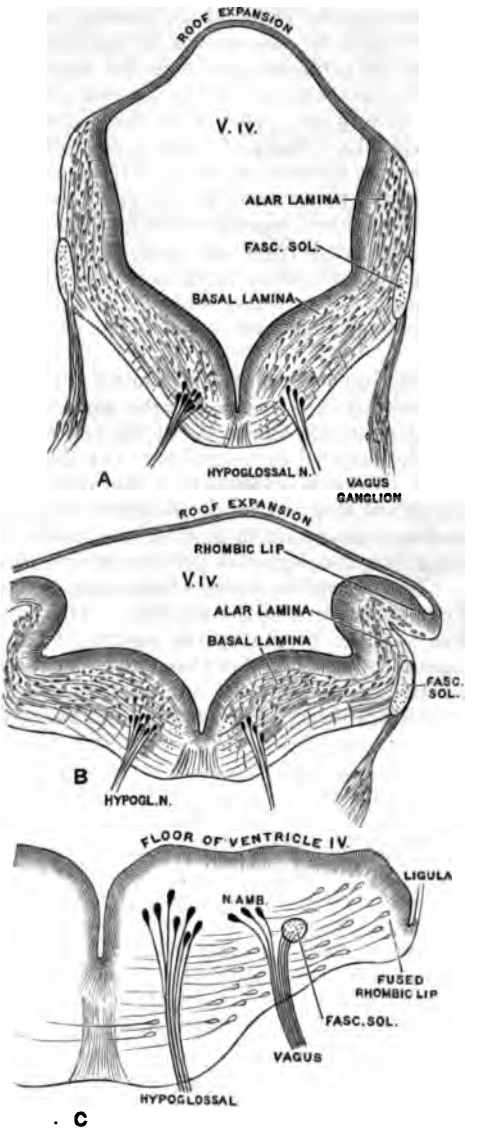

FIG. 422.—THREE STAGES IN THE DEVELOPMENT OF THE MEDULLA OBLONGATA (from His—slightly modified).

Throughout the further stages ıent the fasciculus solitarius in- sufficiently clear manner the point of junction between the alar and e. Very soon it becomes covered over by parts developed on its ventral it ultimately comes to lie deeply in the substance of the medulla. This ıe position of the fasciculus solitarius with reference to the surface is asso- a striking developmental process which leads to certain remarkable results, termed the formation of the **rhombic lip** of His (Fig. 422, B and C). Before ina falls outwards, while it still stands erect and its inner surface faces the g surface of the opposite lamina, its dorsal edge is folded outwards and ed with the outer surface of the remaining portion of the alar lamina. This

is the rhombic lip, and, when the fusion is complete, a multitude of neuroblasts take
within it and migrate in a forward and inwards direction into the ventral parts
alar and basal laminæ. The mid-ventral lamina—which consists of spongioblastic
alone, and which forms a narrow partition between the two basal laminæ—is reach
either side by the axons of many of these migrating cells. Whilst acting as an impe
barrier to the neuroblasts, this spongioblastic septum gives free passage from one
the other to their axons, and a decussation of arcuate fibres in the mesial plane re
In this way the raphe of the medulla is formed. The process is very similar to that w
takes place in the course of the formation of the anterior commissure of the co
which the raphe may be regarded as the equivalent in the medulla.

The development of the inferior olivary nucleus and of its two accessory parts is
wise closely connected with the migration of the neuroblasts from the region of
rhombic lip. Many of these cells collect together so as to form a nuclear lamella, w
afterwards assumes its characteristic crumpled form.

As the neuroblasts of the rhombic lip stream inwards they pass both on the do
and the ventral aspects of the fasciculus solitarius, which thus comes to be covered
and separated from the surface. The spinal root of the trigeminal nerve, like
fasciculus solitarius, is also, in the first instance, throughout its entire course on
surface of the medulla, and its change of position in the greater part of its course wit
the pons and medulla is due to the subsequent development of those parts which cover
over.

The importance of the rhombic lip in the development of the medulla will be bet
appreciated if we enumerate the parts which spring from it: (1) the inferior olivary nuc
(2) the cuneate nucleus; (3) the substantia gelatinosa Rolandi; (4) the arcuate nucle
(5) the internal arcuate fibres; (6) the olivary system of fibres; (7) the restiform bod
From this it is evident that the formation of the rhombic lip constitutes an extreme
important step in the development of the human brain. Recent investigation, howeve
makes it clear that in most of the lower mammals the rhombic lip does not attain an
thing like the degree of prominence which it presents in the early brain of man.

The pyramidal tracts which come down from the cerebral cortex are late in maki
their appearance in the medulla. The formatio reticularis precedes them in development.
They appear in the fourth month of fœtal life, and as they are developed the antero-
median furrow between them takes form on the ventral aspect of the medulla.

His has pointed out that the earliest formed part of the medulla is the floor of the
fourth ventricle, and that the other parts, speaking generally, are added in succession as
we pass towards the surface. "The oldest layer of the medulla is the floor of the fourth
ventricle with its nuclei. It is followed, in the first instance, by the reticular formation,
and afterwards by the layer containing the olivary and other nuclei. Last of all come
the pyramids and the outer (superficial) arcuate fibres" (His).

Pons Varolii.—The information which we possess at the present moment regarding
the development of the pons Varolii is somewhat deficient; but there is little doubt that
the course pursued is, in general, very similar to that which has been described for the
medulla. It has been seen to be composed of parts which are in a great measure
equivalent to those met with in the medulla, the formatio reticularis of the latter
passing into the tegmental substance in the former, while the pyramids and arcuate nuclei
and anterior superficial arcuate fibres of the medulla are represented by the large ventral
part of the pons. Further, as His points out, similar relations between the chronological
and local succession of layers may be recognised. Thus the primitive position of the
motor nucleus of the trigeminal nerve, and also of its spinal root, is a superficial one, and
it is only by a later process of development that the nucleus pontis and the thick layer
of transverse and longitudinal fibres are formed.

From the phylogenetic point of view the tegmentum is the oldest part of the pons.
The study of the comparative anatomy of the brain makes it evident that the large
ventral part is comparatively a recent acquisition. As the cerebral cortex extends with
the increasing evolution of the cerebral hemispheres (pallium), the ventral part of the
pons is seen to keep pace with it in its development. This should easily be understood
from what has been said in regard to its structure and connexions. It is composed
of the nucleus pontis, the transverse fibres, and the pyramidal and cortico-pontine fibres,
all of which stand in direct relation to the cerebral cortex. One of the striking features
of the brain of a microcephalic idiot, where the cerebral cortex is greatly reduced, is the
corresponding marked diminution in the size of the ventral part of the pons.

Cerebellum.—The roof of the fourth ventricle is formed for the most part by the
thin epithelial layer already described as being formed by the expanded mid-dorsal lamina.

s not stretch, however, over its entire extent. As we approach the upper part of ricle, it is seen to become continuous in the region of the isthmus with a thicker

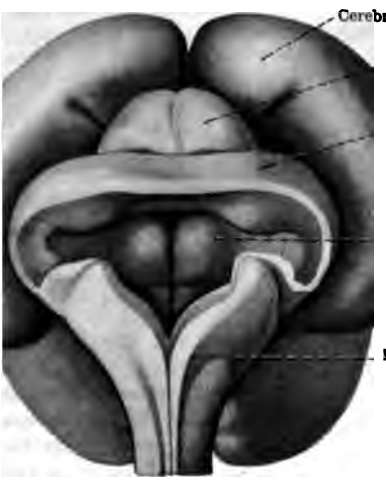
f the fourth ventricle (Fig. 425, A). The lamella which forms the roof or dorsal the ventricle in front of the plica choroidea is developed into the cerebellum, superior medullary velum (valve of Vieussens).

cerebellar part of this lamella consists of two thick lateral plates which meet in the ine and are joined there by an extremely thin dorsal seam or lamina (Fig. 423, A). er extremities of the two cerebellar plates are thus separated by a median groove, pens into the cavity of the hind-brain (fourth ventricle). The statement, there- it the median lobe or vermis of the cerebellum is the most archaic part of the organ and is the part which is developed first is not supported by fact; indeed, the reverse of this is the case, because at this early stage the lateral portions are alone represented.



—THE BRAIN OF AN EMBRYO OF ELEVEN WEEKS, viewed from nd to show the development of the cerebellum. At this stage the ›ellum is in the form of a simple band or plate which arches over ıinder aspect of the fore part of the cavity of the hind brain (from .

In the course of time the inner ends of the cerebellar plates become fused in the middle line, and the median furrow between them disappears. In the process of this fusion the deep part of the intervening furrow remains enclosed within the substance of the median part of the cerebellum and persists for a short time as a minute cerebellar ventricle (Blake).

The cerebellum now presents the appearance of a simple uniform arch which across the dorsal aspect of the upper part of the early fourth ventricle; and very e sulci begin to appear. Of late years the development and morphological import ə sulci have received much attention. Stroud, Kuithan, Blake, Elliot Smith, and have published valuable papers on this subject, and what is written here is gathered from the writings of these observers. Further, the terminology ed by Elliot Smith has been chiefly, but not entirely, followed.

first fissure to appear is the **flocculär fissure**, which cuts off the postero-lateral ›f the cerebellar plate. The portion thus marked off is the **flocculus**, and its early ınce and relatively large size at this stage are significant of its high morphological

importance as a lobule of the cerebellum. The floccular fissure is continued close to the posterior of the cerebellar pla ing its fellow of the (side in the middl Here it receives th of **post-nodular fiss** narrow strip of ce surface is thus mark The median part strip, by special grov comes the **nodulus**, wh part which extends h this and the flocculus narrow and band-lik ultimately forms a of the inferior me velum.

The fissura prima is the deepest of all the of the vermis, and it is developed towards the end of the third month. A little later two other furrows are observed in the vermis. These are the **suprapyramidal** and the **infrapyramidal** (the fissura secunda of Elliot Smith). By the former the pyramid is limited above; by the latter the pyramid is separated from the uvula.

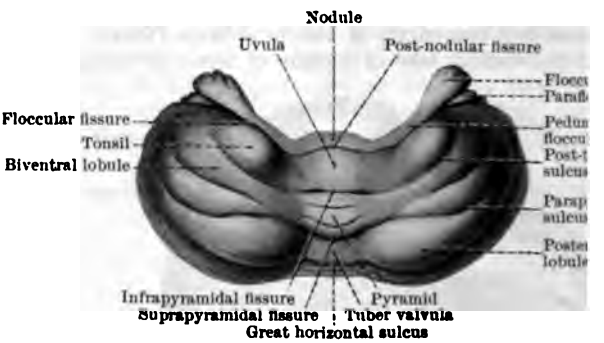

FIG. 426.—UNDER SURFACE OF THE CEREBELLUM OF A HUMA WHICH HAS REACHED THE END OF THE FIFTH MONTH OF DEVE

After the main fissures of the vermis are established, four important sulci on the surface of each cerebellar hemisphere come into view, viz. the postlun post-tonsillar, the parapyramidal, and the great horizontal sulci.

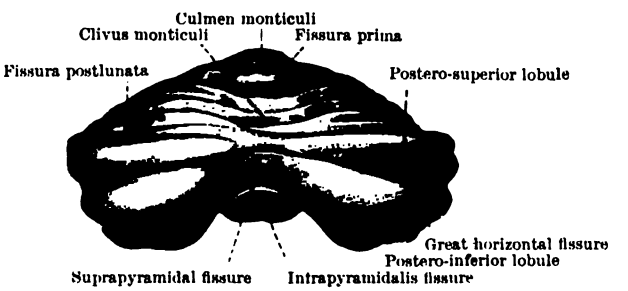

FIG. 427.—CEREBELLUM OF A HUMAN FŒTUS WHICH HAS REACHED THE END OF THE FIFTH MONTH OF DEVELOPMENT. Viewed from above and behind.

The **fissura postlu** pears in the fourth mo curves inwards on th surface of the organ be posterior crescentic lob many cases it becor fluent with its fellow opposite side behind t monticuli. The **post-fissure** is seen on th surface of the cerebellu the beginning of the fift It circumscribes the p and conspicuous to becomes confluent w fissura infrapyramidalis. The **parapyramidal fissure** appears on the under surfa cerebellar hemisphere behind the biventral lobule, and usually joins the suprap fissure of the inferior vermis.

The **great horizontal fissure**, in spite of its depth in the adult brain—a depth which ue to the excessive growth in the later months of development of the two lobules that nd it—appears very late in the development of the cerebellum. It is first seen as a broad shallow groove or furrow on the outer margin of the hemisphere. From this uns forwards to the middle peduncle and backwards towards the vermis, where it ally joins the postlunate fissure. At this stage there is no folium cacuminis, so that combined portion of the postlunate and great horizontal fissures intervenes between clivus monticuli and the tuber valvulæ. Even at the time of birth the folium minis is not seen on the surface. It rises up from the bottom of the combined portions ie great horizontal and postlunate fissures so as to form a barrier between them.

Very early a transverse groove appears on the smooth anterior or ventricular surface ie cerebellum (Fig. 425, B, T). This is placed much nearer the lower than the upper er of the organ, and it represents at this stage the angular peak of the tent-like roof e fourth ventricle in the adult brain. As growth goes on, the portions of the cere- m in front and behind this groove approach each other, so as to deepen the groove ring about the backward prolongation of the ventricular cavity towards the cerebellum.

The leading distinctive characters of the human cerebellum are: (1) the small size e flocculus; (2) the large size of the tonsil; (3) the excessive development of the al hemisphere, and particularly of the postero-superior and postero-inferior lobules h bound the great horizontal fissure.

THE MESENCEPHALON.

The mesencephalon or mid-brain is the short, narrow part of the brain-stem h occupies the aperture of the tentorium cerebelli (incisura tentorii), and ects the cerebrum which lies above with the parts which occupy the posterior ial fossa. It is about three-quarters of an inch in length, and it consists of a al part, composed of the **corpora quadrigemina**, and a much larger ventral part, h is formed by the two **crura cerebri**.

In the undissected brain the corpora quadrigemina are completely hidden from by the splenium of the corpus callosum, which projects backwards over them, also by the superimposed cerebral hemispheres. The hinder end of each optic amus likewise, to some extent, overhangs the upper part of the mesencephalon ts dorsal and lateral aspect (Fig. 388, p. 482). On this portion of the optic amus are seen two projections, which are specially related to the mesencephalon. se are the cushion-like **pulvinar**, which forms the inner and hinder part of the amus, and the **corpus geniculatum externum**, an ill-defined oval swelling on the r and under aspect of the posterior end of the thalamus.

The crura cerebri can to some extent be seen on the base of the brain, where bound the posterior part of the interpeduncular space. Encircling the upper of each crus cerebri, where it plunges into the cerebrum, is the optic tract . 380, p. 474).

The mesencephalon is tunnelled from below upwards by a narrow passage, ed the **aqueduct of Sylvius**, which connects the fourth ventricle with the third tricle (Fig. 429, p. 533). This channel lies much nearer the dorsal than the tral aspect of the mesencephalon.

Corpora Quadrigemina.—This name is applied to four rounded eminences on posterior aspect of the mesencephalon (Fig. 388, p. 482). The **superior pair** are er and broader than the **inferior pair**, but they are not so well defined nor are so prominent. A longitudinal and a transverse groove separate the quad- minal bodies from each other. The longitudinal groove occupies the mesial plane extends upwards to the posterior commissure of the brain. The upper end of groove widens out into a shallow depression, in which the **pineal body**, a small ical structure which belongs to the diencephalon, rests. From the lower end of same groove a short but well-defined and projecting band, the **frenulum veli**, es to the valve of Vieussens, which lies immediately below the inferior pair quadrigeminal bodies. The transverse groove curves round below each of the erior pair of quadrigeminal bodies and separates them from the inferior pair. is also continued in an upward and forward direction on the lateral aspect the mesencephalon.

The quadrigeminal bodies are not marked off laterally from the sides of t mesencephalon, but each has in connexion with it, on this aspect, a promin strand of white matter, which is prolonged upwards and forwards under projecting pulvinar and corpus geniculatum externum. These strands are ca the **brachia of the corpora quadrigemina**, and they are separated from each other a continuation on the side of the mesencephalon of the transverse groove, wh intervenes between the two pairs of bodies.

The **corpus geniculatum internum** (corpus geniculatum mediale) is clo associated with the brachia. It is a small, sharply-defined oval eminence, wh lies on the side of the upper part of the mesencephalon under shelter of the pulvi of the optic thalamus.

The **inferior brachium** (brachium quadrigeminum inferius), proceeding upw from the lower quadrigeminal body, advances towards the corpus geniculat internum and disappears from view under cover of this prominence. Upon t opposite side of the same geniculate body the mesial root of origin of the optic tr takes shape on the surface, and the appearance is such that the conclusion mig very naturally be arrived at that the inferior brachium and this root of the opti tract are continuous with each other under the genic late elevation. This is not the case, however; th fibres of the inferior brachium, to a large exte proceed into the subjacent tegmentum under cover the internal geniculate body and help to constitute ascending tract from the inferior quadrigeminal bod which proceeds upwards to the optic thalamus. Of th fibres of the mesial root of the optic tract some end i the gray matter of the internal geniculate body, whil others arise within it. They constitute what is calle **Gudden's commissure.**

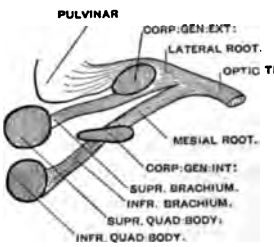

FIG. 428.—DIAGRAM OF THE ROOTS OF THE OPTIC NERVE.

The **superior brachium** (brachium quadrigeminum superius) is carried upwards and forwards between the overhanging pulvinar and the corpus geniculatum internum. A surface examination of the mesencephalon is sufficient to show that, while a large part of this strand enters the corpus geniculatum externum, a considerable portion runs into the lateral root of the optic tract.

The **optic tract** is thus attached to the brain-stem by two roots, viz. a mesial and a lateral, which are separated from each other by a distinct groove. The **mesial root** disappears under the internal geniculate body. The **lateral root** spreads out and some of its fibres enter the superior quadrigeminal body through its brachium, whilst others find their way into the corpus geniculatum externum and the pulvinar of the optic thalamus (Fig. 428).

Crura Cerebri (pedunculi cerebri).—The crura cerebri constitute the chief bulk of the mesencephalon (Fig. 429, p. 533). Upon the basal aspect of the brain they appear as two large rope-like strands, which emerge close together from the upper aspect of the pons Varolii and diverge as they proceed upwards to enter the cerebrum. At the place where each crus disappears into the corresponding side of the cerebrum, it is encircled by the optic tract.

Each crus cerebri is composed of two parts, viz. a **dorsal tegmental part** (tegmentum), which is prolonged upwards into the region below the optic thalamus (subthalamic tegmental region), and a **ventral pedal portion** or **crusta** (basis pedunculi), which, when traced upwards into the cerebrum, is seen to take up a position on the outer side of the optic thalamus and to be continuous with the internal capsule of the brain. When the base of the brain is examined it is the crusta which is seen, and it is observed to be white in colour and streaked in the longitudinal direction. In the tegmentum the longitudinally-arranged fibres are, for the most part, *corticipetal*, or, in other words, fibres which are ascending towards the cortex of the cerebrum; the crusta, on the other hand, is entirely composed of longitudinal strands of fibres which are *corticifugal*, or fibres which descend from the cortex cerebri.

On the surface of the mesencephalon the separation between the tegmental and

ions of the crus cerebri is clearly indicated by an inner and an outer groove.
· or mesial furrow is the more distinct of the two. It looks into the
icular space, and from it emerge the fascicles of the third or oculo-motor
is, therefore, termed the **sulcus oculo-motorii** (sulcus nervi oculo-motorii).
· groove, which is placed on the lateral aspect of the mesencephalon,
ıe name of the **sulcus lateralis mesencephali**. When traced downwards, it
l to become continuous with the furrow which intervenes between the
l superior peduncles of the cerebellum.
ɜ inspection of the outer surface of the tegmental part of the crus cerebri,
level of the quadrigeminal brachia, will reveal some faintly-marked
· fibres curving obliquely upwards and backwards to reach the inferior
inal body (Fig. 390, p. 484). These are fibres of the **lateral fillet**, coming
·face at the sulcus lateralis and sweeping over the subjacent superior
peduncle to gain the inferior quadrigeminal body.

INTERNAL STRUCTURE OF THE MESENCEPHALON.

transverse sections are made through the mesencephalon the aqueduct of

quite three-quarters of an inch in length, and it lies much nearer
than the ventral surface of the mesencephalon. When examined in
section, it presents a triangular outline as it passes into the fourth
ınd a T-shaped outline close to the third ventricle. In the intermediate
ɜ course it assumes different outlines, and not always the same form at
evel in different individuals.
ueduct of Sylvius is lined by ciliated epithelium, and outside this is the
r of Sylvian gray matter, which is directly continuous below with the gray
ead out on the floor of the fourth ventricle, and above with gray matter
or and sides of the third ventricle. Scattered more or less irregularly
t the Sylvian gray matter are numerous nerve-cells of varying forms and
ɜt in addition to these there are three definite collections or clusters of
h constitute the nuclei of origin of the trochlear nerve, the oculo-motor
l the mesencephalic root of the trigeminal nerve. The position and
f these will be given at a later stage.
ıntia Nigra.—When seen in transverse section, the substantia nigra
semilunar outline. It consists of a mass of gray matter, in the midst of
large numbers of deeply pigmented nerve-cells. It is only when this
is examined in bulk that it appears dark; in thin sections it does not
h in colour from ordinary gray matter, although, under the microscope,
-coloured cells stand out very conspicuously, even under low powers.

The substantia nigra is disposed in the form of a thick layer, interposed between the tegmental and pedal portions of the crus cerebri. It begins below at the upper border of the pons Varolii and extends upwards into the subthalamic region. The margins of this layer of dark-coloured substance come to the surface at the oculo-motor and the lateral sulci of the mesencephalon, and its inner part is traversed by the emerging fascicles of the oculo-motor nerve. It is not equally thick throughout. Towards the lateral sulcus it becomes thin, whilst it thickens considerably near the inner aspect of the crus cerebri. The surface of the substantia nigra, which is turned towards the tegmentum, is concave and uniform; the opposite surface is convex and rendered irregular by the presence of numerous slender prolongations of the substance into the crusta.

The morphological and physiological significance of the substantia nigra is not fully understood, and the connexions established by its cells are imperfectly known.

Inferior Quadrigeminal Bodies (colliculi inferiores).—Each of the inferior quadrigeminal bodies is largely composed of a mass of gray matter which, in transverse section, presents an oval outline (Fig. 432, p. 537). This central nucleus is, to a large extent, encapsulated by white matter. Numerous cells of different sizes are scattered throughout it, and the whole mass is pervaded by an intricate interlacement of fine fibres, which, to a large extent, are derived from the lateral fillet and the inferior brachium.

In transverse sections, through this region, the lateral fillet is seen to abut against the outer margin of the central nucleus. Many of the fibres of this tract enter it at once and become dispersed amongst its cells; others sweep over its dorsal surface, so as to give it a superficial covering; whilst a third group is carried in the form of a thin layer inwards on its ventral aspect, so as to mark it off from the subjacent Sylvian gray matter of the aqueduct (Fig. 432, p. 537). In this manner, therefore, the inferior quadrigeminal nucleus becomes partially circumscribed by the fibres of the lateral fillet. Several of the lateral fillet fibres, which proceed over the superficial or dorsal aspect of the nucleus, reach the mesial plane and form a loose decussation with the corresponding fibres of the opposite side.

The intimate connexion which is thus exhibited between the fibres of the lateral fillet and the nucleus of the inferior quadrigeminal body is very significant. It has already been shown that the lateral fillet, to a large extent, comes from the nuclei of termination of the cochlear nerve of the opposite side, although most of its fibres have to pass through several nuclear internodes before they reach the inferior quadrigeminal body. We must associate, therefore, the inferior quadrigeminal body, and also the corpus geniculatum internum, which likewise receives lateral fillet fibres, with the organ of hearing.

This view of the inferior quadrigeminal bodies is supported both by experimental and by morphological evidence. Speaking broadly, it may be stated that the inferior quadrigeminal bodies are only present as distinct eminences in mammals, and then they are invariably correlated with a spirally-wound and well-developed cochlea. That they have nothing to do with sight, is shown by the fact that, when the eyeballs are extirpated in a young animal, the inferior quadrigeminal bodies remain unaffected, whilst the superior quadrigeminal bodies after a time atrophy (Gudden). When, on the other hand, the cochlear terminal nuclei are destroyed, fibres which have undergone atrophy may be followed to the inferior quadrigeminal bodies of both sides, but particularly to that of the opposite side (Baginski, Bumm, and Ferrier and Turner). A very considerable tract of ascending fibres takes origin within the inferior quadrigeminal body and passes upwards, in the inferior brachium, into the tegmentum subjacent to the internal geniculate body. Within the tegmentum they proceed up to the optic thalamus (Ferrier and Turner).

Superior Quadrigeminal Bodies (colliculi superiores).—The superior quadrigeminal body presents a more complicated structure (Fig. 431). Superficially, it is coated with a very thin layer of white matter, which is termed the **stratum zonale**. Underneath this there is a gray nucleus, called the **stratum cinereum**, which in transverse section exhibits a crescentic outline and rests in a cap-like manner upon the subjacent part of the eminence. The succeeding two strata, which respectively receive the names of **stratum opticum** and the **stratum lemnisci**, present this feature in common, that they are composed of gray matter, traversed by numerous fibres. The source from which the fibres are derived differs, however, in each case.

Nerve-fibres reach the superior quadrigeminal body through—(1) the lateral and mesial fillets, and (2) through the superior brachium. The **fillet fibres** enter

stratum lemnisci, and, in all probability, end there. The **superior brachium** ains fibres of two different kinds, viz. fibres from the optic tract and fibres from cortex of the occipital lobe of the cerebrum. By the former it is connected h the retina, and by the latter with the visual centre in the occipital region of cerebral cortex. The *retinal fibres*, for the most part, spread out on the surface the quadrigeminal body and form the stratum zonale. Most of them dip down o the substance of the body and end in connexion with the cells of the deeper ers; several, however, are carried across the mesial plane, to end in the superior drigeminal body of the opposite side. The *occipital fibres*, and probably also e of the retinal fibres, enter the stratum opticum. The fibres from the occipital ex form part of the optic radiation, and the course which they pursue will be lt with later on.

Tegmental Portions of the Crura Cerebri (tegmenta).—The tegmentum of crus cerebri may be regarded as the continuation upwards of the formatio cularis of the medulla the dorsal or tegmental tion of the pons into mesencephalon. It refore consists of fine idles of longitudinal es intersected by arch- fibres, which take a nsverse and curved rse. The interstices ween these nerve- idles is occupied by y matter containing ir- ularly scattered nerve- s. On its dorsal aspect tegmentum is con- uous, at the side of the vian gray matter, with bases of the corpora drigemina, whilst ven- lly it is separated from crusta by the sub- ntia nigra. The two menta of opposite sides , to some extent, marked from each other in the sial plane by a pro- gation upwards of the dian raphe of the pons d medulla, although, in the lower part of the mesencephalon, this is much scured by the decussation of the superior peduncles of the cerebellum. The two gitudinal strands, termed the **posterior longitudinal bundle** and the **fillet**, are olonged upwards throughout the entire length of the mesencephalon; and they esent the same relations to the tegmentum as in the lower parts of the brain. e former is placed in relation to its dorsal aspect, whilst the fillet is carried up its ventral part.

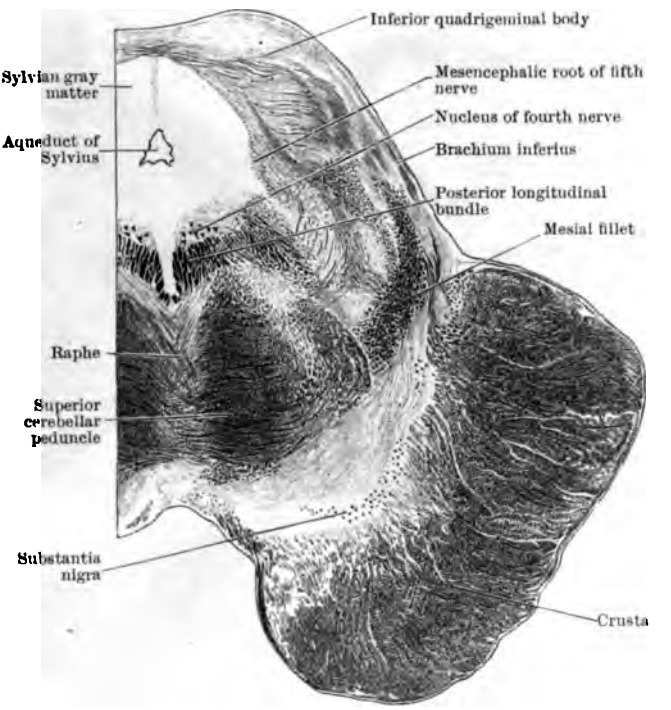

FIG. 430.—TRANSVERSE SECTION THROUGH THE HUMAN MESENCEPHALON AT THE LEVEL OF THE INFERIOR QUADRIGEMINAL BODY.

The tegmentum of the crus cerebri may be considered as presenting two parts: z. (1) a lower part, which is placed subjacent to the inferior quadrigeminal bodies d which is largely occupied by the decussation of the superior cerebellar peduncles ig. 430); and (2) a superior part, subjacent to the superior quadrigeminal dies, which is traversed by the emerging bundles of the third nerve and which ntains a large and striking nuclear mass, termed the nucleus ruber or the red tegental nucleus (Fig. 431). In the lower part of the mesencephalon is the nucleus the fourth nerve; in the upper part, the nucleus of the third nerve.

Superior Cerebellar Peduncles (brachia conjunctiva).—As the superior cere-

bellar peduncles leave the pons and sink into the tegmenta of the mesencephal they undergo a complete decussation subjacent to the inferior quadrigeminal bod and the Sylvian gray matter (Figs. 407, p. 505; 432, p. 537; and 430, p. 5 In this manner each peduncle is transferred from one side, across the me plane, to the opposite side. The decussation is completed at the level the upper borders of the inferior quadrigeminal bodies, and then each pedu proceeds upwards into the superior part of the tegmentum, where it encoun the red nucleus. Into this a large proportion of its fibres plunge and come to end in connexion with the nuclear cells. Many of the peduncular fibres, h ever, are carried around the nucleus so as to form for it a capsule which is thic on the inner than on the outer side (Fig. 431). These are prolonged into subthalamic region, and ultimately penetrate the ventral aspect of the optic tha

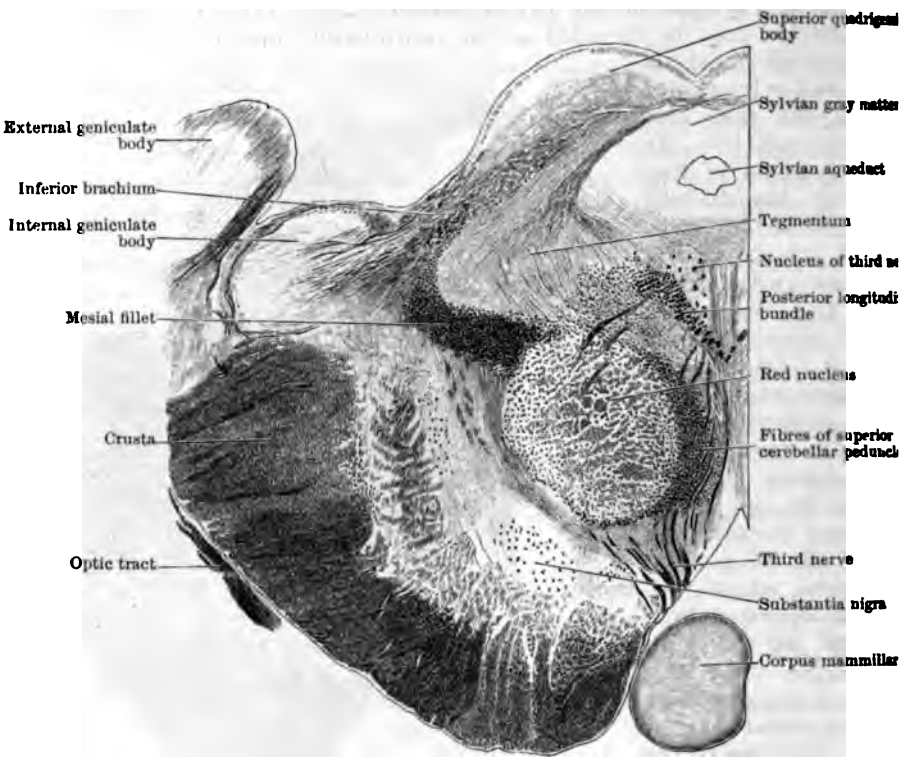

FIG. 431.—TRANSVERSE SECTION THROUGH THE HUMAN MESENCEPHALON AT THE LEVEL OF THE SUP QUADRIGEMINAL BODY.

mus, where they end in connexion with the thalamic cells. The superior cereb peduncle is, therefore, a great efferent tract which issues from the la hemisphere of the cerebellum, crosses the mesial plane in the lower part of mesencephalon, and ends in the red nucleus and the ventral part of the thalamus.

Red Nucleus (nucleus ruber).—This is a rounded nuclear mass, of a red tint in the fresh brain, which lies in the upper part of the tegmentum, and in path of the superior cerebellar peduncle. In transverse section it presents a cir outline. It begins at the level of the lower border of the superior quadrigem body and it extends upwards into the subthalamic tegmental region. At first small and is placed at a little distance from the mesial plane; but as it pro towards the subthalamic region, it increases in bulk and approaches more n to the mesial raphe, and its neighbour of the opposite side. The curved emer bundles of the third nerve pass through it on their way to the surface. relation which the fibres of the opposite superior cerebellar peduncle present has been described. These fibres traverse its lower part in such numbers th Weigert-Pal specimens it presents a very dark colour; but higher up, as the

ually absorbed by the nuclear mass, they become less numerous in its nd the nucleus assumes a paler tint.

rous fibres which descend from the cerebral cortex and others from the corpus striatum red nucleus. It likewise sends out fibres which proceed in two directions: (1) upwards halamus; (2) downwards to the spinal cord. The former may be regarded as carrying ntinuity of the superior cerebellar path after its internodal interruption in the red The fibres to the spinal cord, called the *rubro-spinal tract* and first described by , cross to the opposite side and then descend in the tegmentum to reach the lateral the cord.

erior Longitudinal Fasciculus.—This is a very conspicuous tract of longi- fibres which extends throughout the whole length of the medulla, pons, and phalon, in the formatio reticularis or tegmental part of each. Below, at the the decussation of the pyramids, it becomes continuous with the anterior ndle of the spinal cord (p. 491), whilst, by its opposite or upper end, it ies intricate connexions in .on immediately above the phalon. Throughout its ength it lies close to the plane and its fellow of the side. In the mesen- it is applied to the aspect of the Sylvian gray whilst in the pons and it is situated immediately it to the gray matter of the the fourth ventricle. One iost salient features is the association which it pre- th the three motor nuclei hich the nerves for the f the muscles of the eye- origin, viz. the oculo-motor nucleus, the trochlear or nucleus, and the abducent nucleus. The first two of e closely applied to its inner sal aspect, whilst the ab- nucleus is placed on its de. Into each of these nuclei it sends many collaterals, and probably also its constituent fibres, and these end in terminal arborisations around the cells. It would appear, therefore, that one of the most important functions strand is to bind together these nuclei, and thus enable them to act in y with each other. Fibres also enter the posterior longitudinal fasciculus e auditory system and perhaps, also, from the facial and other motor The results obtained by degeneration would seem to indicate that, to a tent, it is formed of fibres which run a short course within it.

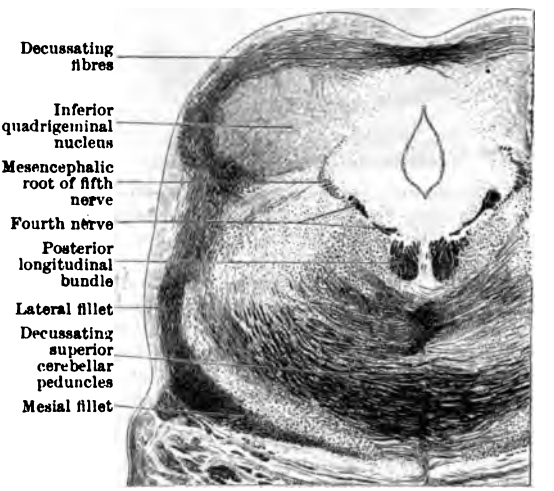

FIG. 432.—SECTION THROUGH THE INFERIOR QUADRIGEMINAL BODY AND THE TEGMENTUM OF THE MESENCEPHALON BELOW THE LEVEL OF THE NUCLEUS OF THE FOURTH NERVE IN THE ORANG. (The decussation of the superior cerebellar peduncles and the course of the fourth nerve in the Sylvian gray matter are seen.)

te of the large amount of attention which has been given to the study of the posterior nal bundle, it must be admitted that there is little unanimity of opinion regarding its as and functions. That it is a brain tract of high importance, is evident from the fact present in all vertebrates, and, further, that its fibres assume their medullary sheaths remely early period. In fish, amphibians, and reptiles, it is one of the most powerful of the medulla. In man its fibres medullate between the sixth and seventh months of , and at the same time as the fibres of the anterior basis-bundle of the cord, with which in connexion.

ling to Van Gehuchten and Edinger, it extends upwards beyond the level of the tor nucleus, and in the subthalamic region its fibres take origin from a special nucleus of n the gray matter of the third ventricle, immediately below the level of the corpora aria. Fibres also enter the posterior longitudinal bundle from a nucleus common to it osterior commissure of the brain. This nucleus is placed in the fore-part of the Sylvian ter of the mid-brain. Held asserts that numerous fibres, arising from cells in the superior ninal body, curve in an arcuate manner in the tegmentum outside the Sylvian gray

matter, to take part on the ventral aspect of this in what is called the "fountain decu Reaching the opposite side these fibres turn downwards and join the posterior long fasciculus. The same authority considers that fibres from the ventral part of the commissure can also be traced wards into the posterior long bundle. Edinger, on the othe places these fibres as a distinct the ventral and lateral aspect posterior longitudinal bundle, a in apposition with it.

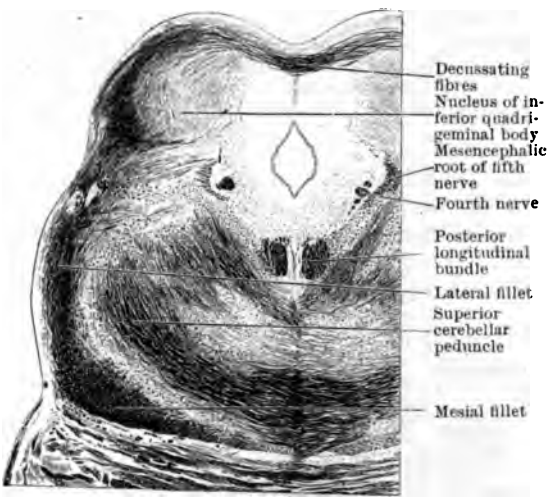

FIG. 433.—SECTION THROUGH THE INFERIOR QUADRIGEMINAL BODY AND THE TEGMENTUM OF THE MESENCEPHALON, AT A SLIGHTLY LOWER LEVEL THAN FIG. 432.

Mendel believes that fibres f oculo-motor nucleus are carried the posterior longitudinal bund from this, into the facial nerve supply of the orbicularis palp and the corrugator supercilii, these muscles therefore under the of the same nucleus as the levato bræ superioris muscle. This v received corroboration at the Tooth and Turner. It has been suggested that fibres from the hy nucleus may, by the posterior long fasciculus, reach the facial ne through it the orbicularis oris. manner the same nucleus wou sway over the tongue and the s muscle of the lips. The close which exists between the ascend of the intrapontine portion of t nerve and the posterior longitudinal bundle would render the passage of fibres from o other a matter which could easily be understood. Another interchange of fibres thr posterior longitudinal bundle has been described by Duval and Laborde. According authorities, fibres from the abducent nucleus ascend in the posterior longitudinal bundle into the mesencephalon, and establish connexions with that part of the oculo-motor nucleus from which the nerve for the internal rectus of the opposite side derives its fibres. If this view be correct, it affords a ready and simple anatomical explanation of the harmonious action of the external and internal recti muscles in producing movements of the two eyeballs simultaneously to the right and to the left. From the investigations of E. H. Fraser it would appear that no fibres from the abducent nucleus go directly into the oculo-motor nerve. The same observer has shown that many fibres from Deiters' nucleus, through the path afforded by the posterior longitudinal bundle, enter the third and the fourth nuclei.

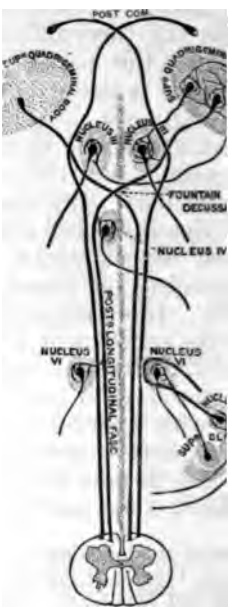

FIG. 434.—DIAGRAM OF NEXIONS OF THE LONGITUDINAL BUNDL Held—modified).

Lateral Fillet (lemniscus lateralis).—The lateral fillet is a definite tract of longitudinal fibres, which extends upwards through the lateral part of the tegmental substance of the upper portion of the pons and the mesencephalon. It is formed by the fibres of the corpus trapezoides in the lower part of the pons, abruptly turning upwards and taking a course towards the quadrigeminal region. Entering into its constitution, therefore, are fibres from several sources, viz. (1) from the terminal cochlear nuclei of the opposite side; (2) from the terminal cochlear nuclei of the same side; (3) from the superior olivary nuclei. As the tract proceeds upwards a continuation of the gray matter of the superior olivary nucleus is carried up in connexion with it to form the nucleus of the lateral fillet, and fr fibres are also added to the strand. In the mesencephalon the fibres lateral fillet end in the nucleus of the inferior quadrigeminal body (p. 5 in the gray substance of the corpus geniculatum internum, whilst a carried into the superior quadrigeminal body. The fibres which go to the drigeminal body sweep outwards round the outer side of the superi

peduncle, and to some extent appear on the surface of the mesencephalon 3).

t the lateral fillet cannot be considered as a tract composed entirely of ascending fibres ing to the auditory system. It also contains descending fibres, the connexions and ms of which are not fully understood. These have been traced by Ferrier and Turner h the pons and medulla into the lateral column of the cord.

lesial Fillet (lemniscus mesialis).—The mesial fillet has already been followed gh the medulla and pons, and its position in each of these portions of the -stem has been defined (pp. 493 and 504). In the tegmentum of the lower of the mesencephalon it is carried up in the form of a more or less flattened on the ventral aspect of the decussating superior cerebellar peduncles. To ıter side, and forming an angle with it (as seen in transverse section), is the ıl fillet (Figs. 432 and 433), and at this level there is no clear demarcation een these two tracts. In the r part of the mesencephalon the arance of the red nucleus in the ıentum causes the mesial fillet to up a more lateral and dorsal ion, so that it now comes to lie ıcent to the corpus geniculatum num (Fig. 431, p. 536). At this it exhibits a crescentic outline ansverse section, and the lateral has to a large extent disappeared its outer side.

he mesial fillet takes origin in lower part of the medulla ob- ıta from the gracile and cuneate ıi of the opposite side (p. 493). ıg that the posterior column of ord ends in these nuclei, the fillet be considered to continue that ın upwards into the brain. In ıesencephalon a considerable con- tion of fibres is given by the mesial to the superior quadrigeminal , and then the remainder of the proceeds through the subthalamic ental region into the hinder part ıe lateral nucleus of the optic mus. Here its fibres end in ter- l arborisations around the thala- ells.

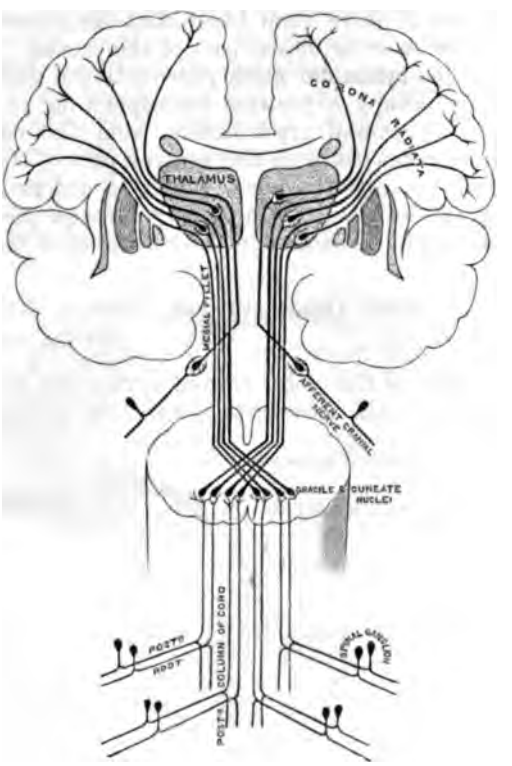

FIG. 435.—DIAGRAM OF THE CONNEXIONS OF THE MESIAL FILLET AND ALSO OF CERTAIN OF THE THALAMO-CORTICAL FIBRES.

ınglion Interpedunculare and Fasci- Retroflexus.—On the ventral aspect of the tegmentum, close to the surface and to the l plane, there is a small group of cells in the lower part of the gray matter which forms cus perforatus posticus. This is termed the *ganglion interpedunculare*.

ıe *fasciculus retroflexus* is a small band of fibres which arises above in the ganglion ıula—a nuclear mass which will be studied in connexion with the diencephalon—and runs downwards and forwards in the tegmentum of the upper part of the mesencephalon en the inner aspect of the nucleus ruber and the mesial plane, to end in the ganglion ıedunculare.

ountain Decussation.—If the region in front of the posterior longitudinal bundles be ined in the upper part of the mesencephalon a very close decussation of fibres in the mesial will be observed in the interval between the two red nuclei. This is the "fountain sation." According to Held, the fibres which take part in the dorsal portion of the ain decussation (decussation of Meynert) come from the superior quadrigeminal bodies, and, they have gained the opposite side, they turn downwards in the posterior longitudinal ulus. The ventral part of the decussation (decussation of Forel) would appear to be formed cuate fibres of the tegmentum which arise in the gray matter of the Sylvian aqueduct.

rusta or Pes of the Crus Cerebri (basis pedunculi).—The crusta presents a

somewhat crescentic outline when seen in section, and it stands quite apart fr its fellow of the opposite side. It is composed of a compact mass of longitudina directed fibres, all of which, as Déjerine has shown, arise in the cortex of t cerebrum and pursue an unbroken corticifugal course into and through the cr of the crus cerebri. These fibres may be classified into two distinct sets, v cortico-pontine and pyramidal.

The **cortico-pontine fibres** possess this leading peculiarity: in their course do wards they are all arrested in the ventral part of the pons Varolii and end fine terminal arborisations around the cells of the nucleus pontis. They come fr certain well-defined areas of cerebral cortex, viz. (1) the cortex of the prefro part of the frontal lobe, and (2) the cortex of the middle portion of the tempo lobe. These tracts would appear to hold a very definite position within the cr Thus it has been satisfactorily established that the *temporo-pontine strand* forms t outer or lateral fifth of the crusta, whilst the researches of Ferrier and Tur render it more than likely that the *fronto-pontine strand* holds a similar positi in the inner or mesial part of the crusta.

The **pyramidal fibres** constitute the great motor tract from the cerebral cort They occupy a position corresponding to the middle three-fifths of the crus The pyramidal tract differs from the cortico-pontine strands in being carri downwards through the ventral part of the pons and on the ventral aspect of t medulla into the cord, which it enters in the form of the crossed and dire pyramidal tracts. On its way through the pons and medulla it sends fibres to th various motor nuclei in those sections of the brain-stem.

Deep Origin of the Cranial Nerves which arise within the Mesencephalon.

Two of the motor cranial nerves, viz. the oculo-motor and the trochlear nerves, as well as the mesencephalic root of the trigeminal nerve, obtain origin within the mesencephalon. The nuclei from which they spring are all situated within the gray matter of the Sylvian aqueduct.

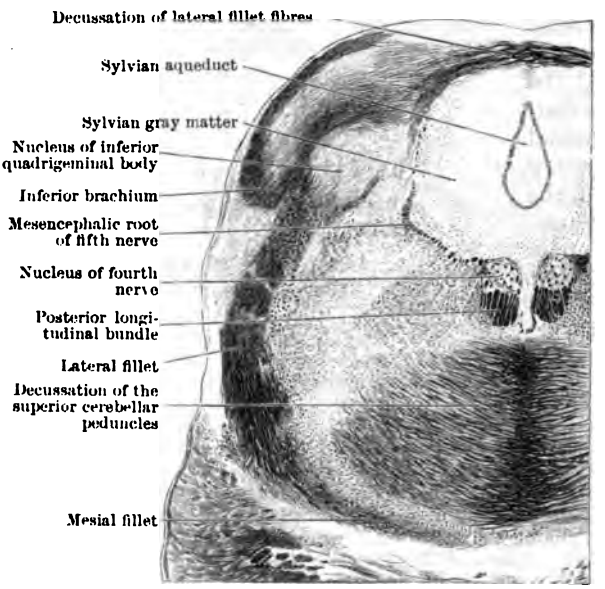

Fig. 436.—Section through the Inferior Quadrigeminal Body and the Tegmentum of the Mesencephalon at the Level of the Middle Part of the Nucleus of the Trochlear Nerve (Orang).

Mesencephalic Root of the Trigeminal Nerve (radix descendens).—The fibres of this root arise from a column of large, sparsely-arranged cells, which extends throughout the entire length of the mesencephalon. These cells lie in the outer part of the Sylvian gray matter, close to the tegmentum. The axons which emerge from the cells run downwards close to the outer surface of the Sylvian gray matter in the form of a small, gradually-increasing tract. In the lower part of the mesencephalon this tract assumes a crescentic outline, and ultimately comes to lie on the inner aspect of the superior cerebellar peduncle (Fig. 406, p. 504). The further course of the mesencephalic root of the fifth nerve through the upper part of the pons, to the point where it joins the emerging motor root of the trigeminal nerve, has already been traced (p. 526).

Trochlear or Fourth Nerve (nervus trochlearis).—The trochlear nerve supplies

or oblique muscle of the eyeball. It emerges from the brain, on its ect, at the upper part of the superior medullary velum, immediately lower border of the inferior quadrigeminal body (Fig. 438, p 543). The om which it arises is a small oval mass of gray matter, placed in the rt of the Sylvian gray matter at the level of the upper part of the uadrigeminal body. The close association of this nucleus with the ngitudinal bundle has already been alluded to. It is sunk deeply in a i is hollowed out on the dorsal and inner aspect of that tract. The a course of some length within the mesencephalon. The axons of the the outer aspect of the nuclear mass, and curve backwards and outwards lvian gray matter until they reach the concave inner surface of the alic root of the trigeminal nerve. Here they are gathered together into o round bundles, which, bending sharply, turn downwards at a right descend on the inner side of the trigeminal root. When the region inferior quadrigeminal body is reached, the nerve makes another sharp is time it turns inwards, enters the upper end of the superior medullary which it decussates with its fellow of the opposite side. Having thus e mesial plane, the trochlear nerve emerges at the inner border of the rebellar peduncle. The course pursued by the fourth nerve within the ay matter may be traced by examining in succession Fig. 437; Fig. 432, g. 433, p. 538; and Fig. 407, p. 505.

motor or Third Nerve (nervus oculo-motorius).—The oculo-motor nerve ie levator palpebræ superioris, all the ocular muscles, with the exception perior oblique and ial rectus, and also es within the eyeball, phincter iridis and ulus ciliaris. The origin is placed in l part of the Sylvian er subjacent to the quadrigeminal body p. 536). In length es from 5 to 6 mm. end is partially con- ith the nucleus of ear nerve, whilst its extends upwards for listance beyond the alon into the gray the lateral wall of entricle. Its relation sterior longitudinal even more intimate ; of the trochlear It is closely applied sal and inner aspect rand; many of its py a position in the some even are seen on its ventral or tegmental aspect. The axons of ir cells leave the nucleus in numerous bundles, which describe a series as they proceed forwards through the posterior longitudinal bundle, the n, red nucleus, and inner margin of the substantia nigra, to finally emerge brain-stem along the bottom of the sulcus oculo-motorius on the inner he crus cerebri.

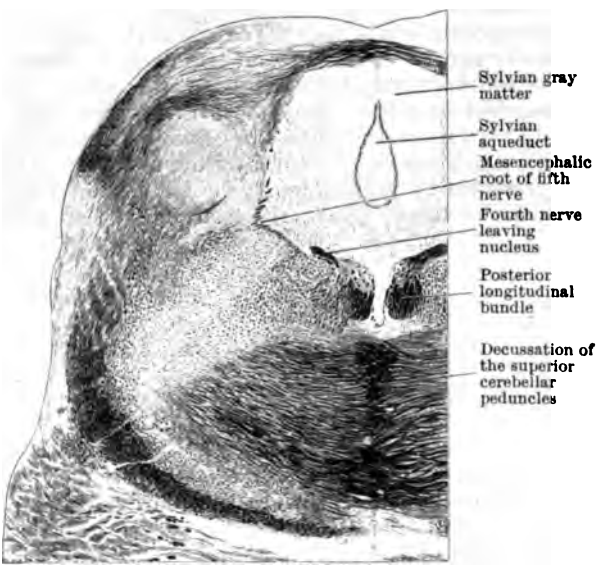

FIG. 437.—SECTION THROUGH THE INFERIOR QUADRIGEMINAL BODY AND THE TEGMENTUM OF THE MESENCEPHALON AT THE LEVEL OF THE LOWER PART OF THE NUCLEUS OF THE TROCHLEAR NERVE (Orang).

s of the oculo-motor nucleus are not uniformly distributed throughout it. They are o several more or less distinct collections or clumps, some of which possess cells which e and appearance from the others. These cell-clusters are very generally believed to finite relation to the several branches of the nerve and the muscles which they rlia recognises no less than seven such cell-clusters in each nucleus, with a small

median nucleus placed accurately on the middle line, and from which fibres for both ... spring. Whilst the majority of the fibres in the oculo-motor nerve arise from the cell-g... which lie on its own side of the mesial plane, it has been satisfactorily established that a c... proportion of its fibres are derived from the nucleus of the opposite side, thus forming a c... connexion and giving rise to a median decussation. These crossed fibres are supposed by ... to supply the internal rectus muscle; and we have seen that there is reason to believe that ... part of the nucleus from which these fibres are derived stands in connexion through the post... longitudinal fasciculus with the abducent or sixth nucleus from which proceeds the nerv... supply for the external rectus muscle. The harmonious action of the internal and external ... in producing the conjugate movements of the eyeballs is thus explained.

The oculo-motor nucleus is connected—(1) with the occipital part of the cerebral cortex ... fibres which reach it through the optic radiation; (2) with the trochlear and abducent nu... (and probably with other nuclei) by fibres which come to it through the posterior longitud... bundle; (3) possibly with the facial nerve by fibres which pass out from it into the poste... longitudinal bundle (p. 538); (4) with the visual system by fibres which enter it from the cells ... the superior quadrigeminal body.

Development of the Mesencephalon.

Even in the early embryo the mesencephalon constitutes the smallest section of t... brain-tube, although the disproportion in size between it and the other primitive s... divisions of the brain is not nearly so marked as in the adult. Owing to the cephal... flexure, the mid-brain for a time occupies the highest part of the summit of the he... Later on it becomes completely covered over by the expanding cerebral hemispheres.

The corpora quadrigemina are derived from the alar laminæ of the lateral walls of t... brain-tube, whilst the basal laminæ thicken and ultimately form the tegmenta and cru... of the two crura cerebri. The original cavity of the mid-brain is retained as the aqued... of Sylvius.

For a considerable time the cavity of the mesencephalon remains relatively large, a... the lower part of its dorsal wall is carried downwards in the form of a diverticulum ... recess, which overlaps the cerebellar plate. About this time, also, the dorsal wall show... median fold or ridge. Both of these conditions are transitory. As the corpora qua... gemina take shape, the median ridge disappears and is replaced by the median longitudi... groove, which separates the quadrigeminal bodies. Only its lower part is retained, and t... is represented by the frenulum veli of the adult brain. The diverticulum of the cav... gradually becomes reduced, and finally disappears as the aqueduct assumes form.

FORE-BRAIN.

Parts derived from the Diencephalon.

Under this heading we have to consider: (1) the **thalamus**; (2) the **epithalam...** which comprises the pineal body and the habenular region; (3) the **metathalam...** or the corpora geniculata; and (4) the **hypothalamus.**

The hypothalamus consists of two portions, viz. the **pars mammillaris hypothala...** which comprises the corpus mammillare and the portion of the central gray matt... which forms the floor of the third ventricle in its immediate vicinity; and the p... **optica hypothalami**, which embraces the tuber cinereum, the infundibulum, t... pituitary body, and the lamina cinerea. Strictly speaking, the optic part of t... hypothalamus does not belong to the diencephalon, but it is convenient to stu... the parts which it represents at this stage. It is also convenient to examine, ... the same time, the **subthalamic tegmental region**, although a very considerable part... this is apparently developed in connexion with the mesencephalon.

The original cavity of that part of the brain-tube which forms the diencepha... is represented by the greater part of the third ventricle of the brain.

Optic Thalamus (thalamus).—The optic thalamus is the principal object ... this section of the brain (Fig. 438). It is a large ovoid mass of gray matter, wh... lies obliquely across the path of the crus cerebri as it ascends into the cerebr... The smaller anterior end of the thalamus lies close to the mesial plane, and is o... separated from the corresponding part of the opposite side by a very nar... interval. The enlarged posterior ends of the two thalami are placed more wid... apart, and in the interval between them the corpora quadrigemina are situa... As previously stated, the crusta of the crus cerebri, composed of **corticifugal** fil...

gradually inclines outwards as it is traced upwards, and thus it assumes a place on the outer aspect of the optic thalamus and passes into the internal capsule of the brain. The tegmental part of the crus, on the other hand, comes into relation with the under surface of the thalamus, and forms in this situation the **subthalamic tegmental region**. To a large extent the longitudinal fibres of the tegmentum are corticipetal. For the most part they enter the thalamus, and end within it in fine arborisations around the thalamic cells.

The two optic thalami, in their anterior two-thirds, lie close together on either side of a deep mesial cleft, which receives the name of the third ventricle of the brain. Each thalamus presents an anterior and a posterior extremity and four surfaces. The inferior and external surfaces are in apposition, and, indeed, directly connected with adjacent parts of the brain, and on this account it is only possible to study them by means of sections through the brain. The superior and internal surfaces are free.

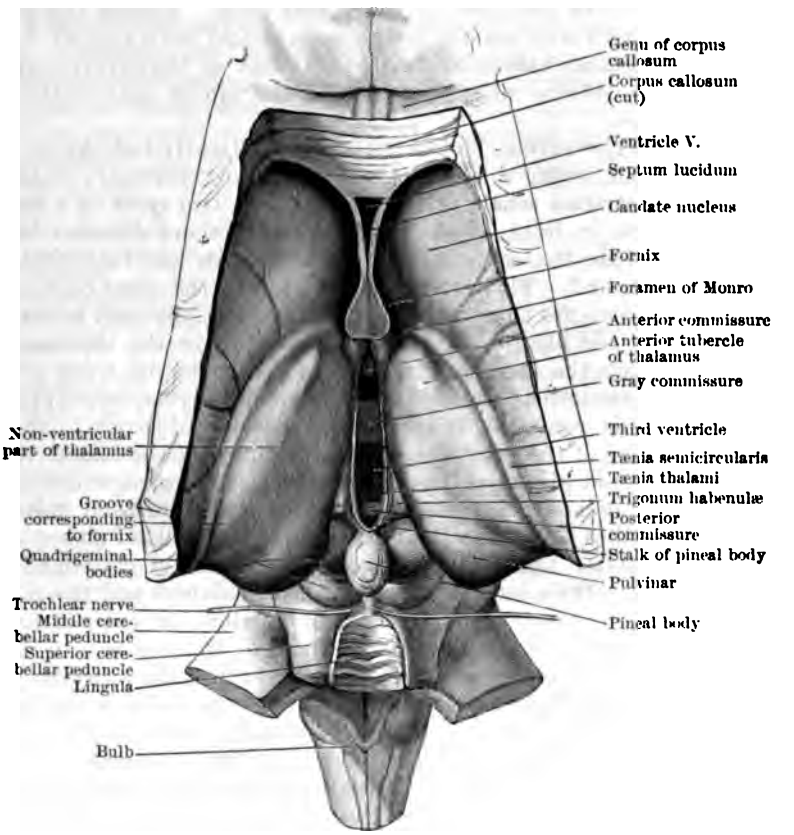

FIG. 438.—THE TWO OPTIC THALAMI (as seen from above).

The *external* or *lateral surface* of the thalamus is applied to a thick layer of white matter interposed between it and the lenticular nucleus, called the **internal capsule**, and composed of fibres passing both upwards towards and downwards from the cerebral cortex. A large proportion of these fibres descend to form the crusta or ventral part of the crus cerebri. From the entire extent of the external surface of the thalamus large numbers of fibres stream out and enter the internal capsule, to reach the cerebral cortex; over the same area other fibres which arise in the cortex of the cerebrum enter the thalamus. Both of these sets of fibres constitute what is termed the **thalamic radiation**, and by this the thalamus establishes a double connexion with the entire extent of the cerebral cortex. As the fibres leave and enter the thalamus they intersect each other at acute angles, and over the whole of the external surface of the ganglionic mass they form a very distinct reticulated zone or stratum, which is termed the **external medullary lamina**.

The *inferior* or *ventral surface* of the thalamus rests chiefly on the subthalamic tegmental region and the corpus mammillare. In front, however, as the tegmental substance gradually disappears, the thalamus comes to lie over the outer part of the tuber cinereum. From the subthalamic region many fibres enter the thalamus on its under aspect, whilst other fibres leave this surface of the thalamus to take part in the thalamic radiation.

The *superior* or *dorsal surface* of the thalamus is free. Externally it is bou by a groove, which traverses the floor of the lateral ventricle of the brain intervenes between the thalamus and the caudate nucleus. In this groove placed a slender band of longitudinal fibres, termed the tænia semicularis, a its fore-part the vein of the corpus striatum. Internally, the superior surfa the thalamus is separated from the internal or mesial surface in its anterior half a sharp edge or prominent ledge of the ependyma of the third ventricle. Th termed the **tænia thalami**, and the ridge which it forms is accentuated by the that, subjacent to it, there lies a longitudinal strand of fibres called the **medullaris**. When these two structures, viz. the ependymal ridge and the subja tract, are traced backwards, they are seen to turn inwards and become contin with the stalk or peduncle of the pineal body. Behind the portion of the t thalami which turns inwards towards the pineal body a small depressed triangu area, the **trigonum habenulæ**, situated in front of the superior quadrigeminal bo forms a very definite inner boundary for the hinder part of the superior surface the thalamus.

The superior surface of the thalamus is slightly bulging or convex, and is o whitish colour, owing to the presence of a thin superficial covering of nerve-fib termed the **stratum zonale**. It is divided into two areas by a faint oblique groo which begins in front at the inner border, a short distance behind the anter extremity of the thalamus, and extends outwards and backwards to the outer p of the hinder end. This groove corresponds to the outer edge of the fornix. T two areas which are thus mapped out are very differently related to the ventri of the brain, and also to the parts which lie above the thalamus. The *outer ar* which includes the anterior extremity of the thalamus, forms a part of the floor the lateral ventricle. It is covered with ependyma, overlapped by the chor plexus of this ventricle, and lies immediately subjacent to the corpus callosum. Along the line of the groove the epithelial lining of the lateral ventricle is reflected over the choroid plexus of this cavity. The *inner area*, which includes the hinde end of the thalamus, intervenes between the lateral and third ventricles of th brain, and takes no part in the formation of the walls of either. It is covered by a fold of pia mater, termed the velum interpositum, above which is the fornix, and these two structures intervene between the thalamus and the corpus callosum.

The *anterior extremity* of the thalamus, called the **anterior tubercle** (tuberculum anterius thalami), forms a marked bulging. It projects into the lateral ventricle, behind and to the outer side of the free portion of the anterior pillar of the fornix. The foramen of Monro, a narrow aperture of communication between the lateral and third ventricles of the brain, is bounded in front by the anterior pillar of the fornix and behind by the anterior tubercle of the thalamus.

The *posterior extremity* of the thalamus is very prominent and forms a cushion-like projection, which overhangs the brachia of the corpora quadrigemina. This prominence is called the **pulvinar**. Another oval bulging on the hinder part of the thalamus receives the name of the **corpus geniculatum externum**. It is situated below, and to the outer side of, the pulvinar, and presents a very intimate connexion with the optic tract.

The *mesial surfaces* of the two thalami are placed close together, and are covered not only by the lining ependyma of the third ventricle, but also by a tolerably thick layer of gray matter, continuous below with the central gray substance which surrounds the aqueduct of Sylvius in the mesencephalon. A band of gray matter, termed the **gray** or **soft commissure** (commissura mollis), crosses the third ventricle and joins the inner surfaces of the two thalami together.

Intimate Structure and Connexions of the Optic Thalamus.—The upper surface of the thalamus is covered by the **stratum zonale**, a thin coating of white fibres derived to some extent from the optic tract, and probably also from the optic radiation. The inner surface has a thick coating of central gray matter, whilst intervening between the internal capsule and the outer surface is the **lamina medullaris externa**. The lower surface merges into the subthalamic region.

The gray matter of the optic thalamus is marked off into three very apparent parts—termed the anterior, the mesial, and the lateral thalamic nuclei—by a thin

ıl **sheet** of white matter, continuous with the stratum zonale, termed the **medullaris interna.** The **lateral nucleus** (nucleus lateralis thalami) is by far ırgest of the three. It is placed between the internal and the external **lary laminæ**, and it stretches backwards beyond the mesial nucleus, and thus les the whole of the pulvinar (Fig. 440). The **mesial nucleus** (nucleus medialis ni) only reaches as far back as the habenular region. It is placed between entral gray matter of the third ventricle and the internal medullary lamina. ateral nucleus is more extensively pervaded by fibres than the mesial nucleus. the lateral nucleus by far the greatest number of the fibres which form the **ıio thalami** pass, and these are seen crossing it in various directions towards ımina medullaris externa. The **anterior nucleus** (nucleus anterior thalami) is nallest of the three thalamic nuclei. It forms the prominent anterior tubercle, is prolonged in a wedge-shaped manner, for a short distance, downwards and ards between the anterior parts of the mesial and lateral nuclei. The internal llary lamina splits into two parts and partially encloses the anterior nucleus. ɔnnexion with its large cells a very conspicuous bundle of fibres, the **bundle icq d'Azyr** (fasciculus thalamo-mammillaris), which arises in the corpus millare, comes to an end

diffuse gray mass imperfectly marked off from the under surface of the lateral nucleus es the name of the *ventral nucleus*. Its lower part is composed of the **central nucleus of** and the **nucleus arcuatus**. In section the former appears as a circular mass of gray matter, comes into view immediately behind the point where the internal medullary lamina pears. It would seem to be intimately connected with fibres which reach it from the red us and from the posterior commissure. These fibres pass round it so as to mark it off from st of the thalamus, and in front of the nucleus many of them enter the internal medullary a. The **nucleus arcuatus** is a small semilunar mass of gray matter placed below and to the side of the central nucleus of Luys.

'he **connexions of the thalamus** are of an extremely intricate kind. It would ar to be a ganglionic mass interposed between the tegmental corticipetal tracts ;he cerebral cortex. In its hinder part, and through its stratum zonale, it also mportant connexions with the optic tract. The corticipetal tegmental tracts, h enter it from below, will be noticed in connexion with the subthalamic n. Suffice it to say, for the present, that these fibres end in the midst of the ımus in connexion with the thalamic cells. In addition to these, enormous bers of fibres, arising within the thalamus as the axons of its cells, stream out its outer and under surfaces to form the thalamic radiation. These **thalamo-cal fibres** pass to every part of the cortex; and although there is no separation ıem into distinct groups as they leave the thalamus, it is customary to regard ı as constituting a frontal stalk, a parietal stalk, an occipital stalk, and a ral stalk. But fibres from the cortex, **cortico-thalamic fibres**, likewise stream the thalamus in large numbers, and end in fine arborisations around its cells. ɔuble connexion with the cerebral cortex is thus established by the thalamus.

'he **frontal stalk** of the thalamic radiation emerges from the anterior part of the lateral ce of the thalamus and passes through the anterior limb of the internal capsule, to reach the x of the frontal lobe. Many of these fibres end in the caudate and lenticular nuclei, between h they proceed. The **parietal stalk** issues from the lateral surface of the thalamus, and, ng through the internal capsule (and to some extent, also, through the lenticular nucleus the external capsule), gains the cortex of the hinder part of the frontal lobe and of the ital lobe. The **occipital stalk** emerges from the outer aspect of the pulvinar and constitutes o-called optic radiation. These fibres sweep outwards and backwards round the outer side ıe posterior horn of the lateral ventricle to gain the cortex of the occipital lobe. The **ral stalk** streams out from the under aspect of the anterior part of the thalamus, in front ıe subthalamic tegmental region and the corpus mammillare. Its fibres arise in both the al and lateral nuclei, and sweep downwards and outwards to reach the region below the icular nucleus. One very distinct band which lies dorsal to the other fibres (ansa lenticu-) enters the lenticular nucleus, whilst the remainder (ansa peduncularis) continue in an ard direction below the lenticular nucleus and gain the cortex of the temporal lobe and of insula or island of Reil.

Flechsig divides the thalamo-cortical fibres of ordinary sensation into three sensory systems. se he has been able to distinguish by studying the order in which they assume their sheaths ıyelin in the fœtus and infant.

Ferrier and Turner, by the degenerative method of investigation, corroborate Flechsig's lts. They confirm the observation of Flechsig that, while thalamic fibres are distributed to

the several regions of the cerebral cortex to an almost equal extent, there is one district, frontal pole, to which the supply is scanty. Another very important result has been c by these authors. They have est the fact that many of the thalam cross the mesial plane in the cor losum, and thus gain the cortex opposite cerebral hemisphere. Ha crossed callosal tract thus receiv formation.

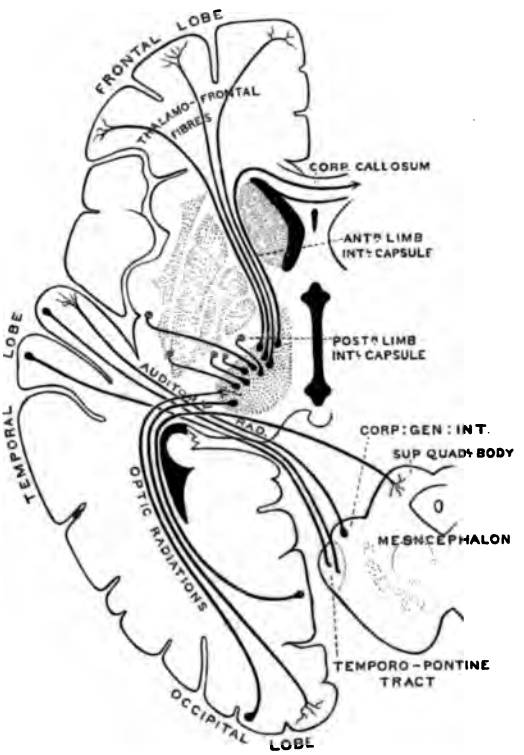

FIG. 439.—SCHEMA. Founded on the observations of Flechsig, and Ferrier and Turner.

Intimate Structure of the Geniculatum Externum. — S through the external geniculat reveal the fact that it is comp a series of alternately placed gr white curved laminæ. This g a very characteristic appearanc white laminæ are composed o which enter the body from th tract and the optic radiation connexions of the geniculate will be studied with the tract.

Subthalamic Tegmental I —The tegmental part of the cr bri is prolonged upwards and a position below the hinder pa thalamus. The **red nucleus** i spicuous object in sections thro lower part of this region (Fig. presents the same appearance down in the mesencephalo gradually diminishing, it dis before the level of the corpu millare is reached. Carried up around it are the same longitudinal tracts which have been studied in relation to it in the tegmental part of the mesenc Certain of these fibres, placed in immediate relation to the red nucleus, coating or capsule for it. This coating is partly derived from those fibre superior cerebellar peduncle which pass directly up into the thalamus a partly from fibres which issue from the nucleus itself. The **mesial fill** which in the upper part of the mesencephalon is observed to take up a pos the lateral and dorsal aspect of the red nucleus, maintains a similar positio subthalamic region. When the red nucleus comes to an end these variou are continued onwards and form, in the position previously occupied by the a very evident and dense mass of fibres. The fibres of the mesial fillet, superior cerebellar peduncle, and of the red nucleus are prolonged upwards ventral part of the thalamus, where they end in connexion with the thalam

The **substantia nigra** is likewise carried into the subthalamic region, maintains its original position on the dorsal aspect of the crusta of the crus As it is traced upwards, it is seen to gradually diminish in amount. It from within outwards, and finally disappears when the hinder part of the mammillare is reached.

In coronal sections through the subthalamic region, the most conspicuou which comes into view is the **corpus subthalamicum** or the **nucleus of Luys** (F It is a small mass of gray matter, shaped like a biconvex lens, which makes its ance on the dorsal aspect of the crusta of the crus cerebri immediately to tl side of the substantia nigra. At first it lies in an angle, which is formed meeting of the crusta and the internal capsule; but, rapidly enlarging in an direction, it takes the place of the diminishing substantia nigra on the surface of the crusta at the level of the lower part of the corpus mammillar corpus subthalamicum is rendered all the more evident by the fact th

mi, it occupies the depression on the dorsal aspect of the mesencephalon,
intervenes between the two superior quadrigeminal bodies. Its base, which
rected upwards, is attached by a hollow stalk or peduncle. This stalk is
ated into a dorsal and a ventral part by the prolongation backwards into it
small pointed recess of the cavity of the third ventricle. The dorsal part of
talk curves outwards and forwards, and on each optic thalamus becomes
nuous with the tænia thalami and the subjacent stria medullaris; the
al part is folded round a narrow but conspicuous cord-like band of white
er, which crosses the mesial plane immediately above the base of the pineal body
eceives the name of the **posterior commissure** of the cerebrum (Fig. 438, p. 543).

ne pineal body is not composed of nervous elements. The only nerves in its midst are the
athetic filaments which enter it, with its blood-vessels. It is composed of spherical and
ar follicles, filled with epithelial cells, and containing a variable amount of gritty, calcareous
r.

ne pineal body is a rudimentary structure, but in certain vertebrates it attains a much
r degree of development than in man. In the lizard, blind-worm, etc., it is present in the
of the so-called pineal eye. In structure it resembles, in these animals, an invertebrate eye,
t possesses a long stalk, in which nerve-fibres are developed. Further, it is carried through
erture in the cranial wall, and consequently lies close to the surface on the dorsum of the
between the parietal bones.

Trigonum Habenulæ.—The small, triangular, depressed area which receives this
e is placed immediately in front of the superior quadrigeminal body in the
val between the peduncle of the pineal body and the hinder end of the thalamus
. 438, p. 543). It marks the position of an important collection of nerve-cells,
h constitute the **ganglion habenulæ**. The axons of these cells are collected on
ventral aspect of the ganglion into a bundle, called the **fasciculus retroflexus**,
h takes a curved course downwards and forwards in the tegmentum of the

mesencephalon. The fasciculus retroflexus lies close to the inner side of red nucleus, and finally comes to an end in a group of cells termed the **ganglion interpedunculare**, situated in the lower part of the locus perforatus post (see p. 539).

The ganglion habenulæ is likewise intimately connected with the stria me laris and the dorsal part of the stalk of the pineal body.

As previously stated, the **stria medullaris**—a very evident band of w matter—lies on the optic thalamus, subjacent to the ependymal ridge termed tænia thalami. When traced backwards, many of the fibres of the stria medull are observed to end amongst the cells of the ganglion habenulæ, whilst others continued past the ganglion to enter the peduncle of the pineal body, and, thro it, to reach the ganglion habenulæ of the opposite side, in connexion with the of which they terminate. The stria medullaris, therefore, ends partly in ganglion habenulæ of its own side and partly in the corresponding ganglion of opposite side. The decussation of fibres across the middle line forms the d part of the pineal stalk or peduncle, and is frequently termed the **commis habenularum**.

When the stria medullaris is traced in the opposite direction, it is notice split into a dorsal and ventral part near the anterior pillar of the fornix. *dorsal part* turns abruptly upwards, and, joining the fornix, is carried in it t hippocampus major or cornu ammonis from cells in which its fibres take o The *ventral part* turns downwards and appears to spring from a collection of in the gray matter on the base of the brain close to the optic chiasma. The medullaris is believed to form a part of the olfactory apparatus.

Commissura Posterior.—The posterior commissure is a slender band of matter, which crosses the middle line under cover of the stalk of the pineal and overlies the entrance of the aqueduct of Sylvius into the third ventricle. fibres which enter into the formation of the posterior commissure are believ arise in a special nucleus, which is placed in the central gray matter immedi above the oculo-motor nucleus. They decussate with each other across the plane and thus the commissure is formed. The other connexions of this band are not satisfactorily established, but Held believes that some of its v fibres pass downwards into the posterior longitudinal bundle.

Locus Perforatus Posticus (substantia perforata posterior).—This has al been described on p. 475. Some delicate bands of white matter, termed the **pontis**, may frequently be seen emerging from the gray matter of this region; then curve round the crura cerebri in close relation to the upper border o pons, into which they ultimately sink (Fig. 390, p. 484).

Corpora Mammillaria.—The corpora mammillaria are two round white b each about the size of a pea, which lie side by side in the interpeduncular spa the base of the brain, immediately in front of the locus perforatus posticus.

Each corpus mammillare is coated on the outside by white matter de from the anterior pillar of the fornix, and contains, in its interior, a composite nucleus with numerous nerve-cells. Several important strands of fibres are nected with the corpus mammillare: (1) The **anterior pillar of the fornix** c downwards in the lateral wall of the third ventricle to reach the corpus mammi and its fibres end amidst the cells of that body. (2) A bundle of fibres, the **bundle of Vicq d'Azyr**, which at first sight appears to be continuous wit anterior pillar of the fornix, takes origin in its midst and extends upward the optic thalamus, to end in fine arborisations around the large cells in the an thalamic nucleus. (3) Another bundle of fibres, the **pedunculus corporis mammi** takes form within the corpus mammillare and extends downwards in the matter of the floor of the third ventricle, to reach the tegmentum of the m cephalon. The ultimate destination of these fibres is doubtful.

Tuber Cinereum and Infundibulum.—The tuber cinereum is a small, sli prominent field of gray matter, which occupies the anterior part of the peduncular space between the corpora mammillaria behind and the optic ch in front. From its fore-part the **infundibulum**, or stalk of the pituitary projects downwards and connects that body with the base of the brain.

the infundibulum is hollow, a small, funnel-shaped diverticulum of the he third ventricle being prolonged downwards into it.

ıry Body (hypophysis). a small oval structure, rom above downwards, its long axis directed ly, which occupies the ossa in the floor of the It is composed of two ırge anterior lobe and a sterior lobe, which are lied the one to the other. dibulum, which extends s from the tuber cin- ttached to the posterior

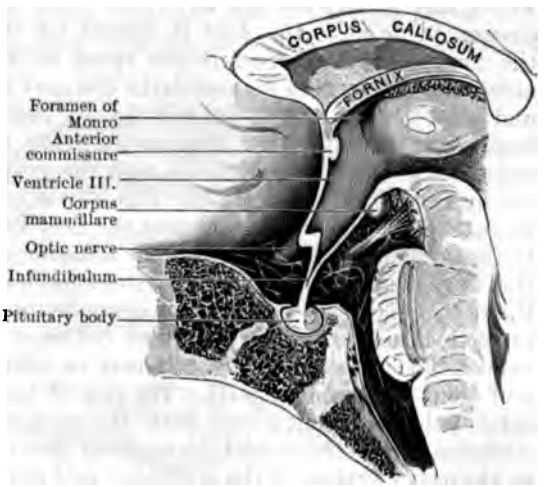

FIG. 441.—MESIAL SECTION THROUGH THE PITUITARY REGION IN A CHILD OF TWELVE MONTHS OLD.

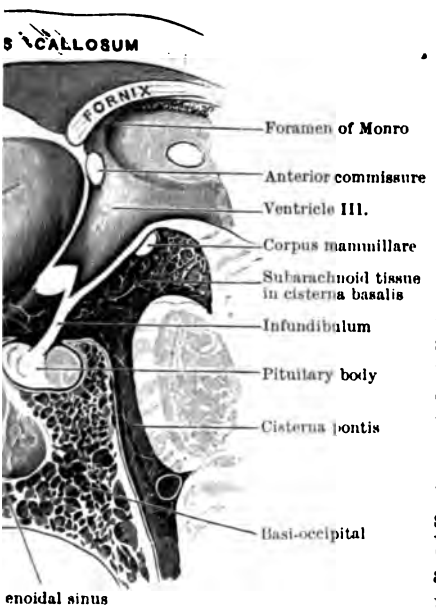
In this section, as well as in the section figured in Fig. 442, the infundibulum has the appearance of being attached to the anterior lobe. This is due to the way in which the larger anterior lobe grows backwards so as to embrace the smaller posterior lobe. The latter is, as it were, accommodated in a hollow in the hinder aspect of the anterior lobe.

From a photograph by Professor Symington.

undibulum and posterior e pituitary body are de- the form of a hollow diver- ich grows downwards from that part of the embryonic h afterwards forms the icle. The original cavity rticulum becomes obliter- t in the upper part of the ım. In structure, the pos- of the pituitary body shows of its origin from the brain-tube. It is chiefly composed of connective tissue and blood-vessels, with lls scattered throughout it.

erior lobe has quite a different origin, and may be regarded as the functional part of the pituitary body. It is derived from a tubular diverticulum, which grows upwards from the primitive buccal cavity or stomodæum. Its connexion with the latter (canalis cranio-pharyngeus) is in the course of time cut off, and the diverticulum becomes encased within the cranial cavity in intimate association with the cerebral portion of the organ. Structurally, it consists of tubules or alveoli, lined by epithelial cells and surrounded by capillary vessels. Its structure is in some respects not unlike that of the parathyroid bodies. In giants, and in cases of acromegaly, the pituitary body is usually greatly enlarged.



SIAL SECTION THROUGH THE PITUITARY REGION IN THE ADULT.

Lamina Cinerea.—This is a thin, delicate lamina which may be seen on the basal aspect of the brain, stretching from the upper aspect of the optic chiasma in an upward direction to become connected with the rostrum of the corpus callosum.

ɔr Commissure of the Cerebrum.—In the anterior part of the cleft, e two optic thalami and immediately in front of the anterior pillars of a round bundle of fibres crosses the mesial plane. This is the anterior . It is much larger than the posterior commissure.

Third Ventricle (ventriculus tertius). — This is the narrow cleft wh separates the two optic thalami. Its depth rapidly increases from behind f wards, and it may be said to extend from the pineal body behind to the lam cinerea in front. Its *floor* is formed by the structures already studied wit the area of the interpeduncular space on the base of the brain, viz. the tu cinereum, the corpora mammillaria, the gray matter of the locus perforatus postic and also to some extent behind this by the tegmenta of the crura cerebri. It interesting to note that the central gray matter which surrounds the Sylv aqueduct is directly continuous with the gray matter of the locus perforatus pos cus and tuber cinereum, and in this way it comes to the surface in the base of t brain. The optic chiasma crosses the floor in front and marks the place where latter becomes continuous with the anterior wall of the cavity. The *front wall* the third ventricle is formed by the lamina cinerea, which extends upwards fr the optic chiasma. The anterior commissure, as it crosses from one side to the oth projects into the ventricle, but of course it is excluded from the cavity by ventricular epithelial lining. It may be taken as indicating the place where roof joins the anterior wall. The *roof* of the third ventricle is formed by a t epithelial layer, continuous with the thin epithelial lining of the cavity, wh stretches across the mesial plane from one tænia thalami to the other. App to the upper surface of the epithelial roof is the fold of pia mater, termed the ve interpositum, and the roof is invaginated into the cavity along its whole length two delicate choroid plexuses, which hang down from the under surface of fold. When the velum interpositum is removed the thin epithelial roof is t away with it, leaving only the lines of attachment in the shape of the ta thalami.

The *lateral wall* of the third ventricle is formed for the greater part of extent by the inner surface of the optic thalamus, covered by a thick laye

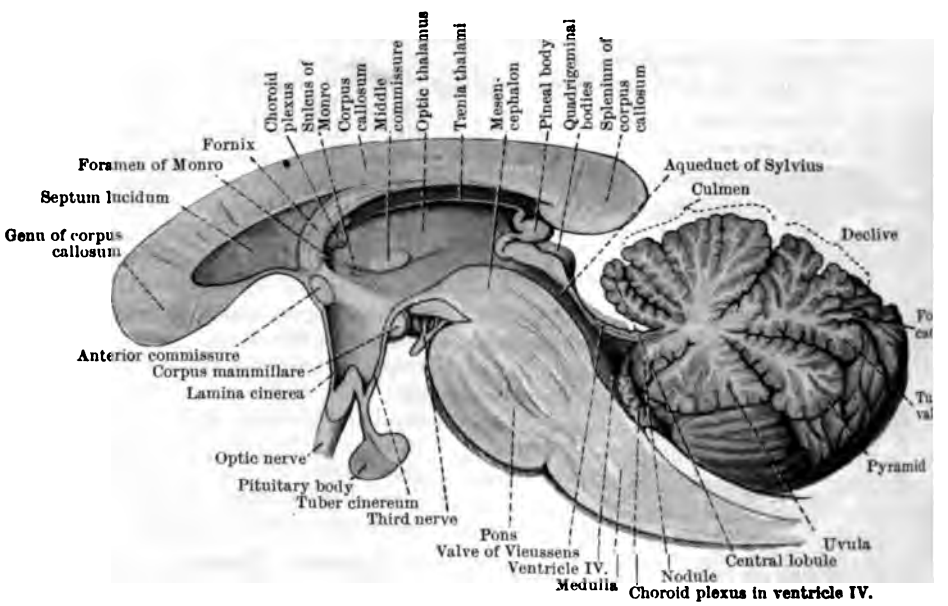


FIG. 443. — MESIAL SECTION THROUGH THE CORPUS CALLOSUM, DIENCEPHALON, ETC.
Shows the third and fourth ventricles connected by the aqueduct of Sylvius.

central gray matter continuous with the Sylvian gray matter of the mesencepha A little in front of the middle of the ventricle the cavity is crossed by the mi or **soft commissure**, which connects the thalami with each other, and in front of the anterior pillar of the fornix is seen curving downwards and backwards in lateral wall. At first the bulging which it forms is distinctly prominent, bu gradually subsides as the strand, on its way to end in the corpus mammil becomes more and more sunk in the gray matter on the side of the ventricle.

The third ventricle communicates with both of the lateral ventricles, and also with the fourth ventricle. The **aqueduct of Sylvius**, the narrow channel which tunnels the mesencephalon, brings it into communication with the fourth ventricle. The opening of this aqueduct is placed at the posterior part of the floor of the third ventricle, immediately below the posterior commissure. The **foramina of Monro**

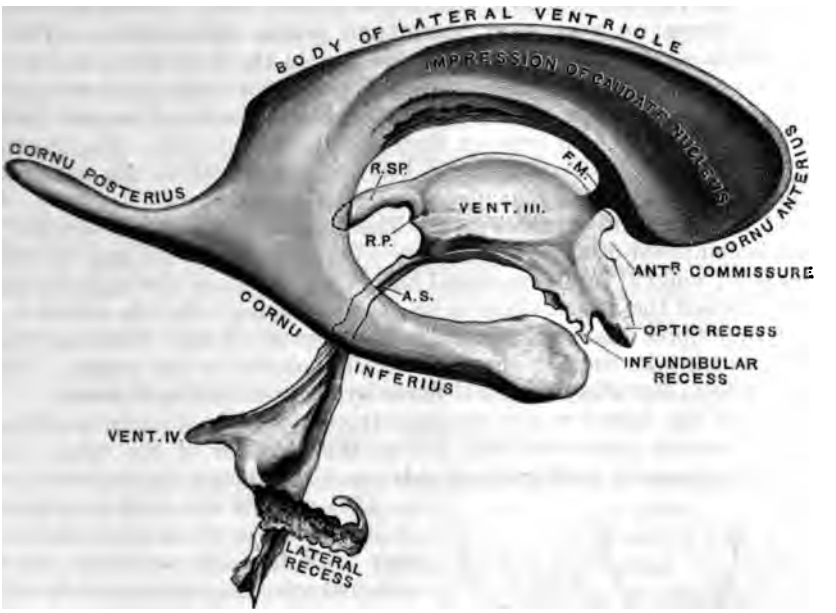

FIG. 444.—PROFILE VIEW OF A CAST OF THE VENTRICLES OF THE BRAIN (from Retzius).

R.SP. Recessus suprapinealis. A.S. Aqueduct of Sylvius.
R.P. Recessus pinealis. F.M. Foramen of Monro.

bring it into communication with the lateral ventricles. These apertures are placed at the upper and fore parts of the lateral walls, and lead outwards and slightly upwards between the most prominent parts of the anterior pillars of the fornix and the anterior tubercles of the optic thalami. They are just large enough to admit a crow-quill, and through these passages the epithelial lining of the three ventricles becomes continuous. From the foramen of Monro a distinct groove on the lateral wall of the ventricle leads backwards towards the mouth of the Sylvian aqueduct. It is termed the **sulcus of Monro**, and is of interest, inasmuch as it is considered by His to represent in the adult brain the furrow which divides the lateral wall of the embryonic brain-tube into an alar and a basal lamina.

The outline of the third ventricle, when viewed from the side in a mesial section through the brain, or as it is exhibited in a plaster cast of the ventricular system of the brain, is seen to be very irregular (Fig 444). It presents several diverticula or recesses. Thus, in the fore-part of the floor there is a funnel-shaped pit or recess, leading down through the tuber cinereum into the infundibulum of the pituitary body. Another recess, the *recessus opticus*, leads forwards immediately in front of this, above the optic chiasma. Posteriorly two diverticula are present. One, the *recessus pinealis*, passes backwards above the posterior commissure and the mouth of the Sylvian aqueduct for a short distance into the stalk of the pineal body. The second is placed above this and is carried backwards for a greater distance. It is a diverticulum of the epithelial roof, and, therefore, is difficult to demonstrate. It is termed the *recessus suprapinealis*.

CEREBRAL CONNEXIONS OF THE OPTIC TRACT.

One nerve, the optic nerve or the nerve of sight, is connected with this section of the brain. At the optic chiasma the optic nerves of the two sides are joined together and a partial decussation of fibres takes place. The fibres which arise in the mesial half of each retina cross the mesial plane and join the optic tract of the

opposite side. The optic tract proceeds backwards round the crus cerebri, the neighbourhood of the corpora geniculata divides into two roots, viz. a and a mesial (p. 532).

Mesial Root of the Optic Tract—Commissure of Gudden.—The mes of the optic tract disappears under cover of the corpus geniculatum internum large proportion of its fibres arise or end in this nuclear body. As to the com of the other fibres, we possess at present no precise information. The root, although it is composed of fibres which run in the optic tract, has abs nothing to do with the optic nerve. These fibres, when traced forwards, cr mesial plane in the posterior angle of the optic chiasma and are carried bac in the opposite optic tract, to form on that side its mesial root. The fibres fore, are commissural, and constitute a bond of union, called the commis Gudden, between the internal geniculate bodies.

Lateral Root of the Optic Tract.—The lateral or true visual root optic tract is composed of fibres which come—(1) from the lateral half of the of its own side; and (2) from the mesial half of the retina of the opposite si which have crossed the mesial plane in the optic chiasma. But in addition afferent retinal fibres there are a certain number of efferent fibres in th tract, fibres which take their origin in the brain and end in the retina. Th distinguished from the afferent retinal fibres by their exceeding fineness.

The fibres of the lateral root of the optic tract end in the superior quadri body, in the external geniculate body, and in the pulvinar of the optic th The fibres to the **superior quadrigeminal body** reach it through the superior br (p. 435), and for the most part spr on its surface in the stratum zonal they sink into its substance, to terminal arborisations around its ce **corpus geniculatum externum** recei largest contribution of fibres fr lateral root of the optic tract. Thes sink into its interior and partly sp over its surface. The former en the construction of the curved of white matter which traverse this mass, and to a large extent end gray matter which intervenes these lamellæ. The deep fibres wh not exhausted in this way proceed through the external geniculate b enter the pulvinar. Of the superfici which spread over the surface of the geniculate body some dip into its su and end there, but the majority ar over it and enter the stratum z the pulvinar. The fibres of the root of the optic tract, which en **pulvinar**, therefore reach their des by passing either over or thro external geniculate body.

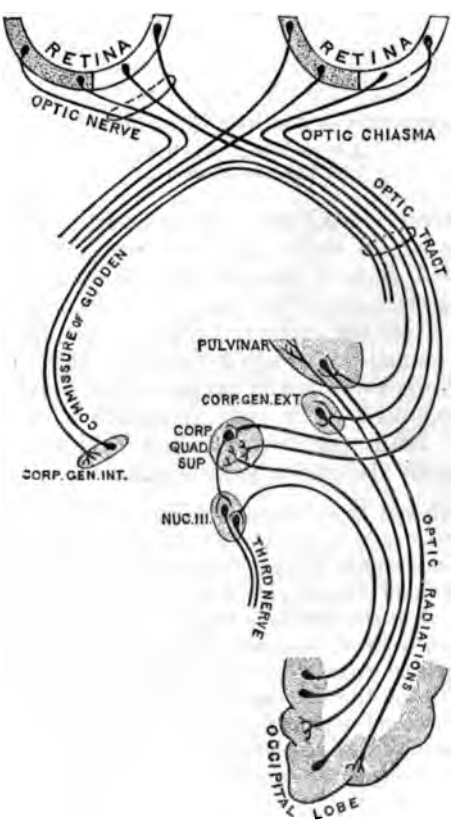

FIG. 445.—DIAGRAM OF THE CENTRAL CONNEXIONS OF THE OPTIC NERVE AND OPTIC TRACT.

Cortical Connexions of th Nerve.—The superior quadrigemin the external geniculate body, and vinar constitute the lower visual or terminal nuclei of the visu of the optic tract. The highe centre is placed in the cortex occipital lobe of the cerebral hemisphere, and the connexions between t the lower centres are established by a large strand of fibres which run central white matter of the hinder part of the cerebral hemisphere, an

s the optic radiation. The optic radiation is composed both of corticipetal cifugal fibres. The former arise as the axons of the cells in the external e body and the pulvinar, around which the retinal fibres end, and they in the cortex of the occipital lobe. The corticifugal fibres take origin rtex of the occipital lobe and end in the pulvinar and superior quadri- body (Ferrier and Turner). Thus constituted, the optic radiation forms uous strand (Figs. 462, p. 576; 465, p. 579; 473, p. 592), which, reaching lenticular part of the internal capsule, sweeps backwards into the occipital he cerebral hemisphere on the outer side of the posterior horn of the ntricle. Its connexions will be studied more fully at a later stage.

g does not believe that the pulvinar is an internode interposed in the path of the optic proceeds towards the visual area of the cerebral cortex. He states that he has not o convince himself that any fibres of the optic tract end in the optic thalamus.

Connexions of the Lower Group of Visual Centres.—(1) The nuclei of the nerves ply the muscles which move the eyeball would appear to stand in intimate connexion ower group of visual centres. Most probably this connexion is established through or longitudinal bundle. As previously stated, Held believes that axons of certain of f the superior quadrigeminal body enter this tract. (2) Through the mesial fillet, the uadrigeminal body is connected with the medulla and cord.

THE PARTS DERIVED FROM THE TELENCEPHALON.

Cerebral Hemispheres.

erebral hemispheres form the largest part of the fully-developed brain. ewed from above they form an ovoid mass, the broadest end of which is backwards, and the longest transverse diameter of which will be found in ıity of the parts which lie subjacent to the parietal eminences of the

The massive rounded character of the anterior or frontal end of each hemisphere constitutes a leading human characteristic; but the hinder or end is narrow and pointed, and is directed somewhat downwards. The bral hemispheres are separated from each other by a deep mesial cleft, he great longitudinal fissure.

t Longitudinal Fissure (fissura longitudinalis cerebri).—In front and he great longitudinal fissure passes from the dorsal to the ventral aspect of ral hemispheres, so as to separate them completely from each other. In lle part, however, the fissure is interrupted and floored by the corpus , a white commissural band, which passes between the hemispheres and them together. The upper surface of the corpus callosum can be l by gently drawing asunder the contiguous mesial surfaces of the hemispheres. The great longitudinal fissure is occupied by a mesial lura mater, termed the falx cerebri, which partially subdivides the part anial cavity allotted to the cerebrum into a right and left chamber.

rnal Configuration of each Cerebral Hemisphere.—Each cerebral hemi- resents an external, an internal, and an inferior surface. The *external* s convex and is adapted accurately to the deep surface of the cranial The *internal* or *mesial surface* is flat and perpendicular, and bounds the gitudinal fissure. In great part it is in contact with the falx cerebri; and at partition is deficient, it is applied to the corresponding portion of the surface of the opposite hemisphere. The *inferior surface* is irregular and d to the anterior and middle cranial fossæ of the cranial floor and, behind the upper surface of the tentorium cerebelli. Traversing this surface in a e direction, nearer the anterior end of the hemisphere than the posterior ıe stem of the Sylvian fissure. This deep cleft divides the inferior surface nterior or *orbital area*, which rests on the orbital plate of the frontal bone, nsequently concave from side to side, and a more extensive posterior or *area*, which lies on the floor of the lateral part of the middle cranial fossa n the upper surface of the tentorium cerebelli. This surface is arched ore backwards, and looks inwards as well as downwards. In its hinder ls it lies above the cerebellum, from which it is separated by the tentorium

The borders which intervene between these surfaces are the supero-mesia superciliary, the infero-lateral, and the internal occipital. The *supero-m border*, convex from before backwards, intervenes between the convex ext surface and the flat internal surface of the hemisphere. The *superciliary bor* highly arched and separates the orbital surface from the external surface. *infero-lateral border* marks off the tentorial surface from the external surface. *internal occipital border* can only be seen in cases where the brain has been hard *in situ* and faithfully retains the natural form. It extends from the posterio of the hemisphere towards the hinder extremity of the corpus callosum, and i venes between the mesial and tentorial surfaces. It is the border which lies the straight blood sinus, and it therefore occupies the angle which is formed b attachment of the posterior part of the falx cerebri to the upper surface o tentorium cerebelli.

The most projecting part of the anterior end of the cerebral hemisphere is the **frontal pole**, whilst the most projecting part of the hinder end is terme **occipital pole**. On the under surface of the hemisphere the prominent poi cerebral substance which extends forwards below the Sylvian fissure receive name of the **temporal pole**. In a well-hardened brain a broad groove is us present on the inner and lower aspect of the occipital pole of the right hemis This corresponds to the commencement of the right lateral venous sinus. distinct groove on the occipital pole of the left hemisphere frequently indicat commencement of the left lateral sinus. On the tentorial surface, a short dis behind the temporal pole, a well-marked depression is always visible. This sponds to the elevation on the anterior surface of the petrous portion o temporal bone over the superior semicircular canal.

Cerebral Gyri and Sulci.—The surface of the cerebral hemispheres is rem highly irregular by the presence of convolutions or gyri, separated from each by intervening furrows of very varying depth, termed sulci or fissures. The s pattern which is presented by these gyri and sulci is, in its general featur same in all normal human brains; but when the comparison is pushed into many differences become manifest, not only in the brains of different indivi but also in the two cerebral hemispheres of the same individual.

There are two varieties of furrows, viz. complete and incomplete. The co **fissures** are few in number, and are formed by inwardly-directed info involving the entire thickness of the cerebral wall. They consequently in the interior of the cerebral cavity or lateral ventricle in the form of in elevations on its wall. The complete fissures are the following: (1) the dent hippocampal fissure; (2) the anterior part of the calcarine fissure; and portion of the collateral fissure. The **incomplete fissures** are merely surface fu of varying depth, which do not produce any effect on the inner surface o ventricular wall.

General Structure of the Cerebral Hemispheres.—Each cerebral hemis is composed of an outside coating of gray matter, spread in a continuous an interrupted layer over its surface, and an internal mass of white matter, which a considerable part of the immediate wall of the ventricular cavity. The coating is termed the **cerebral cortex**, and the internal white matter is calle **medullary centre**. Each convolution shows a corresponding structure. On verse section it is seen to present an external covering of gray cortex, support a central core of white matter.

But, in addition to the gray matter on the outside, there are certain deposits of gray matter embedded in the basal part of each cerebral hemis These cerebral nuclei constitute the **corpus striatum**, and, although to some e isolated from the gray matter on the surface, it can be easily shown that at c points they are directly continuous with it.

By means of the convolutions and sulci, the gray matter on the surface hemisphere is enormously increased in quantity without unduly adding to the of the organ; and, further, the vascular pia mater, which dips into every fiss increased in extent to a like degree. Opportunity is, therefore, afforded t cortical vessels of breaking up into twigs of exceeding fineness before they ent

stance of the hemisphere. The distribution of blood to the gray cortex is, in way, equalised and rendered uniform.

Cerebral Lobes and Interlobar Fissures.—Certain of the fissures which verse the surface of the cerebrum are more or less arbitrarily chosen for subiding the surface into districts or areas, which are termed lobes. These fissures termed **interlobar**, and are the following: (1) the fissure of Sylvius; (2) the ure of Rolando; (3) the parieto-occipital; (4) the calloso-marginal; (5) the lateral; and (6) the limiting sulcus of Reil.

The lobes which are mapped out by these fissures are: (1) the frontal; (2) the rietal; (3) the occipital; (4) the temporal; (5) the insula, or the island of Reil; the limbic. To these may be added a seventh lobe, in no way related to the terlobar fissures, viz. the olfactory lobe. With the exception of the occipital and factory lobes and the insula, this subdivision of the hemisphere possesses little rphological value, and is chiefly adopted for topographical purposes.

Fissure of Sylvius (fissura cerebri lateralis).—This is the most conspicuous

fissure on the surface of the cerebral hemisphere. It is composed of a short main stem, from the outer extremity of which three branches or limbs radiate. The stem of the Sylvian fissure is placed on the inferior surface of the hemisphere. It begins at the locus perforatus anticus in a depression termed the **vallecula Sylvii**. From this it passes horizontally outwards, forming a deep cleft between the temporal pole and the orbital surface of the frontal lobe. Appearing on the outer surface of the hemisphere at a point called the **Sylvian point**, the Sylvian fissure immediately divides into three radiating branches. These are: (1) the

ramus horizontalis posterior; (2) the ramus horizontalis anterior; (3) the ra anterior ascendens.

The **posterior horizontal limb** is the longest and best marked of the three li It extends backwards, with a slight inclination upwards on the outer surface of hemisphere for a distance which may vary from about two to three inches intervenes between the frontal and parietal lobes which lie above it and temporal lobe which lies below it, and it finally ends in the region subjacent to parietal eminence of the cranial wall by turning upwards into the parietal lob the form of an *ascending terminal piece.*

The **anterior horizontal limb** extends horizontally forwards in the frontal lob a distance of about three-quarters of an inch immediately above and parallel to posterior part of the superciliary margin of the hemisphere.

The **ascending limb** proceeds upwards, with a slight inclination forwards, into lower part of the outer surface of the frontal lobe for a distance of about an i In many cases the two anterior limbs spring from a common stem of greate less length, and not infrequently both are replaced by a single anterior limb.

Limiting Sulcus of Reil (sulcus circularis Reilii).—If the lips of the post horizontal limb of the Sylvian fissure be widely pulled asunder from each other insula or island of Reil will be seen at the bottom. The insular district of cortex is completely hidden from view when the Sylvian fissure is closed by lapping portions of the cerebral hemisphere, and, when brought into view in manner indicated, it is observed to present a triangular outline and to be surrou by a limiting sulcus, of which three parts may be recognised, viz.: an *upper* bounding it above and separating it from the parietal and frontal lobes; a *part,* marking it off below from the temporal lobe; and an *anterior part,* separ it in front from the frontal lobe.

Opercula Insulæ.—The overlapping portions of the cerebral substance v cover over the insula are termed the insular opercula, and they form, by the ap tion of their margins, the three limbs of the Sylvian fissure. The opercula are in number and are named: (1) temporal; (2) fronto-parietal; (3) frontal; an orbital. The limbs of the Sylvian fissure cut right through between the diff opercula and extend from the exposed surface of the hemisphere to the subm surface of the insula, and, in this manner, separate the opercula from each oth

The **temporal operculum** extends upwards over the insula from the temporal and its upper margin forms the lower lip of the posterior horizontal limb o Sylvian fissure.

The **fronto-parietal operculum** is carried downwards from the parietal and fr regions over the insula, and its lower margin, meeting the temporal operc forms the upper lip of the posterior limb of the Sylvian fissure.

The **frontal operculum** is the small triangular piece of cerebral substance v intervenes between the ascending and anterior horizontal limbs of the Sy fissure. It covers over a small part of the anterior portion of the insula, a sometimes termed the **pars triangularis.**

The **orbital operculum** is, for the most part, on the under surface of the sphere. It lies below and to the inner side of the anterior horizontal limb o Sylvian fissure, and proceeds backwards from the orbital aspect of the fronta over the fore-part of the insula.

Development of the Sylvian Fissure and of the Insular District of the Cerebral sphere.—It is only during the latter half of the intrauterine period of development th opercula take shape and grow over the insula, so as to shut it out from the surface. In it condition the insula presents the form of a depressed area on the side of the cerebral hemis surrounded by a distinct boundary wall formed by the surrounding more elevated surface hemisphere (Fig. 447, A). After a time this depressed area, which is called the Sylvian assumes a triangular outline, and then the bounding wall is observed to be composed of distinct parts, viz.: an upper or fronto-parietal, a lower or temporal, and an anterior or part (Fig. 447, B). The rounded angle, formed by the meeting of the upper and anterior p of the boundary, now becomes flattened, and a short oblique part of the limiting wall, term frontal portion, assumes shape in this position. Each of these four portions of the bou wall of the Sylvian fossa becomes a line of growth, from which an operculum takes origi by the approximation of these opercula, as they grow over the surface of the Sylvian fos insula becomes closed in and the limbs of the Sylvian fissure are formed (Fig. 448).

he temporal and fronto-parietal opercula make their appearance somewhere about the end e fifth month of fœtal development, long before the other two opercula show any indication owth. The temporal operculum grows more rapidly than the fronto-parietal; so that, when nargins of these two opercula come together to form the posterior limb of the Sylvian fissure, is a greater extent of the Sylvian fossa covered by the temporal operculum than by the fronto-tal operculum. This accounts for the more oblique direction of the Sylvian fissure in the fœtal . But at this stage a growth-antagonism between the two opercula takes place, and in this fronto-parietal culum proves the r. The contiguous lips of the two cula become, in the instance, tightly ed together, and , as the upper operum proves the ger and the more rous in its growth, posterior limb of Sylvian fissure bees gradually deed until it assumes inclination characristic of the adult. would appear that opercular growthgonism which pros this effect in the an brain does not r to the same ex, if indeed it occurs l, in the ape. This ident from the obe direction of the posterior limb of the Sylvian fissure in the simian brain. The greater rth-energy of the fronto-parietal operculum in the human brain is not confined to the l stage of development, but is carried into the earlier stages of infantile growth, and it is able that it is due to an extension of that district of the cortex in which the centres the skilled movements of the upper limbs reside, and also to an extension of Flechsig's eto-occipital association area.

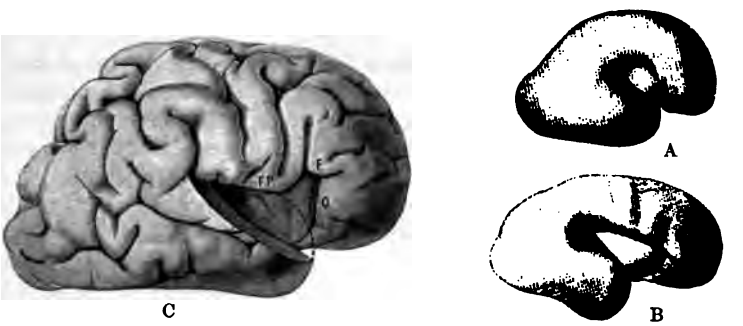

FIG. 447.—THREE STAGES IN THE DEVELOPMENT OF THE INSULA AND THE INSULAR OPERCULA.

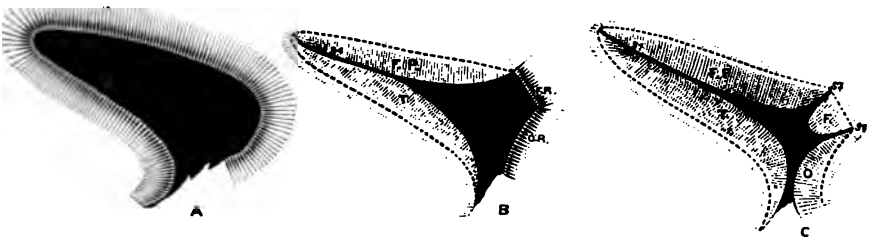
A, Right cerebral hemisphere from a fœtus in the latter part of the fourth month of development; B, Right cerebral hemisphere from a fœtus in the fifth month of development; C, Right cerebral hemisphere from a fœtus in the latter part of the eighth month of development.

In C the temporal operculum has been removed, and thus a large part of the insula is exposed. The outline of the temporal operculum is indicated by a dotted line.

F.P. Fronto-parietal operculum. F, Frontal operculum. O, Orbital operculum.

The orbital and frontal opercula are late in appearing and very tardy in their growth. eed, it is only during the course of the first year of infantile life that they come into apposition



G. 448.—DIAGRAM TO ILLUSTRATE THE DEVELOPMENT OF THE OPERCULA WHICH COVER THE INSULA.

, Sylvian fossa before opercula begin to form; B, Fronto-parietal and temporal opercula well advanced; C, All the four opercula developed but not in apposition.

h each other and with the other two opercula, so as to close in the fore-part of the Sylvian fossa form the anterior limbs of the Sylvian fissure. They do not begin to take shape until more n half of the Sylvian fossa has already been closed by the fronto-parietal and the temporal rcula. The orbital operculum appears first and is much more constant in its growth than frontal operculum, which indeed frequently fails altogether, and, even when present, shows greatest amount of variability in the degree to which it is developed.

Variations in the degree of development of the frontal operculum influence greatly the form sented by the two anterior limbs of the Sylvian fissure, between which it lies. When strongly eloped, it separates the two Sylvian limbs from each other to such an extent that they assume appearance of the letter U; when the frontal operculum is less strongly marked, the anterior vian limbs may assume a V form or a Y form. In the latter case, the orbital and the fronto-ietal opercula meet below the frontal operculum to form the stem of the Y. In those cases

where the frontal operculum is absent altogether, a single anterior limb of the Sylvian
the result.

The late appearance, the slow growth, the variability of these two opercula, and
tendency to abortive growth or complete suppression of the frontal operculum, all bes
fact that, from a phylogenetic point of view, the frontal and orbital opercula are, comp
speaking, recent productions in the evolution of the human brain. In the anthropoid
are absent, and, consequently, the fore-part of the island of Reil is exposed on the surfa
simian brain. The same condition is not at all an uncommon occurrence in the brai
microcephalic idiot.

Fissure of Rolando (sulcus centralis).—The fissure of Rolando takes an
course across the outer convex surface of the cerebral hemisphere, and inte
between the frontal and parietal lobes it forms the immediate posterior bo
of the motor area of the cortex. Its upper end cuts the supero-mesial bo
the hemisphere a short distance behind the mid-point between the fron
occipital poles, whilst its lower end terminates above the middle of the p
horizontal limb of the fissure of Sylvius. Its superior extremity, as a rul
round the supero-mesial border
hemisphere, and is then continued
wards for a short distance on the
surface. Although, in its general
tion, the fissure is oblique, it is
from being straight. It takes a
course across the hemisphere.
largely due to the area of cortex
represents the motor centre for t
and which lies in front of the
growing backwards in the cours
development so as to produce a
the fissure within which this po
the cortex is accommodated. Th
in the fissure which indicate th
and lower limits of the arm centre
baum and Sherrington) are
respectively the *superior* and
genua. The angle which the
direction of the fissure of Roland
with the mesial plane is tern
Rolandic angle. In the adult b
average Rolandic angle is 71° 7′, and the limits of variation would appear t
and 74°.

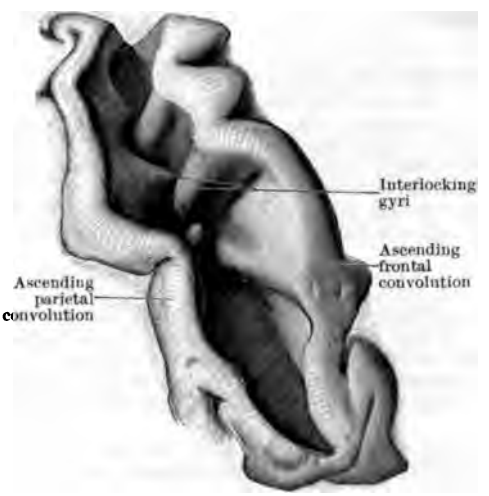

FIG. 449.—FISSURE OF ROLANDO FULLY OPENED UP, so as to exhibit the interlocking gyri and deep annectant gyrus within it.

When the fissure of Rolando is widely opened up, so that its bottom and its opposed
be fully inspected, it will be seen that, between the two genua, the two bounding convol
dovetailed into each other by a number of interlocking gyri, which do not appear on th
(Fig. 449). Further, two of these, placed on opposite sides of the fissure, are frequent
across the bottom of the sulcus in the form of a sunken bridge of connexion, which c
what is termed a *deep annectant gyrus*. The continuity of the fissure is thus, to som
interrupted. This condition is rendered interesting when considered in connexion
